Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment, and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on his or her own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the publisher nor the editors assume any liability for any injury and/or damage to persons or property arising out of or related to any use of the material contained in this book.

Note that the term ESWL has been trademarked by Dornier MedTech in the United States. The generic term for extracorporial shock wave lithotripsy is SWL. As the use of ESWL has become part of the vernacular of urology, some of the authors have elected to use this term in their chapters.

CONTRIBUTORS

Paul Abrams, MD, FRCS
Professor of Urology,
Bristol Urological Institute,
Southmead Hospital,
Bristol, United Kingdom
Overactive Bladder

Mark C. Adams, MD
Professor, Division of Pediatric Urology,
Vanderbilt Children's Hospital,
Vanderbilt University Medical Center,
Nashville, Tennessee
Urinary Tract Reconstruction in Children

Mohamad E. Allaf, MD
Assistant Professor,
James Buchanan Brady Urological Institute,
Johns Hopkins Medical Institutions,
Baltimore, Maryland
Diagnosis and Staging of Prostate Cancer

J. Kyle Anderson, MD
Assistant Professor,
Department of Urologic Surgery,
Veterans Affairs Medical Center,
University of Minnesota Medical School,
Minneapolis, Minnesota
Surgical Anatomy of the Retroperitoneum, Adrenals, Kidneys, and Ureters

Karl-Erik Andersson, MD, PhD
Professor, Lund University;
Head Physician, Clinical Chemistry and Pharmacology,
Lund University Hospital,
Lund, Sweden
Pharmacologic Management of Storage and Emptying Failure

Kenneth W. Angermeier, MD
Associate Professor,
Prosthetic Surgery and Genitourethral Reconstruction,
Glickman Urological Institute,
Cleveland Clinic Foundation,
Cleveland, Ohio
Surgery of Penile and Urethral Carcinoma

Rodney A. Appell, MD
Professor, Scott Department of Urology,
Baylor College of Medicine;
F. Bantley Scott Chair in Urology,
St. Luke's Episcopal Hospital,
Houston, Texas
Injection Therapy for Urinary Incontinence

Dean G. Assimos, MD
Professor,
Division of Surgical Sciences,
Head, Section of Endourology and Nephrolithasis,
Department of Urology,
Wake Forest University School of Medicine,
Winston-Salem, North Carolina
Pathophysiology of Urinary Tract Obstruction

Anthony Atala, MD
W. Boyce Professor and Chair,
Department of Urology,
Wake Forest University School of Medicine;
Director, Wake Forest Institute for Regenerative Medicine,
Winston-Salem, North Carolina
Tissue Engineering and Cell Therapy: Perspectives for Urology

Darius J. Bägli, MDCM, FRCSC, FAAP, FACS
Associate Professor of Surgery,
Institute of Medical Science,
University of Toronto;
Director of Urology Research,
Research Institute,
The Hospital for Sick Children,
Toronto, Ontario, Canada
Reflux and Megaureter

John M. Barry, MD
Professor of Surgery,
Head, Division of Urology and Renal Transplantation,
The Oregon Health & Science University School of Medicine;
Staff Surgeon, Doernbecher Children's Hospital,
Portland, Oregon
Renal Transplantation

Georg Bartsch, MD
Professor and Chairman,
Department of Urology,
Medical University of Innsbruck,
Innsbruck, Austria
Surgery of Testicular Tumors

Stuart B. Bauer, MD
Professor of Surgery (Urology),
Harvard Medical School;
Senior Associate in Urology,
Children's Hospital,
Boston, Massachusetts
Anomalies of the Upper Urinary Tract
Voiding Dysfunction in Children: Non-Neurogenic and Neurogenic

Clair J. Beard, MD
Assistant Professor, Harvard Medical School;
Vice-Chair, Division of Radiation Oncology,
Dana-Farber Cancer Institute,
Brigham and Women's Hospital,
Boston, Massachusetts
Radiation Therapy for Prostate Cancer

Arie S. Belldegrun, MD, FACS
Professor of Urology,
Chief, Division of Urologic Oncology,
Roy and Carol Doumani Chair in Urologic Oncology,
David Geffen School of Medicine,
University of California, Los Angeles,
Los Angeles, California
Cryotherapy for Prostate Cancer

Mark F. Bellinger, MD
Professor of Urology,
Children's Hospital of Pittsburgh,
University of Pittsburgh Medical Center,
Pittsburgh, Pennsylvania
Abnormalities of the Testes and Scrotum and Their Surgical Management

Mitchell C. Benson, MD
George F. Cahill Professor and Chairman,
J. Bently Squier Urological Clinic,
Columbia University Medical Center,
New York, New York
Cutaneous Continent Urinary Diversion

Sam B. Bhayani, MD
Assistant Professor of Surgery,
Department of Urology,
Washington University School of Medicine,
St. Louis, Missouri
Urinary Tract Imaging: Basic Principles

Jay T. Bishoff, MD
Associate Clinical Professor of Surgery,
University of Texas Health Science Center,
San Antonio, Texas;
Director,
Endourology Section,
Wilford Hall Medical Center,
Lackland AFB, Texas
Laparoscopic Surgery of the Kidney

Jerry G. Blaivas, MD
Clinical Professor of Urology,
Weill Medical College of Cornell University;
Attending,
New York-Presbyterian Hospital,
Lenox Hill Hospital,
New York, New York
Urinary Incontinence: Epidemiology, Pathophysiology, Evaluation, and Management Overview

Jon D. Blumenfeld, MD
Associate Professor of Medicine,
Weill Medical College of Cornell University;
Director of Hypertension,
Director of The Susan R. Knafel Polycystic Kidney Disease Center,
The Rogosin Institute;
Associate Attending Physician,
New York-Presbyterian Hospital,
New York, New York
Pathophysiology, Evaluation, and Medical Management of Adrenal Disorders

Michael L. Blute, MD
Professor of Urology,
Mayo Medical School;
Chairman, Department of Urology,
Mayo Clinic,
Rochester, Minnesota
Surgery of the Adrenal Glands

Joseph G. Borer, MD
Assistant Professor of Surgery,
Department of Urology,
Harvard Medical School;
Assistant in Urology,
Children's Hospital Boston,
Boston, Massachusetts
Hypospadias

George J. Bosl, MD
Chairman, Department of Medicine,
Patrick M. Byrne Chair in Clinical Oncology,
Memorial Sloan-Kettering Cancer Center,
New York, New York
Surgery of Testicular Tumors

Charles B. Brendler, MD
Professor and Chief, Section of Urology,
University of Chicago School of Medicine,
Chicago, Illinois
Evaluation of the Urologic Patient: History, Physical Examination, and Urinalysis

Gregory A. Broderick, MD
Professor of Urology,
Mayo Medical School,
Mayo Clinic,
Jacksonville, Florida
Evaluation and Nonsurgical Management of Erectile Dysfunction and Premature Ejaculation

James D. Brooks, MD
Associate Professor,
Department of Urology,
Stanford University Medical Center,
Stanford, California
Anatomy of the Lower Urinary Tract and Male Genitalia

Ronald M. Bukowski, MD
Professor of Medicine,
Cleveland Clinic Lerner College of Medicine of Case Western Reserve University;
Director, Experimental Therapeutics,
Cleveland Clinic Foundation,
Cleveland, Ohio
Renal Tumors

Arthur L. Burnett, MD
Professor of Urology, Cellular and Molecular Biology,
Johns Hopkins University School of Medicine;
Staff Urologist, The Johns Hopkins Hospital,
Baltimore, Maryland
Priapism

Jeffrey A. Cadeddu, MD
Associate Professor,
Clinical Center for Minimally Invasive Urologic Cancer Treatment;
Department of Urology,
University of Texas Southwestern Medical Center,
Dallas, Texas
Surgical Anatomy of the Retroperitoneum, Adrenals, Kidneys, and Ureters

Anthony A. Caldamone, MD, MMS, FAAP, FACS
Professor of Surgery and Pediatrics,
Department of Urology,
Brown University School of Medicine;
Head of Pediatric Urology,
Hasbro Children's Hospital,
Providence, Rhode Island
Prune Belly Syndrome

Steven C. Campbell, MD, PhD
Professor of Surgery,
Cleveland Clinic Lerner College of Medicine of Case Western Reserve University;
Section of Urological Oncology,
Glickman Urological Institute,
Cleveland Clinic Foundation,
Cleveland, Ohio
Renal Tumors
Non–Muscle-Invasive Bladder Cancer (Ta, T1, and CIS)

Douglas A. Canning, MD
Professor of Urology,
University of Pennsylvania School of Medicine;
Director, Division of Urology,
Children's Hospital of Philadelphia,
Philadelphia, Pennsylvania
Evaluation of the Pediatric Urology Patient

Michael Carducci, MD
Associate Professor of Oncology and Urology,
Johns Hopkins University School of Medicine;
Staff Physician, The Sidney Kimmel Comprehensive Cancer Center at Johns Hopkins,
Baltimore, Maryland
Treatment of Hormone-Refractory Prostate Cancer

Michael C. Carr, MD, PhD
Associate Professor of Surgery in Urology,
University of Pennsylvania School of Medicine;
Attending Surgeon, Pediatric Urology,
Children's Hospital of Philadelphia,
Philadelphia, Pennsylvania
Anomalies and Surgery of the Ureteropelvic Junction in Children

Peter R. Carroll, MD
Professor and Chair,
Department of Urology,
University of California, San Francisco, School of Medicine;
Surgeon in Chief, Comprehensive Cancer Center,
University of California, San Francisco, Cancer Center,
San Francisco, California
Treatment of Locally Advanced Prostate Cancer

H. Ballentine Carter, MD
Professor of Urology and Oncology,
James Buchanan Brady Urological Institute,
Johns Hopkins Medical Institutions,
Baltimore, Maryland
Basic Instrumentation and Cystoscopy
Diagnosis and Staging of Prostate Cancer

Anthony J. Casale, MD
Professor and Chairman,
Department of Urology,
University of Louisville;
Chief of Urology,
Kosair Children's Hospital,
Louisville, Kentucky
Posterior Urethral Valves and Other Urethral Anomalies

William J. Catalona, MD
Professor of Urology,
Feinberg School of Medicine,
Northwestern University;
Director, Clinical Prostate Cancer Program,
Robert H. Lurie Comprehensive Cancer Center,
Northwestern Memorial Hospital,
Chicago, Illinois
Definitive Therapy for Localized Prostate Cancer—An Overview

David Y. Chan, MD
Assistant Professor of Urology and Pathology,
Director of Outpatient Urology,
James Buchanan Brady Urological Institute,
Johns Hopkins Medical Institutions,
Baltimore, Maryland
Basic Instrumentation and Cystoscopy

Michael B. Chancellor, MD
Professor of Urology,
McGowan Institute of Regenerative Medicine,
University of Pittsburgh School of Medicine,
Pittsburgh, Pennsylvania
Physiology and Pharmacology of the Bladder and Urethra

C. R. Chapple, BSc, MD, FRCS (Urol)
Professor of Urology (Hon),
Sheffield Hallam University;
Consultant Urological Surgeon,
Royal Hallamshire Hospital,
Sheffield, United Kingdom
Retropubic Suspension Surgery for Incontinence in Women

Robert L. Chevalier, MD
Benjamin Armistead Shepherd Professor and Chair,
Department of Pediatrics,
University of Virginia;
Pediatrician-In-Chief,
University of Virginia Medical School,
Charlottesville, Virginia
Renal Function in the Fetus, Neonate, and Child
Congenital Urinary Obstruction: Pathophysiology

Ben H. Chew, MD, MSc, FRCSC
Assistant Professor of Urology,
University of British Columbia,
Vancouver, British Columbia, Canada
Ureteroscopy and Retrograde Ureteral Access

George K. Chow, MD
Assistant Professor,
Department of Urology,
The Mayo Clinic,
Rochester, Minnesota
Surgery of the Adrenal Glands

Ralph V. Clayman, MD
Professor of Urology,
University of California, Irvine, Medical Center;
Chair of the Department of Urology,
University of California, Irvine, School of Medicine,
Orange, California
Basics of Laparoscopic Urologic Surgery

Craig V. Comiter, MD
Associate Professor of Surgery/Urology,
Instructor of Obstetrics and Gynecology,
University of Arizona;
Chief, Section of Urology,
Director, Urology Residency,
University of Arizona Health Sciences Center,
Tucson, Arizona
Surgical Treatment of Male Sphincteric Urinary Incontinence: The Male Perineal Sling and Artificial Urinary Sphincter

Michael J. Conlin, MD
Associate Professor of Surgery,
Director, Minimally Invasive Urologic Surgery,
Division of Urology and Renal Transplantation,
The Oregon Health & Science University School of Medicine,
Portland, Oregon
Renal Transplantation

Juanita Crook, MD
Associate Professor of Radiation Oncology,
University of Toronto;
Radiation Oncologist,
University Health Network,
Princess Margaret Hospital,
Toronto, Ontario, Canada
Radiation Therapy for Prostate Cancer

Douglas M. Dahl, MD
Assistant Professor of Surgery,
Department of Urology,
Harvard Medical School;
Assistant in Urology,
Massachusetts General Hospital,
Boston, Massachusetts
Use of Intestinal Segments in Urinary Diversion

Anthony V. D'Amico, MD, PhD
Professor of Radiation Oncology,
Harvard Medical School;
Professor and Chief of Genitourinary Radiation Oncology,
Dana-Farber Cancer Institute,
Brigham and Women's Hospital,
Boston, Massachusetts
Radiation Therapy for Prostate Cancer

John W. Davis, MD
Assistant Professor of Urology,
University of Texas MD Anderson Cancer Center,
Houston, Texas
Tumors of the Penis

John D. Denstedt, MD, FRCSC
Professor of Urology,
Chairman, Department of Surgery,
Schulich School of Medicine and Dentistry,
The University of Western Ontario,
London, Ontario, Canada
Ureteroscopy and Retrograde Ureteral Access

Theodore L. DeWeese, MD, PhD
Professor of Oncology,
Johns Hopkins University School of Medicine;
Radiation Oncologist-in-Chief,
Department of Radiation Oncology and Molecular Radiation Science,
Johns Hopkins Medical Institutions,
Baltimore, Maryland
Radiation Therapy for Prostate Cancer

David A. Diamond, MD
Associate Professor of Surgery,
Department of Urology,
Harvard Medical School;
Associate in Urology,
Children's Hospital,
Boston, Massachusetts
Sexual Differentiation: Normal and Abn[illegible]al

Roger R. Dmochowski, MD, FACS
Professor,
Department of Urologic Surgery,
Vanderbilt University Medical Center,
Nashville, Tennessee
Tension-Free Vaginal Tape Procedures

Steven G. Docimo, MD
Professor of Urology,
Vice Chairman of Urology,
University of Pittsburgh School of Medicine;
Director of Urology,
Division of Pediatric Urology,
Children's Hospital of Pittsburgh,
Pittsburgh, Pennsylvania
Pediatric Endourology and Laparoscopy

Marcus Drake, DM, MA
Consultant Urological Surgeon,
Bristol Urological Institute,
Southmead Hospital,
Bristol, United Kingdom
Overactive Bladder

James A. Eastham, MD
Associate Professor,
Department of Urology,
Memorial Sloan-Kettering Cancer Center,
New York, New York
Expectant Management of Prostate Cancer

Louis Eichel, MD
Clinical Associate Professor of Urology,
University of Rochester School of
Medicine and Dentistry;
Director of Minimally Invasive Surgery,
Center for Urology,
Rochester, New York
Basics of Laparoscopic Urologic Surgery

Mario A. Eisenberger, MD
R. Dale Hughes Professor of Oncology and Urology,
The Sidney Kimmel Comprehensive Cancer Center at
Johns Hopkins,
Johns Hopkins University School of Medicine,
Baltimore, Maryland
Treatment of Hormone-Refractory Prostate Cancer

Alaa El-Ghoneimi, MD, PhD
Professor of Pediatric Surgery,
University of Paris;
Senior Surgeon,
Hospital Robert Debré,
Paris, France
Anomalies and Surgery of the Ureteropelvic Junction in Children

Jack S. Elder, MD
Professor and Vice Chairman,
Department of Urology,
Case Western Reserve University School of Medicine;
Division of Pediatric Urology,
Children's Hospital,
Cleveland, Ohio
Abnormalities of the Genitalia in Boys and Their Surgical Management

Jonathan I. Epstein, MD
Professor of Pathology, Urology, and Oncology,
The Reinhard Professor of Urologic Pathology,
Johns Hopkins University School of Medicine;
Director of Surgical Pathology,
Johns Hopkins Medical Institutions,
Baltimore, Maryland
Pathology of Prostatic Neoplasia

Andrew P. Evan, PhD
Chancellor's Professor,
Department of Anatomy and Cell Biology,
Indiana University School of Medicine,
Indianapolis, Indiana
Surgical Management of Upper Urinary Tract Calculi

Robert L. Fairchild, PhD
Professor of Pathology,
Case Western Reserve University School of Medicine;
Staff, Department of Immunology,
Cleveland Clinic Foundation,
Cleveland, Ohio
Basic Principles of Immunology

Amr Fergany, MD, MB, BCh
Staff, Section of Urologic Oncology,
Section of Laparoscopic Surgery and Robotics,
Glickman Urological Institute,
Cleveland Clinic Foundation,
Cleveland, Ohio
Renovascular Hypertension and Ischemic Nephropathy

James H. Finke, PhD
Professor of Molecular Medicine,
Cleveland Clinic Lerner College of Medicine of
Case Western Reserve University;
Staff, Department of Immunology,
Cleveland Clinic Foundation,
Cleveland, Ohio
Basic Principles of Immunology

John M. Fitzpatrick, MCh, FRCSI, FRCS(Glas), FRCS
Professor and Chairman,
Department of Surgery,
University College, Dublin;
Professor of Surgery and Consultant Urologist,
Mater Misericordiae University Hospital,
Dublin, Ireland
Minimally Invasive and Endoscopic Management of Benign Prostatic Hyperplasia

Robert C. Flanigan, MD
Albert J. Jr. and Claire R. Speh Professor and Chair,
Department of Urology,
Stritch School of Medicine,
Loyola University;
Chair of the Department of Urology,
Loyola University Medical Center,
Maywood, Illinois
Urothelial Tumors of the Upper Urinary Tract

Stuart M. Flechner, MD
Professor of Urology,
Cleveland Clinic Lerner College of Medicine of
Case Western Reserve University;
Director of Clinical Research,
Section of Renal Transplantation,
Glickman Urological Institute,
Cleveland Clinic Foundation,
Cleveland, Ohio
Basic Principles of Immunology

Tara Frenkl, MD, MPH
Assistant Professor of Urology,
Director, Female Urology and Reconstructive Surgery,
Robert Wood Johnson Medical School,
The University of Medicine and Dentistry of New Jersey,
New Brunswick, New Jersey
Sexually Transmitted Diseases

Dominic Frimberger, MD
Assistant Professor of Urology,
University of Oklahoma Health Sciences Center;
Pediatric Urologist,
Children's Hospital of Oklahoma,
Oklahoma City, Oklahoma
Bladder Anomalies in Children

John P. Gearhart, MD
Professor of Pediatric Urology,
Johns Hopkins University School of Medicine;
Chief of Pediatric Urology,
The Johns Hopkins Hospital,
Baltimore, Maryland
Exstrophy-Epispadias Complex

Glenn S. Gerber, MD
Associate Professor,
Department of Surgery (Urology),
University of Chicago School of Medicine,
Chicago, Illinois
Evaluation of the Urologic Patient: History, Physical Examination, and Urinalysis

Inderbir S. Gill, MD, MCh
Professor of Surgery,
Head, Section of Laparoscopic and Robotic Urology,
Glickman Urological Institute,
Cleveland Clinic Foundation,
Cleveland, Ohio
Laparoscopic Surgery of the Urinary Bladder

Kenneth I. Glassberg, MD
Professor of Urology,
Columbia University College of Physicians and Surgeons;
Director, Division of Pediatric Urology,
Morgan Stanley Children's Hospital of
New York-Presbyterian,
New York, New York
Renal Dysgenesis and Cystic Disease of the Kidney

David A. Goldfarb, MD
Head, Section of Renal Transplantation,
Glickman Urological Institute,
Cleveland Clinic Foundation,
Cleveland, Ohio
Etiology, Pathogenesis, and Management of Renal Failure

Irwin Goldstein, MD
Editor-In-Chief,
The Journal of Sexual Medicine,
Milton, Massachusetts
Urologic Management of Women With Sexual Health Concerns

Marc Goldstein, MD, FACS
Professor of Urology and Reproductive Medicine,
Surgeon-In-Chief, Male Reproductive Medicine and Surgery,
Executive Director, Men's Service Center,
Cornell Institute for Reproductive Medicine,
Weill Medical College of Cornell University;
Senior Scientist, Center for Biomedical Research,
The Population Council,
New York, New York
Male Reproductive Physiology
Surgery of the Scrotum and Seminal Vesicles

Leonard G. Gomella, MD
Professor and Chairman,
Department of Urology,
Jefferson Medical College;
Director,
Jefferson Prostate Diagnostic Center,
Kimmel Cancer Center,
Thomas Jefferson University Hospital,
Philadelphia, Pennsylvania
Ultrasonography and Biopsy of the Prostate

Mark L. Gonzalgo, MD, PhD
Associate Professor of Urology and Oncology,
Johns Hopkins Medical Center,
Baltimore, Maryland
Management of Invasive and Metastatic Bladder Cancer

Richard W. Grady, MD
Associate Professor of Urology,
The University of Washington School of Medicine;
Director, Clinical Research,
Children's Hospital & Regional Medical Center,
Seattle, Washington
Surgical Techniques for One-Stage Reconstruction of the Exstrophy-Epispadias Complex

Matthew B. Gretzer, MD
Assistant Professor of Clinical Surgery,
Department of Surgery/Urology,
University of Arizona Health Science Center,
Tucson, Arizona
Prostate Cancer Tumor Markers

Mantu Gupta, MD
Associate Professor,
Columbia University College of Physicians and Surgeons;
Director of Endourology, and Director of
Kidney Stone Center,
Columbia University Medical Center New York-
Presbyterian Hospital,
New York, New York
Percutaneous Management of the Upper Urinary Tract

Ethan J. Halpern, MD
Professor of Radiology and Urology,
Jefferson Prostate Diagnostic Center,
Thomas Jefferson University,
Philadelphia, Pennsylvania
Ultrasonography and Biopsy of the Prostate

Misop Han, MD, MS
Assistant Professor,
Department of Urology,
James Buchanan Brady Urological Institute,
Johns Hopkins Medical Institutions,
Baltimore, Maryland
Retropubic and Suprapubic Open Prostatectomy
Definitive Therapy for Localized Prostate Cancer—
An Overview

Philip M. Hanno, MD, MPH
Professor of Urology,
University of Pennsylvania School of Medicine;
Medical Director, Department of Clinical Effectiveness
and Quality Improvement,
University of Pennsylvania Health System,
Philadelphia, Pennsylvania
Painful Bladder Syndrome/Interstitial Cystitis and
Related Disorders

Matthew P. Hardy, PhD
Professor, Department of Urology,
Weill Medical College of Cornell University;
Member, Population Council,
The Rockefeller University,
New York, New York
Male Reproductive Physiology

David M. Hartke, MD
Resident Physician,
Department of Urology,
University Hospitals of Cleveland;
Case Western Reserve University School of Medicine,
Cleveland, Ohio
Radical Perineal Prostatectomy

Jeremy P. W. Heaton, MD, FRCSC, FACS
Professor of Urology,
Assistant Professor Pharmacology and Toxicology,
Queen's University,
Kingston, Ontario, Canada
Androgen Deficiency in the Aging Male

Sender Herschorn, BSc, MDCM, FRCSC
Professor and Chairman, Division of Urology,
Martin Barkin Chair in Urological Research,
University of Toronto;
Attending Urologist,
Director, Urodynamics Unit,
Sunnybrook Health Sciences Centre,
Toronto, Ontario, Canada
Vaginal Reconstructive Surgery for Sphincteric
Incontinence and Prolapse

Khai-Linh V. Ho, MD
Endourology Fellow,
Mayo Clinic,
Rochester, Minnesota
Lower Urinary Tract Calculi

Thomas H. S. Hsu, MD
Assistant Professor of Urology,
Director of Laparoscopic and Minimally
Invasive Surgery,
Department of Urology, Stanford University
School of Medicine;
Director of Laparoscopic, Robotic, and Minimally
Invasive Urologic Surgery,
Stanford University Medical Center,
Stanford, California
Management of Upper Urinary Tract Obstruction

Mark Hurwitz, MD
Assistant Professor,
Harvard Medical School;
Director, Regional Program Development,
Department of Radiation Oncology,
Dana-Farber/Brigham and Women's Cancer Center,
Boston, Massachusetts
Radiation Therapy for Prostate Cancer

Douglas Husmann, MD
Professor of Urology,
Vice Chairman,
Department of Urology,
Mayo Clinic,
Rochester, Minnesota
Pediatric Genitourinary Trauma

Jonathan P. Jarow, MD
Professor of Urology,
James Buchanan Brady Urological Institute,
Johns Hopkins Medical Institutions,
Baltimore, Maryland
Male Infertility

Thomas W. Jarrett, MD
Professor of Urology,
Chairman, Department of Urology,
George Washington University,
Washington, DC
Management of Urothelial Tumors of the Renal Pelvis

Christopher W. Johnson, MD
Clinical Instructor of Urology,
Weill Medical College of Cornell University,
New York, New York;
Assistant Attending,
North Shore-Long Island Jewish Health System,
Manhasset, and St. Francis Hospital, Roslyn, New York
Tuberculosis and Parasitic and Fungal Infections of the Genitourinary System

Warren D. Johnson, Jr., MD
B. H. Kean Professor of Tropical Medicine,
Chief, Division of Internal Medicine and Infectious Diseases,
Weill Medical College of Cornell University;
Attending Physician,
New York-Presbyterian Hospital, Cornell Campus,
New York, New York
Tuberculosis and Parasitic and Fungal Infections of the Genitourinary System

Deborah P. Jones, MD
Associate Professor of Pediatrics,
University of Tennessee Health Science Center;
Attending, Le Bonheur Children's Medical Center,
Children's Foundation Research Center,
Memphis, Tennessee
Renal Disease in Childhood

J. Stephen Jones, MD, FACS
Associate Professor of Surgery (Urology),
Vice Chairman, Glickman Urological Institute,
Cleveland Clinic Lerner College of Medicine of Case Western Reserve University,
Cleveland Clinic Foundation,
Cleveland, Ohio
Non–Muscle-Invasive Bladder Cancer (Ta, T1, and CIS)

Gerald H. Jordan, MD, FACS, FAAP
Professor of Urology,
Eastern Virginia Medical School,
Norfolk, Virgina
Peyronie's Disease
Surgery of the Penis and Urethra

Mark L. Jordan, MD
Harris L. Willits Professor and Chief,
Division of Urology,
University of Medicine and Dentistry of New Jersey,
New Jersey Medical School;
Chief of Urology, University Hospital,
Newark, New Jersey
Renal Transplantation

David B. Joseph, MD
Professor of Surgery,
University of Alabama at Birmingham;
Chief of Pediatric Urology,
The Children's Hospital of Alabama,
Birmingham, Alabama
Urinary Tract Reconstruction in Children

John N. Kabalin, MD
Adjunct Assistant Professor of Surgery,
Section of Urologic Surgery,
University of Nebraska College of Medicine,
Omaha, Nebraska;
Regional West Medical Center,
Scottsbluff, Nebraska
Surgical Anatomy of the Retroperitoneum, Adrenals, Kidneys, and Ureters

Martin Kaefer, MD
Associate Professor, Indiana University,
Riley Hospital for Children,
Indianapolis, Indiana
Surgical Management of Intersexuality, Cloacal Malformation, and Other Abnormalities of the Genitalia in Girls

Irving Kaplan, MD
Assistant Professor of Radiation Oncology,
Harvard Medical School;
Radiation Oncologist,
Beth Israel Deaconess Medical Center,
Boston, Massachusetts
Radiation Therapy for Prostate Cancer

Louis R. Kavoussi, MD
Chairman, The Arthur Smith Institute for Urology,
North Shore-Long Island Jewish Health System,
Manhasset, New York;
Professor of Urology,
New York University School of Medicine,
New York, New York
Laparoscopic Surgery of the Kidney

Mohit Khera, MD, MBA, MPH
Fellow, Division of Male Reproductive Medicine and Surgery,
Scott Department of Urology,
Baylor College of Medicine,
Houston, Texas
Surgical Management of Male Infertility

Antoine Khoury, MD, FRCSC, FAAP
Chief of Urology,
Senior Associate Scientist,
The Hospital for Sick Children;
Professor of Surgery,
The University of Toronto,
Toronto, Ontario, Canada
Reflux and Megaureter

Adam S. Kibel, MD
Associate Professor, Division of Urologic Surgery,
Washington University School of Medicine,
St. Louis, Missouri
Molecular Genetics and Cancer Biology

Roger Kirby, MD, FRCS
Professor and Director, The Prostate Centre;
Visiting Professor, St. George's Hospital,
Institute of Urology,
London, United Kingdom
Evaluation and Nonsurgical Management of Benign Prostatic Hyperplasia

Eric A. Klein, MD
Professor of Surgery,
Cleveland Clinic Lerner College of Medicine of Case Western Reserve University;
Head, Section of Urologic Oncology,
Glickman Urological Institute,
Cleveland Clinic Foundation,
Cleveland, Ohio
Epidemiology, Etiology, and Prevention of Prostate Cancer

John N. Krieger, MD
Professor of Urology,
University of Washington School of Medicine;
Chief of Surgical Urology,
VA Puget Sound Health Care System,
Seattle, Washington
Urological Implications of AIDS and HIV Infection

Bradley P. Kropp, MD
Professor of Urology,
University of Oklahoma Health Science Center;
Chief, Pediatric Urology,
Children's Hospital of Oklahoma,
Oklahoma City, Oklahoma
Bladder Anomalies in Children

John S. Lam, MD
Clinical Instructor in Urology,
David Geffen School of Medicine,
University of California, Los Angeles;
Attending Urologist,
University of California, Los Angeles, Medical Center,
Los Angeles, California
Cryotherapy for Prostate Cancer

Herbert Lepor, MD
Professor and Martin Spatz Chair,
Department of Urology,
New York University School of Medicine;
Chief of Urology,
New York University Medical Center,
New York, New York
Evaluation and Nonsurgical Management of Benign Prostatic Hyperplasia

Ronald W. Lewis, MD
Witherington Chair in Urology,
Professor of Surgery (Urology) and Physiology, and Chief of Urology,
Medical College of Georgia,
Augusta, Georgia
Vascular Surgery for Erectile Dysfunction

James E. Lingeman, MD
Director of Research,
Methodist Hospital Institute for Kidney Stone Disease;
Volunteer Clinical Professor,
Department of Urology,
Indiana University School of Medicine,
Indianapolis, Indiana
Surgical Management of Upper Urinary Tract Calculi

Richard E. Link, MD, PhD
Associate Professor of Urology,
Director, Division of Endourology and Minimally Invasive Surgery,
Scott Department of Urology,
Baylor College of Medicine,
Houston, Texas
Cutaneous Diseases of the External Genitalia

Larry I. Lipshultz, MD
Professor of Urology,
Scott Department of Urology,
Lester and Sue Smith Chair in Reproductive Medicine,
Chief, Division of Male Reproductive Medicine and Surgery,
Baylor College of Medicine,
Houston, Texas
Surgical Management of Male Infertility

Mark S. Litwin, MD, MPH
Professor of Urology and Health Services,
David Geffen School of Medicine,
University of California, Los Angeles;
University of California, Los Angeles, School of Public Health,
Los Angeles, California
Outcomes Research

Yair Lotan, MD
Assistant Professor,
Department of Urology,
University of Texas Southwestern Medical Center;
Attending,
Parkland Health and Hospital Systems,
Zale Lipshy University Medical Center,
Veterans Affairs Medical Center,
Dallas, Texas
Urinary Lithiasis: Etiology, Epidemiology, and Pathogenesis

Tom F. Lue, MD
Professor and Vice Chair,
Emil Tanagho Endowed Chair,
Department of Urology,
University of California School of Medicine, San Francisco,
San Francisco, California
Physiology of Penile Erection and Pathophysiology of Erectile Dysfunction
Evaluation and Nonsurgical Management of Erectile Dysfunction and Premature Ejaculation

Donald F. Lynch, Jr., MD
Professor and Chairman,
Department of Urology,
Professor of Obstetrics and Gynecology,
Eastern Virginia School of Medicine;
Urologic Oncologist,
Sentara Hospitals;
Consultant Urologist,
Jones Institute for Reproductive Medicine,
Norfolk, Virginia
Tumors of the Penis

Michael Marberger, MD, FRCS(Ed)
Professor and Chairman,
Department of Urology,
Medical University of Vienna,
Vienna, Austria
Ablative Therapy of Renal Tumors

Fray F. Marshall, MD
Professor and Chairman,
Department of Urology,
Emory University School of Medicine,
Atlanta, Georgia
Surgery of Bladder Cancer

Brian R. Matlaga, MD, MPH
Assistant Professor of Urology,
Johns Hopkins University School of Medicine;
Director of Stone Disease,
Johns Hopkins Bayview Medical Center,
Baltimore, Maryland
Surgical Management of Upper Urinary Tract Calculi

Ranjiv Mathews, MD
Associate Professor of Pediatric Urology,
James Buchanan Brady Urological Institute,
Johns Hopkins Medical Institutions,
Baltimore, Maryland
Exstrophy-Epispadias Complex

Julian Mauermann, MD
Senior Resident,
Department of Urology,
Medical University of Vienna,
Vienna, Austria
Ablative Therapy of Renal Tumors

Sarah J. McAleer, MD
Chief Resident, Department of Urology,
Brigham and Women's Hospital,
Boston, Massachusetts
Tuberculosis and Parasitic and Fungal Infections of the Genitourinary System

Jack W. McAninch, MD
Professor of Urological Surgery,
Department of Urology,
University of California, San Francisco, School of Medicine;
Chief of Urology, San Francisco General Hospital,
San Francisco, California
Renal and Ureteral Trauma

John D. McConnell, MD
Professor of Urology, Department of Urology,
Executive Vice-President for Health Systems Affairs,
University of Texas Southwestern Medical Center,
Dallas, Texas

University of Pittsburgh School of Medicine,
Pittsburgh, Pennsylvania
Physiology and Pharmacology of the Bladder and Urethra

PREFACE

For each discipline in medicine and surgery, there is generally an acknowledged authoritative text, otherwise known as "the bible." For virtually every urologist in current practice, *Campbell's Urology* has had that distinction. The text, first published in 1954 with Meredith Campbell as its sole editor, has seen the editor-in-chief position pass to J. Hartwell Harrison, and then to Patrick Walsh. Under Dr. Walsh's leadership as editor-in-chief for the past 20 years (4 editions), *Campbell's Urology* has changed as much as the field itself—in virtually every way possible except for its preeminence. The current editorial board felt strongly that Pat's contributions to urologic education through his continuing improvements and innovations to *Campbell's* should be recognized in perpetuity by renaming the text in his honor; thus the new title—*Campbell-Walsh Urology.*

Aside from the name, the 9th edition is quite different from its predecessors, continuing the tradition of a constant evolution paralleling the changing nature of the field and its relevant pertinent information. We have changed the editorial board and increased it by one. Louis Kavoussi, Andrew Novick, Alan Partin, and Craig Peters all have moved up from their associate editor positions. From the standpoint of organization, Volume 1 now covers anatomy; molecular and cellular biology, including tissue engineering; the essentials of clinical decision-making; the basics of instrumentation, endoscopy, and laparoscopy; infection and inflammation; male reproductive function and dysfunction; and sexual function and dysfunction in both men and women. Volume 2 covers all aspects of the upper urinary tract and adrenal, including physiology, obstruction, trauma, stone disease, and neoplasia. Volume 3 includes all topics related to lower urinary tract function and dysfunction, including calculi; trauma, bladder, and prostate disease; and all aspects of urine transport, storage, and emptying. Volume 4 remains a 900-page textbook of pediatric urology. There are 24 totally new chapters; an additional 19 chapters have new authors; and the remaining 89 chapters have all undergone substantial revision. All chapters contain the latest concepts, data, and controversies. Illustrations, algorithms (extensively used), and tables are now in color, as are clinical photographs. Extensive highlighting is utilized, as well as key point boxes. The complete reference list is now online and bound on a CD; a list of suggested key references appears at the end of each chapter. An e-dition includes a fully searchable online version with downloadable images (for powerpoint, papers, etc.) and video clips of the key portions of certain procedures, and it will include weekly content updates (summaries of key journal articles in all areas) for the life of the edition. The *Review*, with questions, answers, and explanations, will continue as a separate publication.

Each of us is grateful for the opportunity to be a part of the continuing tradition of *Campbell-Walsh Urology* and wish to express our immense appreciation to all of our superb authors and to those at Elsevier who facilitated our efforts in bringing the 9th edition to publication: Rebecca Schmidt Gaertner, Senior Acquisitions Editor, and Anne Snyder, Senior Developmental Editor.

ALAN J. WEIN, MD, PhD (Hon)
For the Editors

Summary 1970
Future Research 1971

57 Pathophysiology and Classification of Voiding Dysfunction 1973
ALAN J. WEIN, MD

Normal Lower Urinary Tract Function: Overview 1973
Mechanisms Underlying the Two Phases of Function: Overview 1974
The Micturition Cycle: Simplification and Overview 1976
Abnormalities of Filling/Storage and Emptying/Voiding: Overview of Pathophysiology 1976
Classification Systems 1978

58 Urodynamic and Videourodynamic Evaluation of Voiding Dysfunction 1986
ANDREW C. PETERSON, MD • GEORGE D. WEBSTER, MD

Indications 1986
Preparation of Patients and Precautions 1987
Urodynamic Equipment 1988
Conducting the Urodynamic Evaluation 1990
Ambulatory Urodynamics 2008
Urodynamic Analysis and Interpretation 2009

59 Lower Urinary Tract Dysfunction in Neurologic Injury and Disease 2011
ALAN J. WEIN, MD

Objectives 2011
General Patterns of Neuropathic/Voiding Functions 2012
Disease at or above the Brain Stem 2014
Diseases Primarily Involving the Spinal Cord 2019
Disease Distal to the Spinal Cord 2031
Miscellaneous Neurologic Diseases Causing Voiding Dysfunction 2035
Miscellaneous Conditions Definitely, Probably, or Possibly Related to Neuromuscular Dysfunction 2037
Other Conditions 2043
Treatment of Neurogenic Lower Urinary Tract Dysfunction: Overview 2044

60 Urinary Incontinence: Epidemiology, Pathophysiology, Evaluation, and Management Overview 2046
VICTOR W. NITTI, MD • JERRY G. BLAIVAS, MD

Definition and Classification of Urinary Incontinence 2046
Epidemology of Urinary Incontinence 2047
Continence and the Physiology of Micturition 2049
Etiology and Pathophysiology of Urinary Incontinence 2053
Diagnostic Evaluation 2059
Urinary Incontinence Treatment Overview 2070

61 Overactive Bladder 2079
PAUL ABRAMS, MD • MARCUS DRAKE, DM, MA

Etiology 2079
Prevalence 2081
Clinical Assessment 2082
Distinguishing Overactive Bladder from Painful Bladder Syndrome 2084
Urodynamic Confirmation of Detrusor Overactivity 2085
Management 2089

62 Pharmacologic Management of Storage and Emptying Failure 2091
KARL-ERIK ANDERSSON, MD, PhD • ALAN J. WEIN, MD

Pharmacologic Therapy to Facilitate Bladder Filling and Urine Storage 2091
Pharmacologic Therapy to Facilitate Bladder Emptying 2114

63 Conservative Management of Urinary Incontinence: Behavioral and Pelvic Floor Therapy, Urethral and Pelvic Devices 2124
CHRISTOPHER K. PAYNE, MD

General Considerations 2124
The Tools of Conservative Therapy 2126
Concept of "Therapeutic Package" 2130
Pelvic Floor Rehabilitation 2130
Devices 2136
Practical Approach to Treatment 2140
Summary 2146

64 Electrical Stimulation for Storage and Emptying Disorders 2147
SANDIP P. VASAVADA, MD • RAYMOND R. RACKLEY, MD

History of Electrical Stimulation 2147
Neurophysiology of Electrical Stimulation for Storage and Emptying Disorders 2148
Electrical Stimulation and Storage Disorders 2151
Electrical Stimulation for Emptying Disorders 2163
Future Research and Conclusions 2167

65 Retropubic Suspension Surgery for Incontinence in Women 2168
C. R. CHAPPLE, BSc, MD, FRCS(Urol)

Therapeutic Options 2168
Choice of Surgical Technique 2169
Assessing Outcomes of Therapy 2170
Indications for Retropubic Repair 2172
General Technical Issues 2174
Marshall-Marchetti-Krantz Procedure 2174
Burch Colposuspension 2176
Paravaginal Repair 2178
Vagino-Obturator Shelf Repair 2180
Laparoscopic Retropubic Suspension 2180
Complications of Retropubic Repairs 2182
Comparisons Between Incontinence Procedures 2184

66 Vaginal Reconstructive Surgery for Sphincteric Incontinence and Prolapse 2187
SENDER HERSCHORN, BSc, MDCM, FRCSC

RENAL PHYSIOLOGY AND PATHOPHYSIOLOGY

35 Renal Physiology and Pathophysiology

DANIEL A. SHOSKES, MD, FRCSC • ALAN W. McMAHON, MD

RENAL PHYSIOLOGY

RENAL PATHOPHYSIOLOGY

Renal physiology affects the urologic care of patients in numerous ways. These can include the pathophysiology of surgical disease (renal tubular acidosis, malignant paraneoplastic syndromes), the modification of surgical technique (ischemia reperfusion injury and intrarenal surgery), and iatrogenic complications of surgery (hyponatremia, metabolic complications of urinary diversions). The purpose of this chapter is not to turn urologists into nephrologists but rather to provide a firm fundamental knowledge of renal physiology and pathophysiology to provide the foundation for specific urologic conditions and therapies.

RENAL PHYSIOLOGY

Vascular (Renal Blood Flow and Glomerular Filtration Rate)

Renal Blood Flow

Renal blood flow (RBF) is regulated by changes in vascular resistance of all the arteries up to and including the efferent arteriole, which in turn is regulated by a variety of neurohormonal signals (see later).

Blood enters the kidney through the renal arteries and divides into progressively smaller arteries (interlobar, arcuate, and interlobular arteries) until it enters the glomerular capillary through the afferent arteriole. A portion of the plasma that enters the glomerulus is filtered across the glomerular membrane; this is called the *filtration fraction*. The rest of the blood exits the glomerular capillary through the efferent arteriole. In nephrons located in the renal cortex, these capillaries travel in close proximity to the tubules and modulate solute and water reabsorption. In juxtamedullary nephrons (located deeper in the medulla), the efferent arterioles branch out to form vasa recta, which participate in the countercurrent mechanism through which urine is highly concentrated and body water conserved (see later discussion).

Under normal resting conditions, RBF is 20% of total cardiac output. Total blood flow is different for men and women, averaging 982 ± 184 mL/min in women and 1209 ± 256 mL/min in men (Dworkin and Brenner, 2004). Renal plasma flow (RPF) is slightly less, averaging 592 mL/min in women and 659 mL/min in men, and varies with hematocrit (RPF = RBF × [1 − Hct]). RBF is not evenly distributed to all parts of the kidney. Flow to the outer cortex is two to three times greater than that to the inner cortex, which in turn is two to four times greater than that to the medulla (Dworkin and Brenner, 2004).

Determinants of Glomerular Filtration

The most important function of the kidney is the process of glomerular filtration. Through the passive ultrafiltration of plasma across the glomerular membrane, the kidney is able to regulate total body salt and water content and electrolyte composition and eliminate waste products of protein metabolism.

The process of filtration is analogous to fluid movement across any capillary wall and is governed by Starling's forces. **The glomerular filtration rate (GFR) is thus determined by both hydraulic and oncotic pressure differences between the glomerular capillary and Bowman's space as well as by the permeability of the glomerular membrane:**

$$GFR = LpS - (\Delta \text{hydrostatic pressure} - \Delta \text{oncotic pressure})$$

where Lp = glomerular permeability and S = glomerular surface area.

The rate at which filtration occurs within an individual nephron is termed the single-nephron GFR (SN-GFR). A more relevant measurement is that of total GFR, which is the sum of all SN-GFR and is expressed in milliliters per minute. **GFR is thus a reflection of overall renal function.** Alterations in GFR can occur either with alterations in any aspect of Starling's forces or through a change in RPF.

1. *Transglomerular (hydraulic) pressure (TGP)*—the most significant determinant of GFR is the TGP. Although systemic arterial pressures affect TGP, the glomerular capillary is unique in that it is interposed between two arterioles (the afferent and efferent arterioles) and can thus regulate intraglomerular capillary pressure (IGP) independent of systemic pressures through changes in afferent and efferent arteriolar tone. Under normal circumstances, the pressure within Bowman's space is essentially zero, and only in conditions of urinary

obstruction does the pressure increase to clinically significant levels. Thus, the TGP = IGP.

Renal plasma flow—increases in RPF lead to increases in GFR. Although the filtration fraction cannot exceed 20% under normal circumstances, an increase in RPF leads to an increase in absolute GFR.

Glomerular permeability—generally, an increase in permeability does not lead to an increase in GFR, as the glomerulus is already at maximal permeability for water and other relevant solutes. It may, however, lead to increased filtration of larger molecules not normally filtered, such as albumin. Reductions in permeability or in glomerular surface area can lead to reductions in GFR.

Oncotic pressure—the least relevant of all the variables. Under normal circumstances, plasma proteins are not filtered across the glomerular membrane and so oncotic pressure within Bowman's space is essentially zero.

ulation of Glomerular Filtration Rate

er normal circumstances, GFR is tightly maintained at atively constant level despite large fluctuations in sys-c arterial pressures and RBF. This is accomplished ugh the processes of autoregulation and tubuloglomeru-eedback.

Autoregulation—with increases in mean arterial pressure (MAP), afferent arteriolar tone increases to minimize increases in IGP. Similarly, with reductions in MAP, afferent arteriolar tone decreases to allow increased flow into the glomerulus to maintain IGP, thus maintaining GFR. Autoregulation of IGP is effective to an MAP of about 70 mm Hg; below that, reductions in MAP lead to similar reductions in GFR, and below an MAP of 40 mm Hg, filtration ceases. The mechanism by which autoregulation is achieved is not well understood. It is probably mediated through myogenic stretch receptors in the afferent arteriole wall, possibly mediated by ATP (Schnermann and Levine, 2003), but angiotensin II is also involved with more severe fluctuations.

Tubuloglomerular feedback (TGF)—tubular ultrafiltrate flow rates are monitored by cells in the macula densa. If SN-GFR increases, delivery of Na^+ and Cl^- to the distal tubule also increases. This increased Cl^- delivery triggers a response through the macula densa that ultimately leads to an increase in afferent arteriolar tone and subsequent decrease in RPF, thus returning SN-GFR (and tubular flow) back to baseline (Schnermann et al, 1998). Thus, TGF can be thought of as a mechanism to minimize salt and water losses through regulation of GFR. The mediators of this response are not well understood, but it seems that angiotensin II plays a permissive role in TGF. Both adenosine and thromboxane can cause afferent arteriolar vasoconstriction and have been implicated in TGF. Nitric oxide (NO) (Schnermann and Levine, 2003) is also believed to be important, particularly in minimizing TGF in the setting of increased NaCl intake.

Under abnormal conditions, however, neurohumoral ponses become more important. With significant reduc-ns in effective circulating volume, both norepinephrine and giotensin II play an important role in maintaining GFR through arteriolar vasoconstriction, often at the expense of reduced RPF. It should also be noted that renal prostaglandins (PGs) and NO offset afferent arteriolar vasoconstriction, so that arteriolar tone is a balance between the vasoconstrictive and vasodilatory effects of the aforementioned hormones. Inhibition of PG synthesis (by administration of nonsteroidal anti-inflammatory drugs), particularly in states of high angiotensin II production, can lead to severe vasoconstriction and acute reduction in GFR. In contrast, norepinephrine and angiotensin II levels are diminished in states of volume expansion, whereas dopamine and atrial natriuretic peptide (ANP) levels are increased to facilitate an increase in RPF (dopamine) and natriuresis (ANP), thus returning volume status back to normal.

Clinical Assessment of Glomerular Filtration Rate

Unfortunately, GFR cannot be measured directly. It can, however, be estimated by a variety of methods, some more accurate (but usually more cumbersome) than others.

Renal Clearance. The best estimate of GFR can be obtained by measuring the rate of clearance of a given substance from the plasma. However, in order to be accurate, the substance to be measured must meet certain criteria. It must:

- Be able to achieve a stable plasma concentration,
- Be freely filtered across the glomerulus,
- Not be secreted, reabsorbed, synthesized, or otherwise metabolized by the renal tubules, and
- Not be affected by any other means of removal from the plasma.

If all these criteria are met,

$$\text{Filtered X} = \text{excreted X}$$

and because

$$\text{Filtered X} = \text{GFR} \times \text{plasma [X]}$$

and

$$\text{Excreted X} = \text{urine [X]} \times \text{urine volume (in mL/unit time)}$$

we can now see that

$$\text{GFR} \times \text{P[X]} = \text{U[X]} \times \text{urine volume}$$

$$\text{GFR} = \text{U[X]} \times \text{urine volume/P[X]}$$

This is called the *clearance* of a substance and reflects the amount of plasma that is completely cleared of the substance per unit time. A number of substances have been used clinically to estimate GFR.

1. *Inulin.* Inulin is a fructose polysaccharide that meets the requirements, and inulin clearance is thought to be the best measure of GFR. However, inulin is not clinically useful as it is difficult to administer (requires an intravenous infusion of inulin) and difficult to measure.
2. *Radiolabeled compounds.* These include iothalamate and diethylenetriaminepentaacetic acid (DTPA). These clearances are also very accurate but are again limited in clinical use by their cost and availability (Perrone et al, 1990).
3. *Creatinine.* The most widely used **estimate of GFR is** the 24-hour creatinine clearance (**CrCl**) (Levey, 1990).

It utilizes endogenous creatinine, which is produced at a constant rate. The rate of production varies from individual to individual, but for a single individual daily variability is less than 10%. It has the advantage of being easy to perform (no intravenous infusion), is relatively cheap, and is readily available. However, it is less accurate than inulin clearance, as some creatinine is cleared from plasma through proximal tubular secretion; thus, a CrCl overestimates true GFR, on average, by 10% to 20%. This becomes even more important as GFR declines, as tubular secretion increases in response to increasing serum creatinine levels and may contribute up to 35% of all creatinine removal at GFR levels of 40 to 80 mL/min (Shemesh et al, 1985). **At best, then, the CrCl should be considered the "upper limit" of the true GFR.**

Plasma Markers. An even simpler method to estimate GFR is with the use of plasma levels of substances that can be used as surrogate markers of GFR. To be useful, the substance must fulfill the preceding criteria. Three such substances have been utilized:

1. *Plasma creatinine (PCr),* **the most widely used plasma marker of GFR.** Although creatinine production is constant within an individual from day to day, there is marked variation in production rates between individuals. The absolute rate depends upon muscle mass, which in turn is influenced by age, sex, and body mass. Thus, **there is no single "normal" PCr that reflects a "normal" GFR; it must be individualized for every person.** This can be accomplished through mathematical manipulation (see later). However, the relationship of PCr to GFR is relatively constant (Fig. 35–1), and changes in PCr can be used to predict corresponding changes in GFR. As a general rule, every 50% reduction in GFR results in a doubling of PCr. There are limitations to the use of the PCr that should be noted:
   - As GFR falls, tubular secretion of creatinine increases and PCr may not change noticeably until there has been a significant drop in GFR (Shemesh et al, 1985).
   - Creatinine production may increase in states of increased muscle breakdown (e.g., rhabdomyolysis) or with increased dietary protein intake or supplementation and lead to an underestimation of true GFR.
   - Creatinine production may decrease with liver cirrhosis, leading to an overestimation of true GFR.
2. *Plasma urea,* another widely used plasma marker. Urea production and excretion are highly variable, influenced by such things as dehydration, high-protein diets, and increased tissue breakdown. As a result, it is a much less reliable marker of GFR than is the PCr and should not be used as the sole determinant.
3. *Plasma cystatin C,* an endogenous protein found in all nucleated cells. It has a constant rate of production unaffected by diet, and clearance is not influenced by tubular functions (Filler et al, 2005). This test is not widely available at present but is likely to replace PCr as the standard test in GFR assessment.

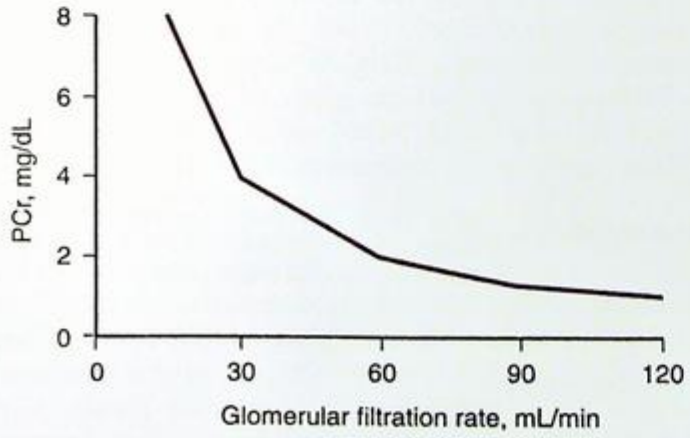

Figure 35–1. Relationship between serum creatinine and creatinine clearance. PCr, plasma creatinine.

Mathematical Correction. A number of mathematical formulas have been developed to improve the accuracy of the PCr estimation of GFR (National Kidney Foundation, 2002). The two most widely used are the Cockcroft-Gault and modification of diet in renal disease (MDRD) formulas.

1. *Cockcroft-Gault,* originally developed from data collected from individuals with normal renal function, is a simple formula to estimate CrCl (not GFR) that corrects for age, sex, and body mass (IBW, ideal body weight) (Cockcroft and Gault, 1976). The formula is

$$\text{CrCl} = \frac{\{[(140-\text{age})\times(\text{IBW in kg})]}{[\text{PCr(mg/dL)}\times 72]\}} \times 0.85\,(\text{women})$$

   It has the advantage of being very simple, but it is not as accurate as other methods when renal function is impaired.
2. *MDRD formulas,* a series of formulas derived from data collected for patients with severe renal impairment, are more complex but more accurate than the Cockcroft-Gault formula. The simplest estimate of GFR is the four-variable equation (PCr, age, sex, and ethnicity) (Manjunath et al, 2001):

$$\text{GFR} = 186 \times (\text{PCr})^{-1.154} \times (\text{age})^{-0.203} \times (0.742 \text{ if female}) \times (1.210 \text{ if African American})$$

In summary, the GFR is analogous to renal function. Total GFR is a summation of all SN-GFR values (which in turn are determined primarily by TGP and the glomerular permeability of the individual nephrons), and it is usually tightly regulated. **A GFR estimate should be obtained for all patients with renal impairment (rather than a PCr alone), and the recommended method is through the use of the four-variable MDRD formula or Cockcroft-Gault formula.**

KEY POINTS: RENAL BLOOD FLOW AND GLOMERULAR FILTRATION RATE

- GFR reflects total renal function.
- GFR can be approximated by creatinine clearance.
- Formulas based on patient's age, weight, and serum creatinine can best estimate GFR.

Hormonal

Control of Renal Vascular Tone

Vascular tone of the renal vessels, the net balance of vasoconstrictive and vasodilatory forces, is key to the maintenance of RBF, GFR, tubular renal function, and systemic blood pressure. **There is a complex network of hormones and vasoactive substances with both direct and indirect effects resulting in a system that is pleiotropic and redundant.** Although much has been learned from animal models about the function of individual molecules, the complexity of the total system can lead to unexpected outcomes when individual pathways are manipulated pharmacologically. A summary of substances known to affect vascular tone is given in Table 35–1.

Vasoconstrictors

Angiotensin II. Angiotensin II is a potent vasoconstrictor. In the kidney, there is a more pronounced constrictive effect on the efferent than the afferent arteriole because of inhibition of angiotensin II actions in the afferent arteriole by nitric oxide and prostaglandin (Arima, 2003). Elevated levels of angiotensin II are important for maintaining GFR in pathologic conditions that reduce RBF (e.g., renal artery stenosis, dietary sodium restriction). The classical effects of angiotensin II (vasoconstriction, aldosterone release, sodium retention) are mediated by the AT1 receptor (Kaschina and Unger, 2003). The AT2 receptor, however, may cause intrarenal dilation and be protective against renal ischemic injury (Carey, 2005).

Table 35–1. Vasoactive Substances That Control Renal Artery Tone

Vasoconstriction
Angiotensin II
Norepinephrine
Vasopressin
Endothelin
Atrial natriuretic peptide
Vasodilation
Nitric oxide
Carbon monoxide
Prostaglandin E_2
Acetylcholine
Serotonin/bradykinin
Glucocorticoids

Norepinephrine. Norepinephrine vasoconstricts all the major vascular beds in the kidney, mediated through the α_1 receptor. In patients who receive norepinephrine as a pressor agent in the presence of systemic vasodilation, renal function is preserved and may actually improve (Albanese et al, 2004).

Endothelin. **Endothelin is the most potent vasoconstrictor yet identified.** There are three isoforms, with ET-1 being the most fully described. An endothelin precursor (big ET-1; 39 amino acids) is cleaved to ET-1 (21 amino acids) by an endothelin converting enzyme found on the endothelial cell membrane. The endothelin receptors are subclassified into ET(A), which are purely vasoconstrictive, and ET(B). The ET(B) receptors may cause either vasodilation, by stimulating the release of nitric oxide from endothelial cells, or vasoconstriction of vascular smooth muscle cells (Fellner and Arendshorst, 2004). ET-1 release is stimulated by angiotensin II, antidiuretic hormone, thrombin, cytokines, reactive oxygen species, and shearing forces acting on the vascular endothelium. ET-1 release is inhibited by nitric oxide as well as by prostacyclin and ANP. Blockade of the ET(A) receptor can reduce the renal vasoconstriction seen in such ischemic conditions as ureteral obstruction (Bhangdia et al, 2003).

ET-1 has a number of other actions besides vasoconstriction. ET-1 stimulates aldosterone secretion, produces positive inotropy and chronotropy in the heart, decreases RBF and GFR, and releases ANP. **Despite reduction in RBF, sodium excretion is increased,** suggesting that ET may be responsible for maintaining sodium balance when the renin-angiotensin system is depressed (Perez del Villar et al, 2005). Medullary blood flow is preserved in the presence of endothelin-induced vasoconstriction, which may explain the relative stimulation of tubular functions (Evans et al, 2004).

Vasopressin. Vasopressin acts directly on blood vessels through the vasopressin V1 receptor but does not directly change RBF at low doses (Malay et al, 2004). Vasopressin does potentiate the vasoconstrictive effects of norepinephrine (Segarra et al, 2002) and can induce renal ischemia at high doses. **At the low doses typically employed in the management of septic shock, renal function is preserved** (Holmes et al, 2001).

Atrial Natriuretic Peptide. ANP is a vasoactive hormone synthesized primarily by the atria in response to stretching, such as that which occurs during physiologic levels of volume expansion (Fig. 35–2). **The primary actions of ANP on the**

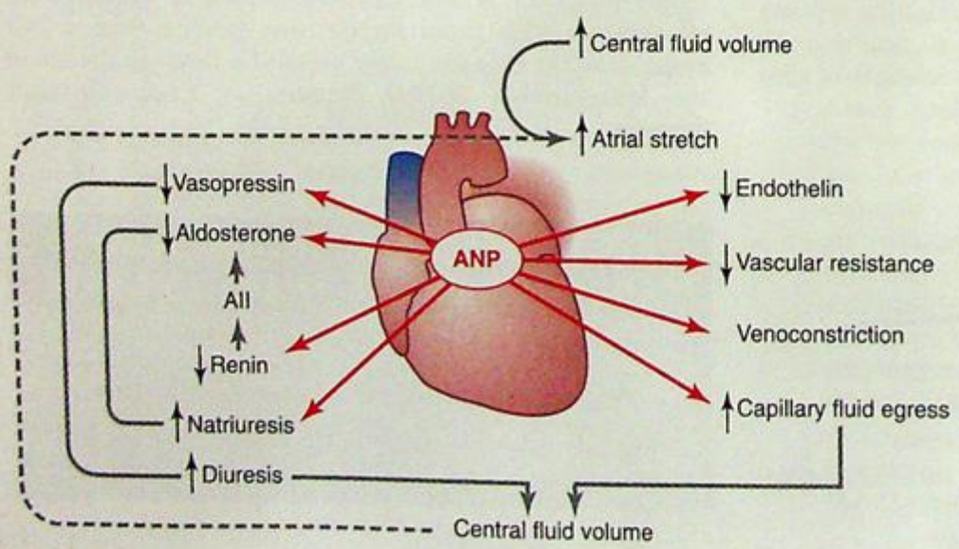

Figure 35–2. Schematic representation of the fundamental biologic processes of atrial natriuretic peptide (ANP). AII, angiotensin II.

kidney are increased GFR and natriuresis. ANP can increase GFR without a change in RBF (Sward et al, 2005) by the combination of afferent arteriolar vasodilatation and efferent arteriolar vasoconstriction. In addition, ANP dilates vessels that have been preconstricted by norepinephrine, angiotensin II, or vasopressin. ANP production increases during bilateral obstructive uropathy, which may be one mechanism of preserving GFR (Kim et al, 2002).

ANP increases natriuresis through increased GFR, decreased renin, and decreased aldosterone production (Laragh, 1985). Clinically, however, infusion of low-dose ANP during surgery increases water and electrolyte excretion without measured systemic changes in cortisol, angiotensin II, or aldosterone (Koda et al, 2005). This approach has also been used to prevent ischemic renal damage in high-risk cardiac surgery (Sward et al, 2004).

Vasodilators

Nitric Oxide. Nitric oxide (NO) is a highly reactive gas that participates in multiple physiologic and pathophysiologic reactions in the body. **NO is synthesized from the reaction between arginine, NADPH, and oxygen to produce citrulline, NADP, water, and NO.** This reaction is catalyzed by a family of enzymes called nitric oxide synthase (NOS). Although all NOS enzymes catalyze the same reaction, they differ in distribution, expression, and stimuli. Neuronal NOS (nNOS, NOS-1) and endothelial NOS (eNOS, NOS-3) are constitutively expressed and iNOS (NOS-2) is inducible. **eNOS is found in the vascular endothelium, and the NO produced there plays a key role in vasodilation and vascular remodeling** (Rudic et al, 1998). eNOS expression is stimulated by shear stress through activation of the tyrosine kinase c-Src (Davis et al, 2004), by heat shock protein 90 (Harris et al, 2003), by oxidant stress (Cai et al, 2001), and by vascular mediators such as bradykinin, serotonin, adenosine, ADP/ATP, histamine, and thrombin (Arnal et al, 1999).

After its formation by vascular endothelial cells, NO diffuses to vascular smooth muscle cells, where it activates soluble guanylyl cyclase (sGC), producing guanosine 3′,5′-cyclic monophosphate (cGMP). Subsequently, cGMP activates both cGMP- and adenosine 3′,5′-cyclic monophosphate (cAMP)-dependent protein kinases (PKG and PKA, respectively), leading to smooth muscle relaxation. eNOS blockade increases renal vascular resistance and decreases the glomerular ultrafiltration coefficient (Gabbai, 2001). NO also helps maintain vascular integrity, with increased expression being linked to decreased neointimal formation and medial thickening (Kawashima et al, 2001). Indeed, the degenerative changes seen in chronic allograft nephropathy related to cyclosporine use can be mitigated by increased nitric oxide expression (Chander et al, 2005). Increased eNOS activity is also associated with protection from renal ischemia-reperfusion injury (Shoskes et al, 1997).

Whereas raised local levels of NO from eNOS can be beneficial to renal function, induction of iNOS and overproduction of NO from inflammatory cells can be deleterious. In the presence of free oxygen radicals at the site of inflammation, NO can interact with reactive oxygen species to form peroxynitrite, which induces protein damage by formation of nitrotyrosine. Increased iNOS has been related to damage from nitrotyrosine in glomerular disease (Trachtman, 2004), lupus nephritis (Takeda et al, 2004), and chronic transplant rejection (Albrecht et al, 2002). Increased iNOS activity has direct renal effects as well, including upregulation of sodium and bicarbonate tubular transport (Wang, 2002).

Carbon Monoxide. Carbon monoxide (CO) gas is another reactive diffusible mediator with multiple effects throughout the body and especially in the kidney. **Heme oxygenase (HO), an essential enzyme in heme catabolism, catalyzes the rate-limiting step in heme degradation, resulting in the formation of iron, carbon monoxide, and biliverdin** (Hill-Kapturczak et al, 2002). Biliverdin is subsequently converted to bilirubin by biliverdin reductase. HO is expressed in two forms, constitutive HO-2 and inducible HO-1. Increased CO production produces vasodilation in the kidney and can counteract catecholamine-induced vasoconstriction (Mustafa and Johns, 2001). In particular, both HO-1 and HO-2 are highly expressed in the medulla and help maintain renal medullary blood flow (Zou et al, 2000). In cirrhosis, decreased renal expression of HO-1 is linked to renal dysfunction (Miyazono et al, 2002). CO also regulates sodium transport in the loop of Henle, with HO-2 blockade inhibiting sodium excretion (Wang et al, 2003) and stimulation increasing natriuresis and diuresis (Rodriguez et al, 2003).

The other primary effect of CO in the kidney is renoprotection from oxidant injury. CO has documented anti-inflammatory, antioxidant, and cytoprotective actions (Sikorski et al, 2004). Indeed, a patient with a genetic HO-1 deficiency had significant tubular and vascular endothelial injury (Ohta et al, 2000). Increased CO is protective against ischemia-reperfusion injury in native and transplant kidneys (Nakao et al, 2005). Induction of HO-1 through agents such as bioflavonoids protects against tubular damage and improves renal transplant function (Shoskes et al, 2005).

KEY POINTS: HORMONAL

- Multiple chemical mediators act on renal vascular tone, which controls renal blood flow.
- Endothelin is the most potent vasoconstrictor.
- Nitric oxide and carbon monoxide are potent vasodilators.

Erythropoiesis

Red blood cell (RBC) production is a tightly regulated process. Basal RBC production is roughly 10 RBCs/hr, but this rate can be greatly increased during times of anemia or hypoxia. The kidney is the major organ involved in this process and is responsible for monitoring RBC levels and increasing RBC output through the production of the hormone erythropoietin.

Erythroid Progenitor Cells. Mature RBCs are produced from a small pool of multipotent progenitor cells (Suda et al, 1984), which in turn are derived from the fetal liver. The earliest committed cell is the erythroid burst-forming unit (BFU-E), which, under appropriate stimulation, divides to produce erythroid colony-forming units (CFU-Es). Further differentiation leads to the production of proerythroblasts, reticulocytes, and ultimately (after extrusion of the nucleus) mature RBCs. The entire process requires about 2 weeks.

Erythropoietin. Maturation of the BFU-E and CFU-E depends on the appropriate growth factors. The most important of these factors is erythropoietin (EPO). The kidney is responsible for the majority of EPO production (90%), and the liver may contribute a smaller amount (10%). Kidney-derived EPO is produced by a subpopulation of interstitial fibroblasts and possibly proximal tubular cells in response to decreased O_2 tension.

EPO-deficient mice die in utero with a marked reduction in erythropoiesis (Munugalavadla and Kapur, 2005). Additional growth factors such as interleukin 3, granulocyte-macrophage colony-stimulating factor, stem cell factor, activin, insulin-like growth factor I (IGF-I), and possibly hepatic growth factor act synergistically with EPO to reduce apoptosis and thus promote proliferation of erythroid cells (Muta and Krantz, 1993).

EPO has also been shown to have effects outside the bone marrow. EPO receptors have been demonstrated in kidney, brain, retina, heart, skeletal muscle, and endothelial cells (Juul et al, 1998). In the kidney, pretreatment with high-dose EPO has been shown to reduce ischemia-reperfusion injury in an animal model related to decreased apoptosis (Patel et al, 2004).

Regulation of Erythropoietin Production and Erythropoiesis. Production of EPO, and hence erythropoiesis, is closely associated with circulating O_2 tension. Under hypoxic conditions, the alpha subunit of the regulatory protein hypoxia-inducible factor-1 (HIF-1) is exposed (Wang et al, 1995). Binding of HIF-1 alpha with HIF-1 beta, hepatic nuclear factor 4 (HNF-4), and p300 turns on erythropoietin transcription (Arany et al, 1996). When the hypoxia has been corrected, HIF-1 alpha is ubiquinated and rapidly degraded by proteosomes, thus shutting down erythropoietin production. There is also in vitro evidence that hypoxia itself may directly increase erythropoiesis through HIF-1–mediated increases in autocrine motility factor production and subsequent decrease in apoptosis (Mikami et al, 2005).

In states of chronic inflammation, erythropoiesis is decreased. Apoptosis of erythroid progenitor cells occurs in the presence of the tumor-associated antigen RCAS1, which is also produced by macrophages under inflammatory conditions (Suehiro et al, 2005).

Erythropoiesis is also decreased in most forms of chronic renal failure, and subsequently anemia is common in the later stages of the disease. This is due to decreased EPO levels as a result of a reduction in the number of functional EPO-producing cells within the kidney. Recombinant human erythropoietin (rHuEPO) has been shown to be an effective treatment for this type of anemia.

Bone Mineral Regulation

Normal regulation of bone mineralization, through maintenance of serum calcium and phosphorus levels, is achieved through the actions of vitamin D and parathyroid hormone (PTH). The actions of both hormones are exerted largely through the kidney (Fig. 35–3).

Vitamin D Regulation. The kidney plays an important role in the regulation of vitamin D activity. The major source of

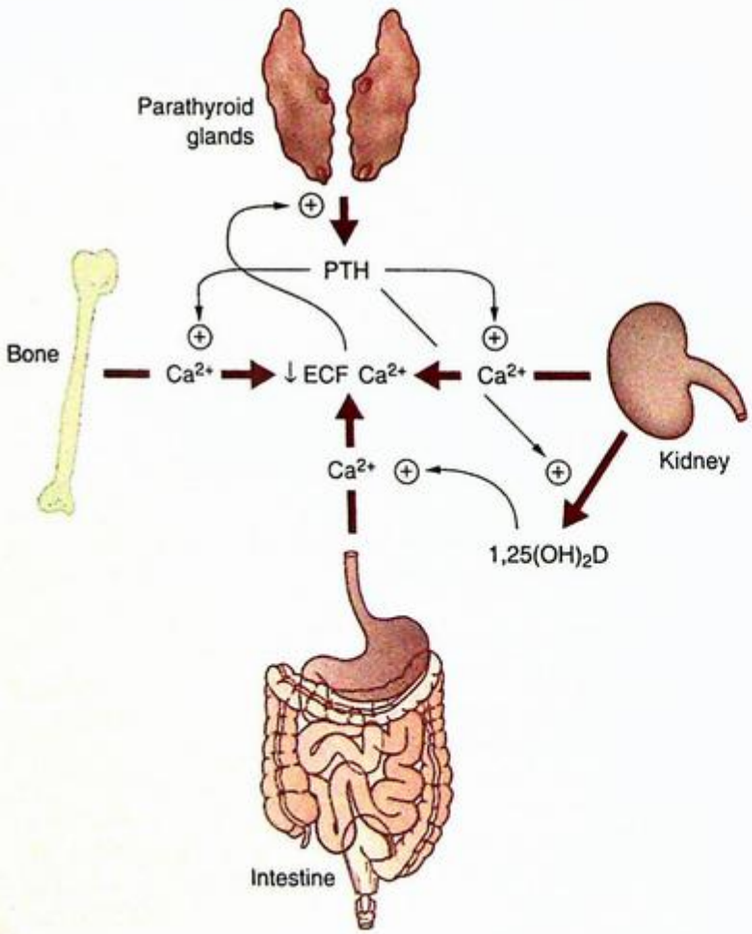

Figure 35–3. Effects of vitamin D and parathyroid hormone (PTH) on calcium homeostasis. EFC, extracellular fluid. (From Yu SLY: Renal transport of calcium, magnesium, and phosphate. In Brenner BM [ed]: Brenner and Rector's The Kidney, 7th ed. Philadelphia, WB Saunders, 2004, p 536.)

vitamin D is dermal synthesis of the precursor compound cholecalciferol (vitamin D_3) or dietary intake of vitamin D_3–fortified foods. Vitamin D_3 has minimal biologic activity and requires two hydroxylations to become active. The first hydroxylation occurs in the liver through the action of 25-hydroxylase to form 25-hydroxycholecalciferol (calcidiol). The calcidiol molecule is bound to vitamin D binding protein and transported to the kidney, where it is filtered and reabsorbed by renal tubular cells. A second hydroxylation occurs within the tubular cell. Because these cells contain both 1α-hydroxylase and 24α-hydroxylase, hydroxylation produces either inactive 24,25-dihydroxycholecalciferol or 1,25-dihydroxycholecalciferol (calcitriol), which is the biologically active form and 100 times more potent than calcidiol. Calcitriol production is regulated by calcidiol levels as well as 1α-hydroxylase levels. These are in turn determined by PTH and plasma phosphate levels (which increase enzyme activity) and serum calcitriol levels (which decrease enzyme activity) (Portale et al, 1989). However, unregulated calcitriol synthesis can occur in macrophages in granulomatous conditions such as sarcoidosis and tuberculosis and in prostate epithelial and cancer cells (Young et al, 2004).

Vitamin D Activity. Calcitriol functions through a single intracellular vitamin D receptor (VDR) to regulate gene transcription (Lowe et al, 1992). Its primary function is the maintenance of serum calcium and phosphorus levels. The four main target organs are the intestine (increases intestinal absorption of calcium and, to a lesser extent, phosphorus), the bones (regulates osteoblast activity and, in combination with PTH, allows osteoclast activation and bone resorption), the kidney (increases reabsorption of calcium), and the parathyroid gland (suppresses PTH release). Evidence suggests that both calcidiol and calcitriol may also function as antiproliferative agents. Prostate epithelial and cancer cells demonstrate VDR, and vitamin D may suppress the growth of these cells, especially in combination with androgens (Tuohimaa et al, 2005).

In summary, vitamin D contributes to normal bone mineralization by maintaining normal serum calcium and phosphorus levels through increased intestinal absorption of calcium and phosphorus and increased renal reabsorption of calcium.

Parathyroid Hormone Regulation. Synthesis, secretion, and degradation of PTH are influenced directly by serum calcium levels through calcium-sensing receptors located on parathyroid cells. During periods of hypocalcemia, PTH synthesis and secretion are increased and degradation is decreased. The opposite occurs during hypercalcemia. In addition, calcitriol has a suppressive effect on PTH synthesis and parathyroid cell proliferation that is mediated through VDRs located on the surface of parathyroid cells. Hyperphosphatemia also directly stimulates PTH release, primarily in advanced renal insufficiency. Finally, other cations such as magnesium and aluminum have slight stimulatory effects, probably mediated through the calcium-sensing receptors.

Parathyroid Hormone Activity. PTH exerts its activity through PTH/PTH-related protein (PTHrP) receptors, which are localized primarily to the kidneys and bone.

Bone. The effect of PTH on bone metabolism depends upon its administration; if given continuously, it stimulates bone resorption and increases serum calcium and phosphorus levels. Given intermittently, it leads to increased bone formation and mineral density.

Kidney. The renal effects of PTH are threefold. First, it increases active calcium reabsorption at the level of the distal tubule (Friedman and Gesek, 1993). Second, it decreases phosphate reabsorption in the proximal convoluted tubule (and the distal tubule, to a lesser degree) through its action on the sodium-phosphorus cotransporter (Pfister et al, 1997). Third, it stimulates calcitriol production by increasing 1α-hydoxylase levels while decreasing 24α-hydroxylase levels (Broadus et al, 1980).

In summary, PTH functions to maintain normal serum calcium and phosphorus levels by increasing bone resorption, increasing renal reabsorption of calium and excretion of phosphorus, and stimulating production of calcitriol.

Antidiuretic Hormone

Antidiuretic hormone (ADH), or arginine vasopressin as it is called in humans, is a polypeptide secreted by the posterior pituitary gland. It functions to maintain serum osmolality and volume through the regulation of free water excretion in the kidney.

ADH Actions. ADH increases the passive reabsorption of water at the level of the collecting duct. Through interaction with the V2 receptor, it facilitates the insertion of preformed water channels known as aquaporin 2 (AQP-2) into the luminal membrane of the principal cells (Agre et al, 2002). This allows luminal water to enter the cell and then diffuse back into the systemic circulation through the basolateral membrane of the cell (Fig. 35–4). ADH increases urea reabsorption in the medullary collecting tubule through specific urea transporters, which helps maintain the high interstitial osmolality required for water reabsorption. ADH also increases systemic vascular resistance through interaction with the V1 receptor; this is of minor physiologic importance. Other effects of ADH include increased sodium reabsorption and potassium excretion, increased prostaglandin synthesis, increased adrenocorticotropic hormone secretion (through V3 receptors), and release of both factor VIII and von Willebrand's factor from vascular endothelium.

Control of ADH Secretion. There are two major stimuli for ADH release, hyperosmolality and decreased effective circulating volume (ECV), as well as a number of less common factors (Table 35–2).

Table 35–2. **Physiologic and Pathologic Factors Affecting the Release of Antidiuretic Hormone**

Stimuli	*Inhibitors*
Hyperosmolality	Hypo-osmolality
Hypovolemia	Hypervolemia
Stress (e.g., pain)	Ethanol
Nausea	Phenytoin
Pregnancy	
Hypoglycemia	
Nicotine	
Morphine	
Other drugs	

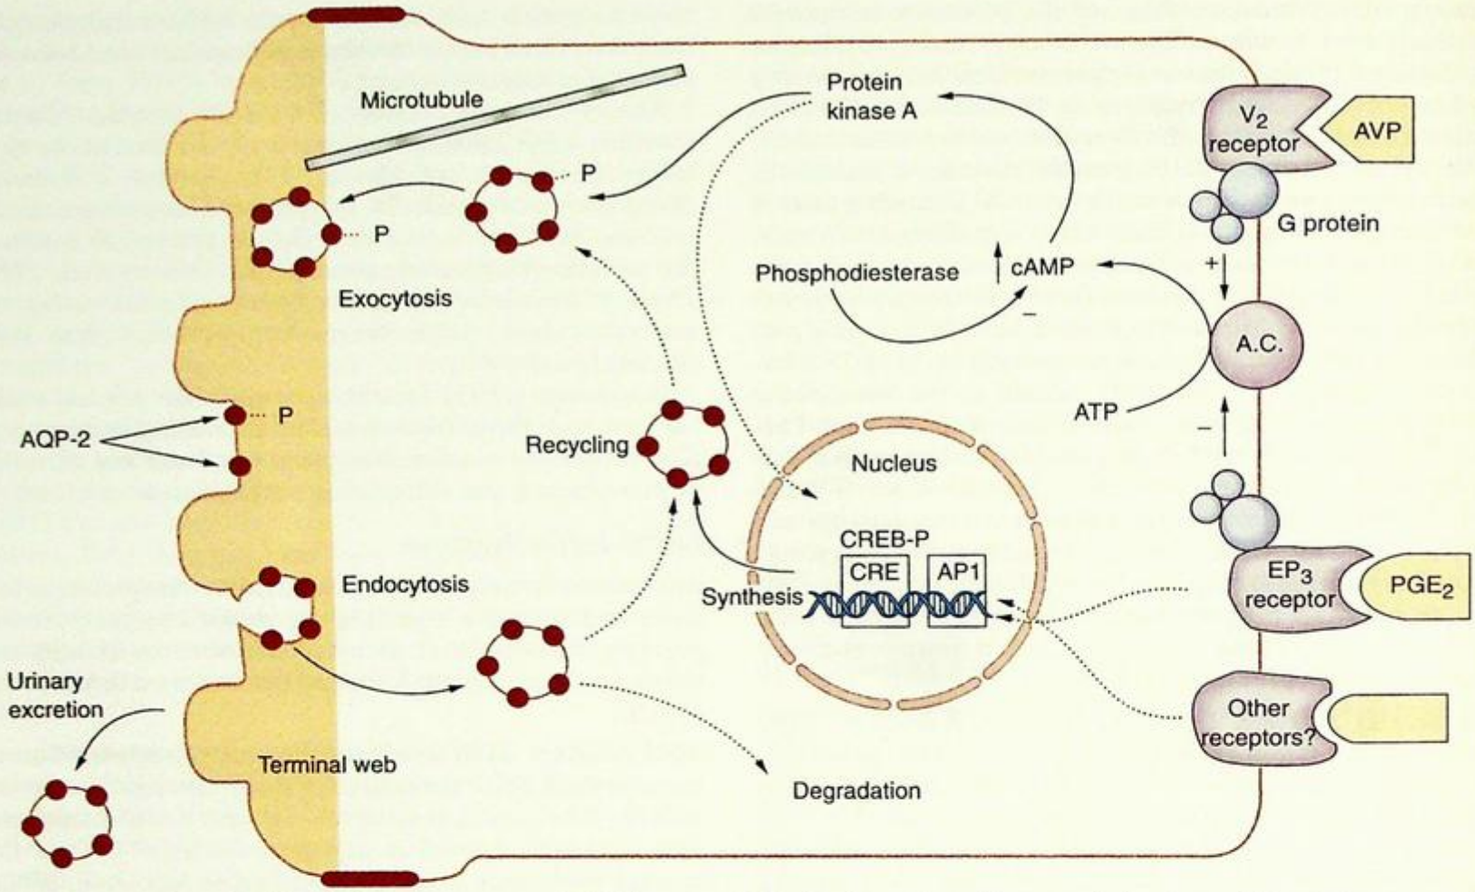

Figure 35–4. Action of antidiuretic hormone on aquaporin (AQP) transport. AC, adenylate cyclase; AP1, transcription factor; AVP, arginine vasopressin; cAMP, cyclic adenosine monophosphate; CRE, cAMP response element; CREB-P, CRE binding protein; EP3, prostaglandin receptor; PGE_2, prostaglandin E_2. (From Brown D, Nielsen S: The cell biology of vasopressin action. In Brenner BM [ed]: Brenner and Rector's The Kidney, 7th ed. Philadelphia, WB Saunders, 2004, p 574.)

Hyperosmolality. The major extracellular osmole is sodium, so for practical purposes ADH release is governed by changes in serum sodium concentrations. Serum osmolality is monitored by osmoreceptors in the hypothalamus, and changes as little as 1% are enough to affect ADH release (Robertson, 1987).

Decreased Effective Circulating Volume. Circulating volume is monitored by pressure (baro) receptors in the carotid sinus, which stimulate ADH release in response to reductions in ECV. These receptors are much less sensitive than the osmoreceptors, and ADH release is not affected until there is a noticeable drop in MAPs (usually around 10% to 15% blood volume loss) and after other vasoconstrictive hormones such as renin and norepinephrine have been activated.

Other Stimuli. A number of other factors can increase ADH secretion (see Table 35–2). Nausea and pain are probably the most clinically relevant, and as a result postsurgical hyponatremia related to excessive ADH release is a potentially life-threatening problem.

When both decreased ECV and hyponatremia coexist, the pressure receptors usually override the osmoreceptors and prevent the inhibition of ADH secretion that is usually seen with hyponatremia (Baylis, 1987). This is clinically relevant in conditions of decreased ECV and hyponatremia such as congestive heart failure in which ADH secretion persists despite significant hyponatremia.

Renal Tubular Function

Basic Functions

The renal tubule has two basic functions: *reabsorption* (transport of substances from lumen to blood) and *secretion* (transport of substances from blood to lumen). Transport can involve one of two pathways, either *transcellular* (across the luminal and basolateral membrane) or *paracellular* (between cells) (Fig. 35–5). **Each section of the tubule** (Fig. 35–6) **is specialized to facilitate absorption and secretion of certain substances through a variety of transport mechanisms.**

Proximal Convoluted Tubule

The proximal convoluted tubule (PCT) is responsible for reabsorption of 60% of the glomerular filtrate. Under normal circumstances it reabsorbs 65% of the filtered sodium, potassium, and calcium; 80% of filtered phosphate, water, and bicarbonate; and 100% of filtered glucose and amino acids (Moe et al, 2004). The PCT is able to increase or decrease reabsorption in response to changes in GFR in order to maintain constant reabsorptive fractions through the process of *glomerulotubular balance.* The majority of this is accomplished by the early (S1 and S2) segments of the PCT. The later (S3) segment is responsible for secretion of numerous drugs and toxins that are too large, or protein bound, to be filtered. As well, the PCT is responsible for the generation of ammonia from glutamine, necessary for urinary acidification.

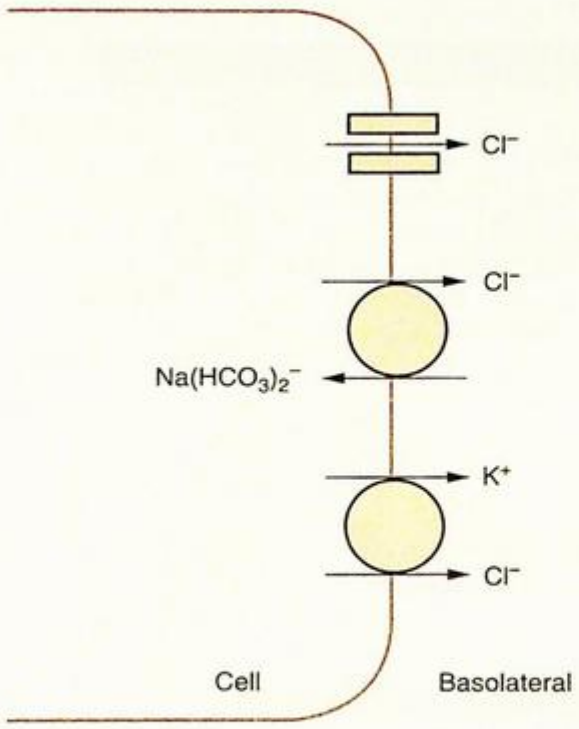

Figure 35–5. Example of transcellular transport between the tubule cell and the basolateral membrane. (From Moe OW, Baum M, Berry CA, Rector FC Jr: Renal transport of glucose, amino acids, sodium, chloride, and water. In Brenner BM [ed]: Brenner and Rector's The Kidney, 7th ed. Philadelphia, WB Saunders, 2004, p 425.)

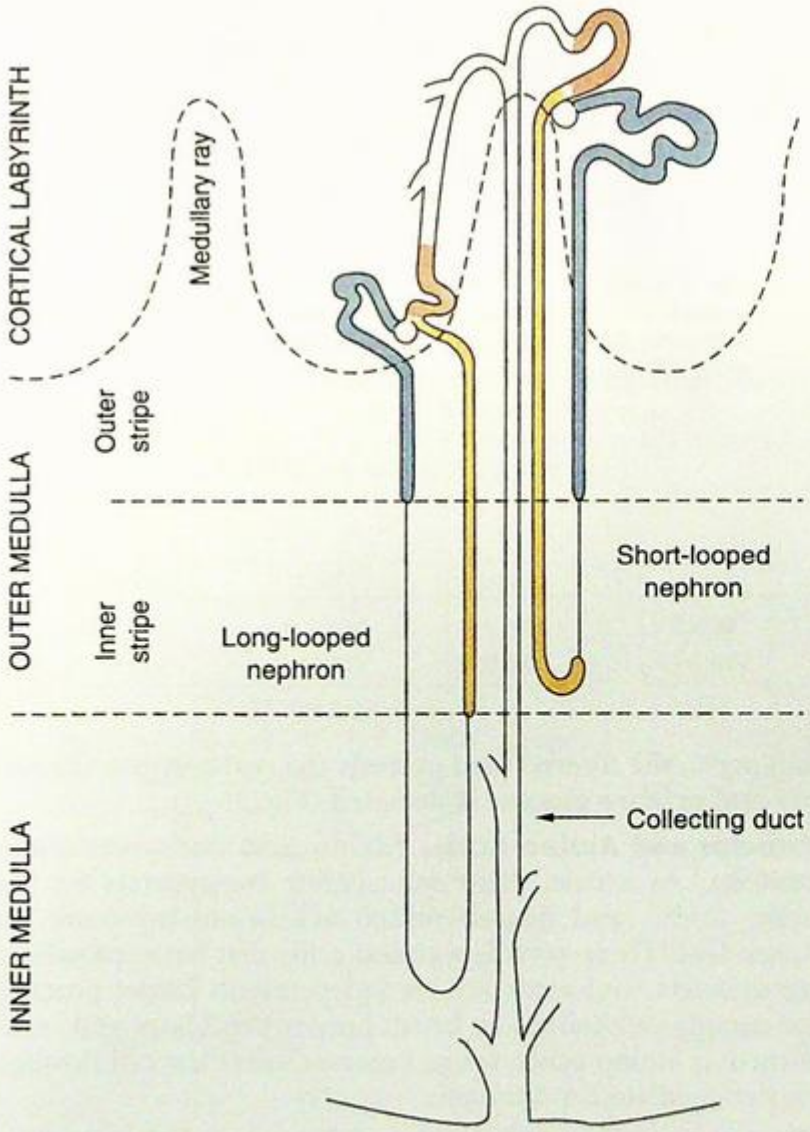

Figure 35–6. Organization of the renal tubule. (From Knepper MA, Gamba F: Urine concentration and dilution. In Brenner BM [ed]: Brenner and Rector's The Kidney, 7th ed. Philadelphia, WB Saunders, 2004, p 601.)

Sodium. The majority of sodium reabsorption occurs in the PCT and occurs through both secondary active and passive mechanisms (Fig. 35–7).

1. *Secondary active reabsorption*—luminal Na^+ moves passively into tubular cells; this movement, however, is driven by osmotic and electrochemical gradients between the luminal and intracellular environments established by the energy-requiring sodium-potassium adenosine triphosphatase (Na^+,K^+-ATPase) located in the basolateral cell membrane. There is an active exchange of three intracellular Na^+ for two extracellular K^+ ions, which keeps the intracellular sodium concentration low and the cell interior negative with respect to the lumen. This is called *secondary passive reabsorption*. Na^+ then enters the cell through coupled transport with other solutes (see later) or in exchange for H^+ through an Na^+/H^+ antiporter. The activity of this transporter is under neurohormonal regulation and can be influenced by angiotensin II, norepinephrine, and dopamine to either increase or decrease Na^+ reabsorption in response to changes in ECV.
2. *Passive reabsorption*—this occurs when Na^+ moves paracellularly into the intercellular space. It is meditated through Cl^- transport across the paracellular pathway, which creates an electrochemical gradient favoring Na^+ movement out of the lumen into the intercellular space.

In summary, then, one can see that sodium is the most significant solute for the PCT for three reasons:

- It is the only solute that is actively reabsorbed (through the basolaterally located Na^+,K^+-ATPase pump).
- All other solutes are passively reabsorbed through Na^+ coupled transport.
- Early reabsorption of Na^+ (as well as other solutes) creates an osmotic gradient that facilitates passive reabsorption of water.

Potassium. The majority of potassium reabsorption occurs by the paracellular route. It is largely dependent on sodium and fluid movement, as potassium reabsorption parallels that of water and sodium.

Bicarbonate. The majority of filtered bicarbonate (90%) is reclaimed in the PCT. There is no upper limit to bicarbonate reabsorption; in states of volume depletion and increased proximal reabsorption of Na^+, bicarbonate reabsorption continues even in the presence of significant alkalemia (Moe et al, 2004). Bicarbonate is not transported across PCT cells; its reabsorption is dependent upon H^+ secretion by the Na^+/H^+ antiporter. Within the lumen, bicarbonate combines with H^+ to form H_2O and CO_2, which can diffuse intracellularly and be converted back to H^+ and bicarbonate and subsequently secreted through the basolateral membrane by an Na^+ coupled transporter and returned to the circulation. Both these reactions are catalyzed by carbonic anhydrase (Fig. 35–8).

Water. Water reabsorption in the PCT is a passive process, driven by the reabsorption of other solutes and the subsequent osmotic gradient that develops between the lumen and intercellular space. The majority of water reabsorption occurs in the late PCT. As with Na^+ movement, water can also move either transcellularly or paracellularly. Transcellular movement accounts for 80% of water reabsorption and occurs through the specialized water channel aquaporin-1 (AQP-1)

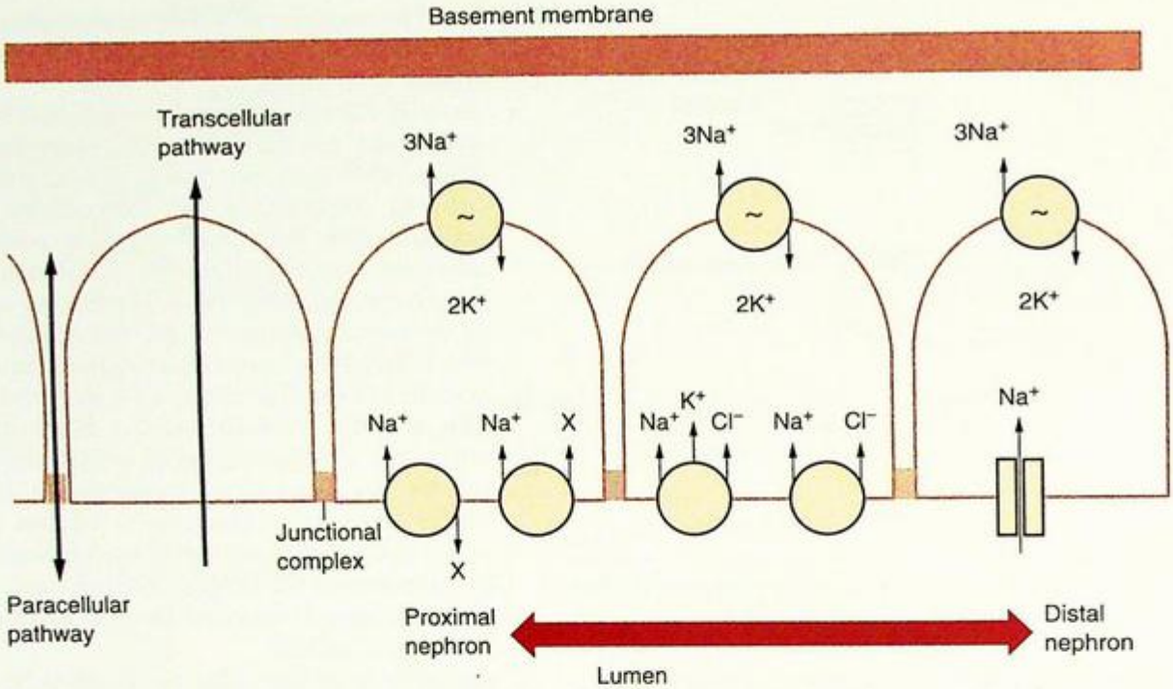

Figure 35–7. Mechanisms of sodium reabsorption in the proximal tubule. (From Moe OW, Baum M, Berry CA, Rector FC Jr: Renal transport of glucose, amino acids, sodium, chloride, and water. In Brenner BM [ed]: Brenner and Rector's The Kidney, 7th ed. Philadelphia, WB Saunders, 2004, p 414.)

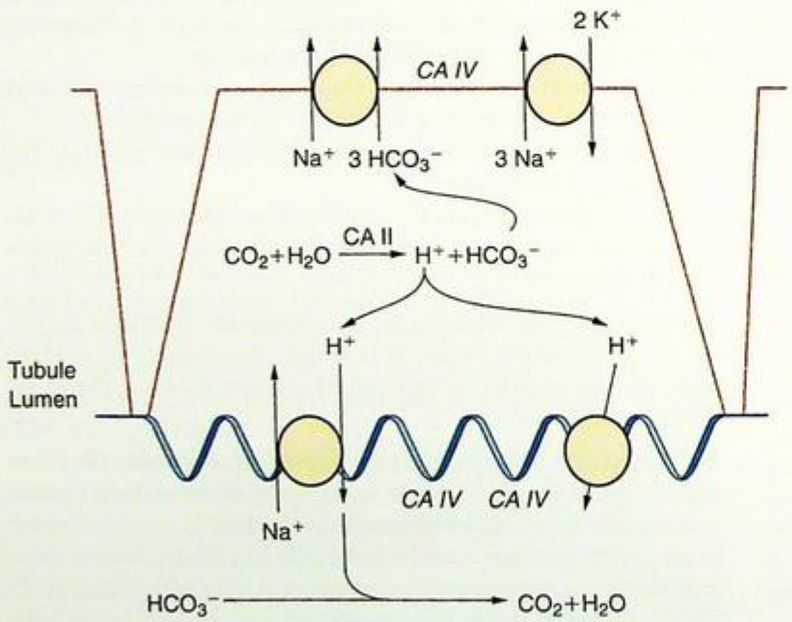

Figure 35–8. Reabsorption of bicarbonate in the renal tubule. CA, carbonic anhydrase. (From Hamm LL: Renal acidification mechanisms. In Brenner BM [ed]: Brenner and Rector's The Kidney, 7th ed. Philadelphia, WB Saunders, 2004, p 500.)

(Agre et al, 2002). Paracellular movement accounts for only 20% of water reabsorption and occurs across the tight junctions between cells.

Glucose. Glucose reabsorption is driven by passive Na^+ reabsorption. In the early (S1 and S2) PCT, this occurs through a high-capacity, low-affinity Na^+/glucose transporter called SGLT-2 (Moe et al, 2004). In the later (S3) segment of the PCT, reabsorption occurs through a low-capacity, high-affinity $2Na^+$/glucose transporter (also found in intestine) called SGLT-1. Intracellular glucose is then transported out of the cell through the basolateral membrane by the facilitative transporter GLUT-2. At normal plasma glucose levels, all filtered glucose is reabsorbed. **However, if plasma levels exceed 200 mg%, the filtered load exceeds the reabsorptive threshold and urinary glucose is detected** (Fig. 35–9).

Proteins and Amino Acids. Amino acid transport is very complex. As a rule, there are separate transporters for the basic, acidic, and neutral amino acids, and most are Na dependent. There are a few amino acids that have specialized transporters, and some are Na independent. Larger proteins are usually catabolized by brush border peptidases and reabsorbed as amino acids; some, however, enter the cell through carrier-mediated endocytosis.

Phosphate. About 85% [illegible] filtered phosphate is reabsorbed, primarily in the [illegible] reabsorption occurs through an Na^+/[illegible] transporter. The activity of this

transporter is regulated by both plasma phosphate levels and PTH levels (Fig. 35–10).

Calcium. Most calcium reabsorption occurs in the late S2 segment and early S3 segment of the PCT. It is a passive process, driven by the lumen (+) potential difference (PD). Calcium movement occurs by the paracellular route, through the specific calcium channel claudin 2 (Amasheh et al, 2002), located in the tight junctions. It is also possible that there is a small amount of active calcium reabsorption in the late S3 segment, but this is poorly characterized (Fig. 35–11).

Magnesium. About 15% of filtered magnesium is reabsorbed in the PCT, but the mechanism is poorly understood (Konrad et al, 2004).

Loop of Henle

The loop of Henle consists of four segments: the thin descending limb (DLH), the thin ascending limb (ALH), the medullary thick ascending limb (mTALH), and the cortical thick ascending limb (cTALH). It receives the 40% of ultrafiltrate not reabsorbed by the PCT. **Each segment of the loop of Henle has specific functions related to fluid, electrolyte, and acid-base balance, but the major function of the loop as a whole is to reabsorb 25% to 30% of the filtered Na^+ and to reabsorb NaCl in excess of water in order to establish an extremely concentrated medullary interstitium, necessary for the excretion of a concentrated final urine.** The loop of Henle, like the PCT, is also controlled by glomerulotubular balance, which maintains a consistent ultrafiltrate delivered to the collecting ducts (Fig. 35–12).

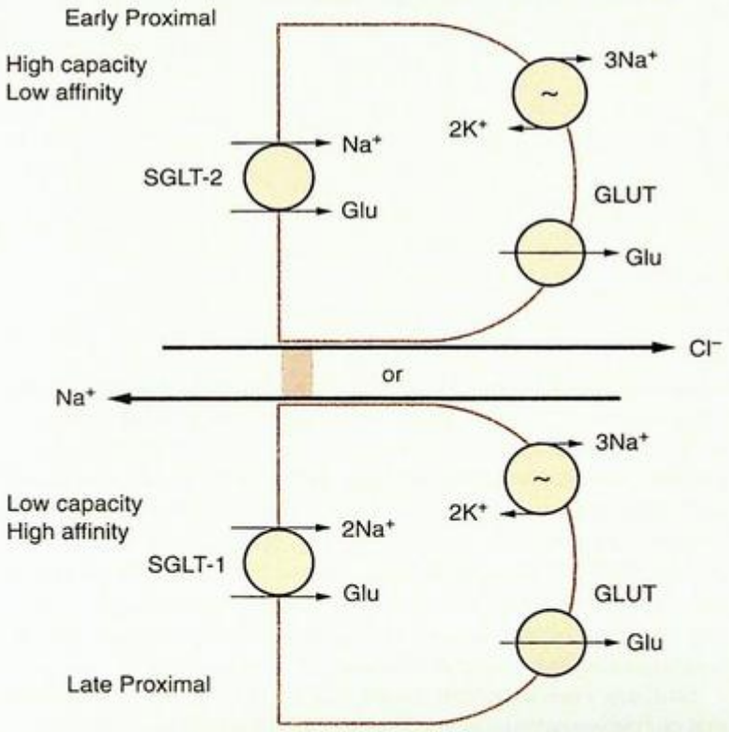

Figure 35–9. Absorption of glucose by the renal tubule. (From Moe OW, Baum M, Berry CA, Rector FC Jr: Renal transport of glucose, amino acids, sodium, chloride, and water. In Brenner BM [ed]: Brenner and Rector's The Kidney, 7th ed. Philadelphia, WB Saunders, 2004, p 417.)

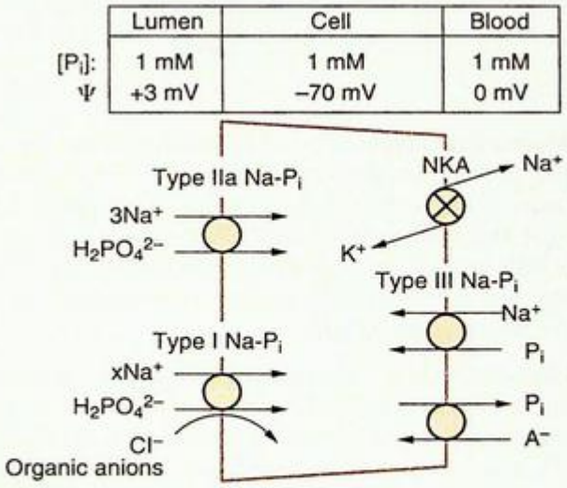

Figure 35–10. Absorption of phosphate by the renal tubule. (From Yu SLY: Renal transport of calcium, magnesium, and phosphate. In Brenner BM [ed]: Brenner and Rector's The Kidney, 7th ed. Philadelphia, WB Saunders, 2004, p 555.)

(From Moe OW, Baum M, Berry CA, Rector FC Jr: Renal transport of glucose, amino acids, sodium, chloride, and water. In Brenner BM [ed]: Brenner and Rector's The Kidney, 7th ed. Philadelphia, WB Saunders, 2004, p 433.)

to achieve this degree of urinary concentration, the kidney must be able to generate an interstitial osmotic gradient of similar degree. Through the process of *countercurrent multiplication,* the loop of Henle is able to produce an interstitial osmotic gradient ranging from 285 mOsm/kg (isosmotic with plasma) in the outer medulla to 1200 mosmol/kg in the inner medulla. The basic steps of countercurrent multiplication are as follows:

1. Medullary interstitium is made hyperosmolar by the reabsorption of NaCl (in the absence of water reabsorption) in the ascending limbs of the loop of Henle.
2. Because of the hairpin (*countercurrent*) configuration of the loop, the concentration of the luminal fluid can be progressively increased *(multiplied*) to as much as 1200 mosmol/kg (Fig. 35–14). This allows the interstitial osmolarity to increase to similar levels.
3. In the presence of ADH, urea diffuses from the medullary collecting tubule into the interstitium, increasing the interstitial osmolarity even further (Yang and Bankir, 2005). This has a secondary benefit of increasing water reabsorption in the DLH, thus increasing luminal sodium and chloride concentrations in the ascending limbs and making step 1 even more efficient (Fig. 35–15).
4. Because of the high interstitial osmolality, water is passively reabsorbed in the medullary collecting tubule (in the presence of ADH). This could potentially lead to dilution of the interstitium. To minimize this effect, the volume of ultrafiltrate is minimized through water reabsorption in the cortical collecting tubule. Also, the vasa recta are arranged in a similar hairpin loop that allows water removal but minimizes removal of interstitial

Figure 35–14. Countercurrent mechanism in the renal tubule. AD, antidiuresis; WD, water diuresis. (From Knepper MA, Gamba F: Urine Concentration and Dilution. In Brenner BM [ed]: Brenner and Rector's The Kidney, 7th ed. Philadelphia, WB Saunders, 2004, p 604.)

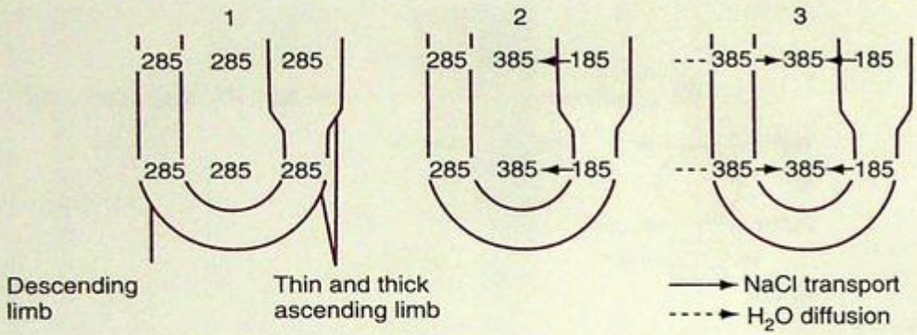

Figure 35–15. Role of active NaCl transport in initiating countercurrent multiplication. In step 1, at time zero, the fluid in the descending and ascending limbs and the interstitium is isosmotic to plasma. In step 2, NaCl is transported out of the ascending limb into the interstitium to a gradient of 200 mosmol/kg. In step 3, the fluid in the descending limb equilibrates osmotically with the hyperosmotic interstitium, primarily by water movement out of the tubule. Dilution of the interstitium by this water movement is prevented by continued NaCl transport out of the ascending limb. The result is the creation of an osmotic gradient between the ascending limb and the relatively hyperosmotic descending limb and interstitium.

The osmotic gradient can be disturbed in certain clinical conditions. Increased medullary blood flow (as seen with osmotic diuresis) increases removal of interstitial solutes through the vasa recta and leads to a lower interstitial osmolality. As well, prolonged use of loop diuretics prevents the transport of NaCl in the ascending limb of the loop of Henle, necessary for the ongoing maintenance of the interstitial hyperosmolality; hence, a prolonged water diuresis may be seen after discontinuation of the drug, until the gradient can be reestablished.

Tamm-Horsfall Mucoprotein. The TALH is also the site of secretion of Tamm-Horsfall mucoprotein, or uromodulin. It is clinically important as it forms the matrix of all urinary casts. It has been shown to be important in the prevention of urinary tract infections. It has also been implicated in the pathogenesis of cast nephropathy, medullary cystic renal disease, and familial juvenile hyperuricemic nephropathy.

Distal Tubule

The distal tubule is primarily involved in sodium and calcium reabsorption. There may be some capacity for H^+ and K^+ secretion, but the importance of this is unknown. The distal tubule can be subdivided into two sections, the distal convoluted tubule (DCT) and the connecting tubule.

Sodium and Chloride. The DCT reabsorbs another 5% to 10% of the sodium filtered through the glomerulus. As in the TALH, it is a secondary active process driven by basolateral Na^+,K^+-ATPase pumps that occurs in the absence of water reabsorption. Na^+ is reabsorbed electroneutrally with Cl^- through an Na^+/Cl^- (NCC) cotransporter, which can be inhibited with the thiazide diuretics. In addition, there may be some Na^+ reabsorption through the Na^+/H^+ exchange transporter in the luminal membrane. It should be noted that Na^+ reabsorption in the DCT is regulated by luminal sodium concentration and not by hormonal influences. **Hence, anything that increases delivery of Na^+ to the DCT leads to increased Na^+ reabsorption in the section of the tubule.** One clinical example would be the use of loop diuretics. By inhibiting the NKCC2 transporter in the TALH, Na^+ delivery increases to the DCT. In response, there is usually a marked increase in Na^+ reabsorption that may significantly diminish the diuretic response achieved with the loop diuretic. Such a response may be minimized by concomitant use of a thiazide diuretic.

The connecting segment can also reabsorb sodium but does so under the influence of aldosterone in a fashion similar to that of the principal cells of the cortical collecting tubule.

Calcium. The DCT accounts for 10% to 15% of calcium reabsorption. Unlike that in either the PCT or loop of Henle, calcium reabsorption in the DCT is independent of Na^+ reabsorption. Calcium enters the cell through the luminal calcium channel $ECaC_1$ and binds to the intracellular binding protein calbindin D_{28} (Loffing and Kaissling, 2003). In this way, free intracellular calcium concentration is kept low, thus facilitating inward movement of calcium. Extrusion from the cell occurs through the basolateral membrane by either a Ca^{2+}/H^+ (PMCA) or Na^+/Ca^+ (NCX) exchanger (Loffing and Kaissling, 2003). In contrast to the situation in the PCT or loop of Henle, movement of calcium by the paracellular route is inhibited by the presence of the protein claudin 8, which markedly decreases calcium permeability through tight junctions.

Calcium reabsorption is regulated in this region by the actions of PTH and, to a lesser degree, calcitriol (vitamin D). PTH increases calcium reabsorption, possibly through alterations in intracellular voltage as a result of increased Cl^- flux through the basolateral membrane. Calcitriol is thought to increase the number of $ECaC_1$ channels and increase calbindin production, both of which would increase calcium reabsorption.

Magnesium. Five percent to 10% of filtered magnesium is actively reabsorbed in the DT by the transcellular route. This probably occurs through the luminal magnesium channel TRPM6 (Voets et al, 2004) and is driven by a basolateral Na-Mg pump that generates an Mg gradient favoring inward flow of Mg.

Collecting Tubule

The collecting tubule consists of two parts, the cortical collecting tubule (CCT) and the medullary collecting tubule (MCT). Although the more proximal portions of the nephron are designed for bulk reabsorption of ultrafiltrate, the collecting tubules are responsible for the final qualitative changes in ultrafiltrate composition in response to dietary intake.

Cortical Collecting Tubule

The CCT consists of two distinct cell types, each with distinct functions. Principal cells (65%) are generally involved in NaCl reabsorption, and intercalated cells (35%) are mostly involved with acid secretion. Both are also involved in K regulation as well.

Principal Cells

Sodium, Potassium, and Chloride. Sodium reabsorption occurs passively through the luminal Na channel ENaC rather than through a cotransporter system (Loffing and Kaissling,

2003). Basolateral Na^+,K^+-ATPase pumps keep intracellular sodium concentration low, facilitating inward movement of sodium. Movement of sodium intracellularly, without an accompanying anion, creates a lumen (−) PD that results in either passive paracellular movement of Cl out of the lumen or secretion of intracellular K into the lumen in order to restore electroneutrality. Sodium reabsorption is regulated in the CCT primarily by aldosterone, which increases the number of open ENaCs. Blockade of the Na channel by the diuretic amiloride leads to reduced Na reabsorption as well as K secretion, as the electrochemical gradient is eliminated and thus the driving force for K secretion is abolished (Fig. 35–16). Prostaglandin E_2 also seems to inhibit Na reabsorption, and reduction of PGE_2 by nonsteroidal anti-inflammatory drugs leads to sodium retention.

K secretion in the CCT depends not only on aldosterone-sensitive inward Na movement but also on luminal flow rates. When flow decreases in the tubular lumen, the local intraluminal potassium concentration increases and minimizes the favorable potassium gradient, thus minimizing secretion. This can be partially offset by the actions of ADH, which increase potassium secretion possibly by the insertion of new K channels in the luminal membrane or by increased Na reabsorption (Wang, 1995). **Thus, any condition that leads to decreased luminal flow rates, or increased aldosterone production, can lead to reduced potassium excretion.**

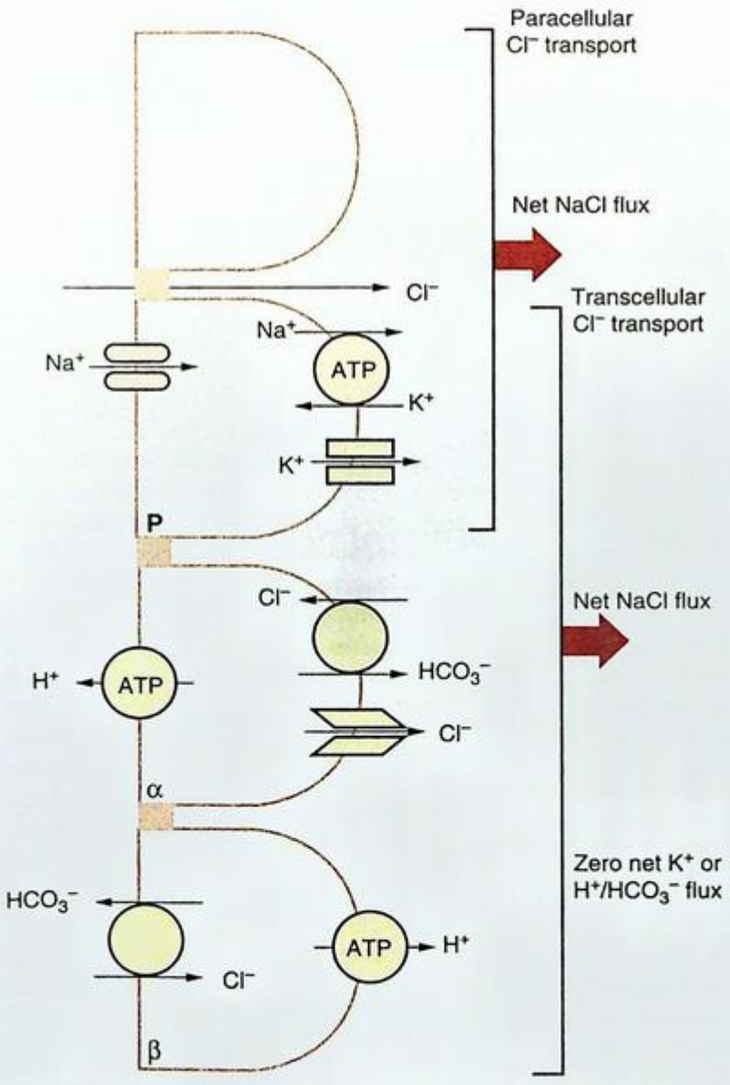

Figure 35–16. Effect of blockade of the Na channel by the diuretic amiloride. (From Moe OW, Baum M, Berry CA, Rector FC Jr: Renal transport of glucose, amino acids, sodium, chloride, and water. In Brenner BM [ed]: Brenner and Rector's The Kidney, 7th ed. Philadelphia, WB Saunders, 2004, p 439.)

Water. The water permeability of the CCT is low in the basal state. However, it can be greatly increased in the presence of ADH. This is due to the insertion of preformed AQP-2 water channels into the luminal membrane (Agre et al, 2002), which allows water to be passively reabsorbed and equilibrate with the cortical interstitium through basolateral AQP-3 and AQP-4 channels. This is important for the development of a highly concentrated final urine, as it decreases the volume of ultrafiltrate delivered to the MCT, where most of the final concentration of urine occurs (Knepper et al, 1994) (Fig. 35–17).

Intercalated Cells. There are two different types of intercalated cells, with different functions: type A intercalated cells, involved mostly with H^+ secretion; and type B intercalated cells, involved mostly with bicarbonate secretion.

Hydrogen and Bicarbonate. **In both cell types, intracellular H_2O, under the influence of carbonic anhydrase, is combined with CO_2 to produce H^+ and HCO_3^-.** As well, in both cell types, the H^+ and HCO_3^- are secreted out of the cell through similar transporters. What is different is the location of the transporters.

Type A intercalated cells have both H^+-ATPase and H^+,K^+-ATPase pumps located on the luminal membrane, which facilitate H^+ secretion into the tubular lumen. Bicarbonate is transported back to the systemic circulation through an HCO_3^-/Cl^- transporter on the basolateral side of the cell. The net effect is acidification of the urine and subsequent increase in extracellular pH. As expected, this process is stimulated under conditions of acidemia. Aldosterone seems to have a permissive effect on this, probably through actions on the H^+-ATPase pump, as increased urine H^+ loss and subsequent systemic alkalosis are seen in conditions of hyperaldosteronism.

Type B intercalated cells have similar transporters, but they have reversed polarity. That is, the H^+-ATPase pumps are located on the basolateral side of the cell, and the HCO_3^-/Cl^- transporters are localized to the luminal membrane. The result of this is net loss of bicarbonate and a decrease in systemic pH. This is necessary in states of alkalemia and thus functions to lower systemic bicarbonate.

Potassium. Although there is normally net secretion of potassium in the CCT, there is the potential for potassium reabsorption through the H^+,K^+-ATPase. This becomes more relevant in states of potassium depletion, when the activity of these pumps is increased. **Although this may help correct systemic hypokalemia, it is often at the expense of increased H^+ secretion and resultant systemic alkalosis.**

Medullary Collecting Tubule

The MCT is divided into the outer MCT (oMCT) and inner MCT (iMCT). Both segments contain cells similar to the principal cells and intercalated cells found in the CCT; hence, the handling of sodium, potassium, hydrogen ion, and bicarbonate is very similar. The main functional difference lies with the MCT's water and urea permeabilities and thus its ability to concentrate the urine to levels far above that of plasma.

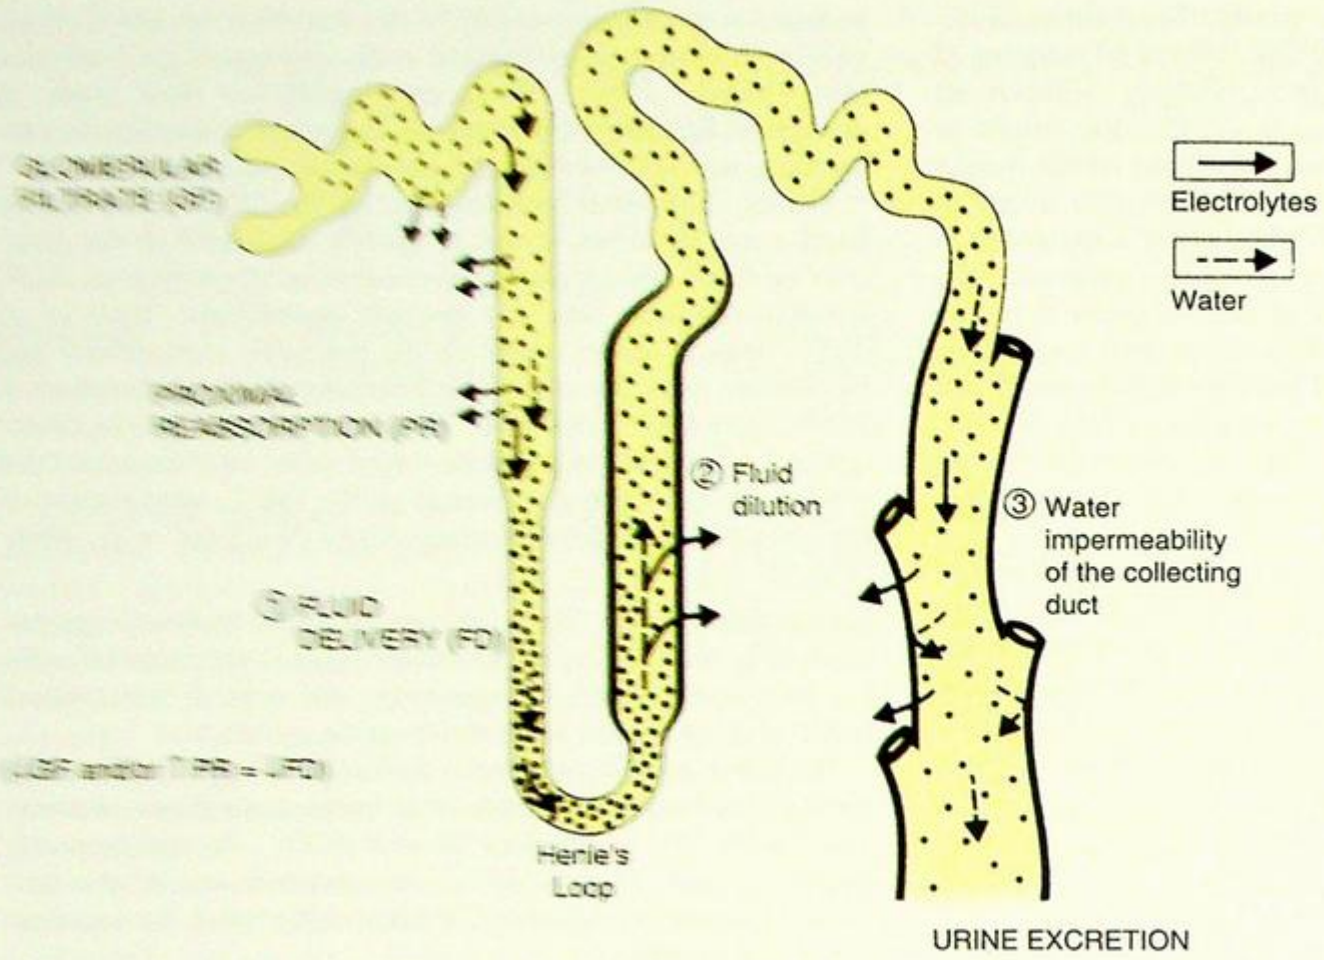

Figure 35–17. The components of the normal urine dilution mechanisms. (Redrawn from Berl T, Schrier RW: Water metabolism and the hypo-osmolar syndrome. In Brenner BM, Stein JH [eds]: Sodium and Water Homeostasis. New York, Churchill Livingstone, 1978, pp 1-23.)

Water and Urea. The MCT is relatively impermeable to water in the basal state, but under the influence of ADH, permeability increases in both the iMCT and oMCT through the insertion of AQP-2 water channels. This allows water to move out of the tubule into the hyperosmolar interstitium and urine concentration to occur. Equally important to this process is urea. The oMCT is relatively impermeable to urea, both in the basal state and under +ADH stimulation. In contrast, the iMCT has a high basal permeability for urea, largely because of specific urea transporters (UT-A1 and UT-A3) located on the basolateral cell membrane as well as, to a lesser extent, the luminal membrane. Short-term regulation is under the influence of ADH, which can increase urea permeability as much as fourfold through an increased number of UTs. Longer term regulation can be affected by protein intake. **This allows a high concentration of urea to develop in the interstitium, thus sustaining the osmotic gradient that is responsible for water reabsorption and ultimately urinary concentration** (Berg and Tenbon 2005).

Sodium. As mentioned earlier, Na reabsorption in the MCT is similar to that occurring within principal cells in the CCT. However, it has been shown the Na reabsorption is diminished in the MCT under conditions of volume expansion. This is due in part to the actions of ANP, which decreases Na reabsorption in the iMCT but not the oMCT. This effect seems to be due to a reduction in the number of open Na channels in the luminal membrane.

KEY POINTS: RENAL TUBULAR FUNCTION

- The nephron has different functional segments that serve unique roles.
- Most reabsorption of bicarbonate and ions occurs in the proximal tubule.
- The architecture of the loop of Henle allows a highly hyperosmotic interstitium to develop, which is key to medullary urinary concentration.

RENAL PATHOPHYSIOLOGY

Sodium and Water Imbalances

Imbalances of sodium and water are often poorly managed and understood by clinicians despite the mechanisms and appropriate therapy being quite well documented. **The most consistent clinical misconception is that sodium concentration reflects total body sodium content.** Because sodium is primarily extracellular, the serum concentration reflects water balance. Therefore, hyponatremia can occur in the presence of total body sodium excess, and hypernatremia can occur with sodium deficits. For an imbalance to occur, there has to be an imbalance between sodium and water that the normal mechanisms of response have not handled. **Therefore, the way to approach serum sodium abnormalities is to determine the water status of the patient and then to determine why the normal compensatory mechanisms have failed** (Fig. 35–18).

Hyponatremia

By definition, hyponatremia exists if there is a water excess relative to [illegible] that has not been handled by the

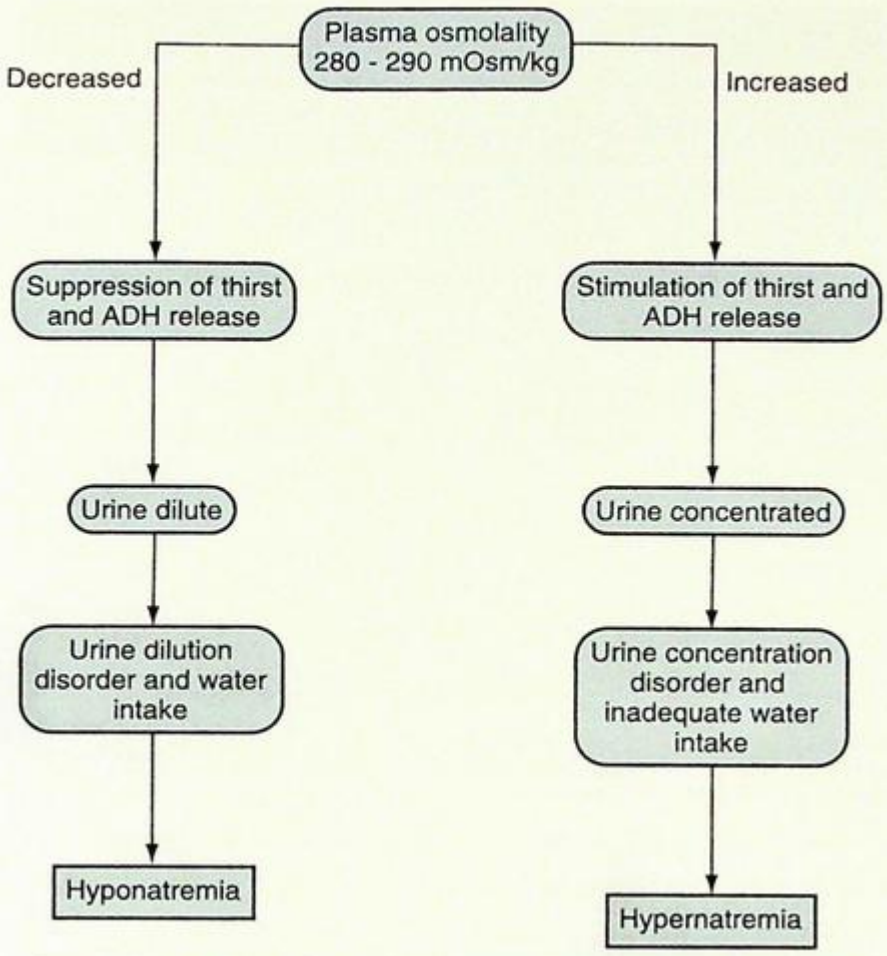

Figure 35–18. Flowchart illustrating the development of disorders of water metabolism. ADH, antidiuretic hormone.

normal compensatory mechanisms of thirst suppression and decreased ADH release, leading to a serum sodium less than 135 mEq/L. Hyponatremia is seldom symptomatic unless severe (<120 mEq/L), but when severe or of sudden onset it can produce seizures, altered mental state, coma, and death. Most commonly hyponatremia occurs because the kidney is unable to excrete urine that is free from solutes (Mallie et al, 1997). **To calculate the amount of water excreted or retained by the kidney, it is useful to consider that urine has two components: one that contains all of the solute in an isotonic solution (termed C_{osm}, or osmolar clearance) and another that contains only solute-free water (termed C_{H_2O} or free water clearance).** The total urine volume (V) (e.g., liters per day) is the sum of C_{osm} and C_{H_2O}:

$$V = C_{osm} + C_{H_2O}.$$

When the urine is hypo-osmotic to plasma, C_{H_2O} is a positive value.

Hyponatremia occurs when one or more of these requirements are not fulfilled, such as when GFR is reduced, when diuretics impair NaCl reabsorption, or when vasopressin is in excess (e.g., syndrome of inappropriate ADH secretion). If water intake exceeds the kidney's capacity to form solute-free water (>10 to 20 L/day), hyponatremia also occurs. This abnormality in solute-free water clearance in hyponatremic patients is reflected by the failure to excrete maximally dilute urine (U_{osm} = 100 mOsm/kg).

The diagnosis of hyponatremia is made by measurement of serum electrolytes. There are several conditions in which a low serum sodium is misleading, however. The reported laboratory value is usually in terms of sodium per volume of plasma rather than water. If large molecules such as lipids or protein are present in large quantities, they decrease the amount of water in a given volume of plasma, but these molecules contribute little to plasma osmolality. **What is truly important is the amount of osmotically active solute per volume of water.** Pseudohyponatremia is most commonly seen with abnormal elevations of serum lipids or glucose. For every 1 g/dL increase in triglycerides, measured sodium is decreased by 2 mEq/L, and for every 100 mg/dL of glucose, measured sodium is decreased by 1.6 mEq/L.

The approach, therefore, to a patient with true hyponatremia begins with an assessment of volume status (Fig. 35–19). Clinical features such as skin turgor, orthostatic hypotension, jugular venous distention, ascites, and respiratory crackles can all be helpful in this decision. Patients who are clinically hypovolemic by definition have a sodium deficit greater than their water deficit. The appropriate renal response would be to excrete urine that is hypo-osmotic with a high C_{H_2O}. Therefore, if the urine is not hypo-osmotic, the etiology is related to the kidney. Measuring the urinary sodium (U_{Na}) is a useful surrogate for urinary osmolality. A hypovolemic patient with an appropriately low U_{Na} (<20) has extrarenal sodium losses such as from trauma, vomiting, diarrhea, burns, or third spacing. In a hypovolemic patient with an inappropriately high U_{Na} of greater than 20, a renal source should be suspected, such as diuretic excess, osmotic diuresis, renal tubular acidosis, or mineralocorticoid deficiency. If the hyponatremic patient is hypervolemic, total body sodium can be low, normal, or high. A high U_{Na} of greater than 20 would point to renal failure. A low U_{Na} of less than 20 would suggest heart failure, cirrhosis, or nephrotic syndrome.

A patient who is euvolemic would have low or normal total body sodium. The differential diagnosis would include glucocorticoid deficiency, hypothyroidism, stress, and the syndrome of inappropriate antidiuretic hormone secretion (SIADH). **SIADH is a syndrome triggered by release of ADH through a mechanism other than low blood volume or high plasma osmolality, associated with increased aquaporin expression in the kidney** (Kwon et al, 2001). The most common causes of SIADH are brain infections and surgery, neoplasm, and drug side effects (Table 35–3). Pharmacologic antagonists that can be used to treat patients with SIADH include lithium and demeclocycline. Lithium inhibits vasopressin action both proximal and distal to cAMP formation in the collecting duct (Miller, 1994). Demeclocycline, in doses ranging from 600 to 1200 mg/day, induces vasopressin-resistant diabetes insipidus that corrects the serum sodium within 1 to 2 weeks (Goh, 2004).

Therapy of hyponatremia is directed at both the cause of the condition and the water imbalance itself (Fig. 35–20). Patients with acute severe hyponatremia symptomatic with confusion, convulsions, or coma should undergo fluid restriction plus administration of hypertonic (3%) saline (about 1 mL/kg/hr). Fluid overload is unlikely as long as fluid is restricted but may be further reduced by simultaneous administration of a loop diuretic such as furosemide (which causes excretion of hypotonic fluid equivalent to half-normal saline). The serum sodium concentration should be raised no more

than 25 mEq/L in the first 48 hours, at a rate of no more than 2 mEq/L/hr, and the target goal should be 120 to 125 mEq/L. Total sodium deficit to reach this point can be calculated as

$$\text{(Volume of distribution)} \times \text{body weight (kg)} \times (125 - \text{plasma [Na]})$$

where volume of distribution is 0.5 for men and 0.6 for women.

If the hyponatremia is severe but chronic, the rate of correction should not exceed 8 to 12 mmol/L/day, or a cerebral demyelination syndrome may occur (Martin, 2004). Therefore, the rate of correction should be slower (0.5 to 1 mEq/L/hr). During acute intervention for severe hyponatremia, frequent electrolyte measurements and reassessment of the patient are required. Aggressive therapy should be discontinued when the serum sodium concentration is raised 10% or symptoms subside. At that point, water restriction and reversal of underlying causes should suffice. This is also the best approach for therapy of asymptomatic hyponatremia. Obviously, patients with associated hypovolemia should have this corrected with the appropriate volume of normal saline.

Hypernatremia

The underlying problem of hypernatremia is a disorder of urine concentration with inadequate water intake (Adrogue and Madias, 2000). **Again, in hypernatremia it is the water balance that matters and total body sodium can be high, normal, or even low.** Symptoms are nonspecific and overlap those seen in hyponatremia, with the early occurrence of restlessness, nausea, and vomiting that can progress to tremor, lethargy, and coma. Indeed, mortality is higher in hypernatremia than in most other electrolyte disorders. **Most patients with an intact thirst mechanism and free access to water can prevent hypernatremia,** and the condition is more common at the extremes of age.

The approach to a patient with hypernatremia again begins with an assessment of fluid status (Fig. 35–21). Hypovolemia is common and may be due to renal causes that fail to concentrate the urine adequately (loop diuretics, postobstructive diuresis) or extrarenal water loss such as seen with burns, diarrhea, or fistulas. Patients with hypervolemia have a metabolic or iatrogenic reason for high sodium in excess of the elevated total body water. Causes include Cushing's syndrome, primary hyperaldosteronism, and excessive exogenous sodium (orally or intravenously). Patients who are euvolemic may have renal or extrarenal losses that may be caused by diabetes insipidus, an impairment in renal concentrating ability related to lack of central production (neurogenic), or impaired renal response (nephrogenic).

In neurogenic diabetes insipidus, vasopressin deficiency is most commonly caused by destruction of the neurohypophysis. To produce symptomatic polyuria, 80% to 90% of the neurosecretory neurons must be destroyed at or above the level of the infundibulum. As a consequence of the reduced vasopressin level, the kidney excretes a high volume of dilute urine. This leads to a reduction in total body water, a rise in total body osmolality, and thus hypernatremia. The related cellular dehydration stimulates thirst. Compensatory water intake decreases plasma osmolality (and Na^+ concentration) toward normal, but they stabilize at the threshold level for thirst, which is slightly above normal. **As in all forms of diabetes insipidus, the ability of the kidney to concentrate the urine maximally in response to vasopressin is also impaired in neurogenic diabetes insipidus. This abnormality occurs because the medullary osmotic gradient is reduced by the high urine flow.** In nephrogenic diabetes insipidus, secretion of vasopressin by the neurohypophysis is normal, but renal responsiveness to the hormone is attenuated or absent and urinary concentrating ability is impaired (Sasaki, 2004). Several different mutations of the aquaporin gene have been identified that contribute to the pathogenesis of this disorder (Leung et al, 2005).

Therapy of hypernatremia is directed at fluid deficit, water replacement, and reversal of underlying causes. Hypovolemia should be initially corrected with half-normal saline. If the patient is awake and not symptomatic, oral hydration with water is sufficient. Otherwise, intravenous therapy should be started with the goal of slowly lowering plasma osmolality at no more than 2 mOsm/L/hr to avoid cerebral edema. The water deficit can be calculated as

$$\text{(Volume of distribution)} \times \text{body weight (kg)} \times ((\text{plasma [Na]}/140) - 1)$$

where again the volume of distribution is 0.5 for men and 0.6 for women.

For patients with central diabetes insipidus, desmopressin, a synthetic exogenous vasopressin, can be given intranasally. For nephrogenic diabetes insipidus, the underlying cause (lithium, hypercalcemia) should be treated. If polyuria persists while the kidney recovers, therapy includes modest sodium restriction, thiazide diuretics, and nonsteroidal anti-inflammatory drugs (Pattaragarn and Alon, 2003).

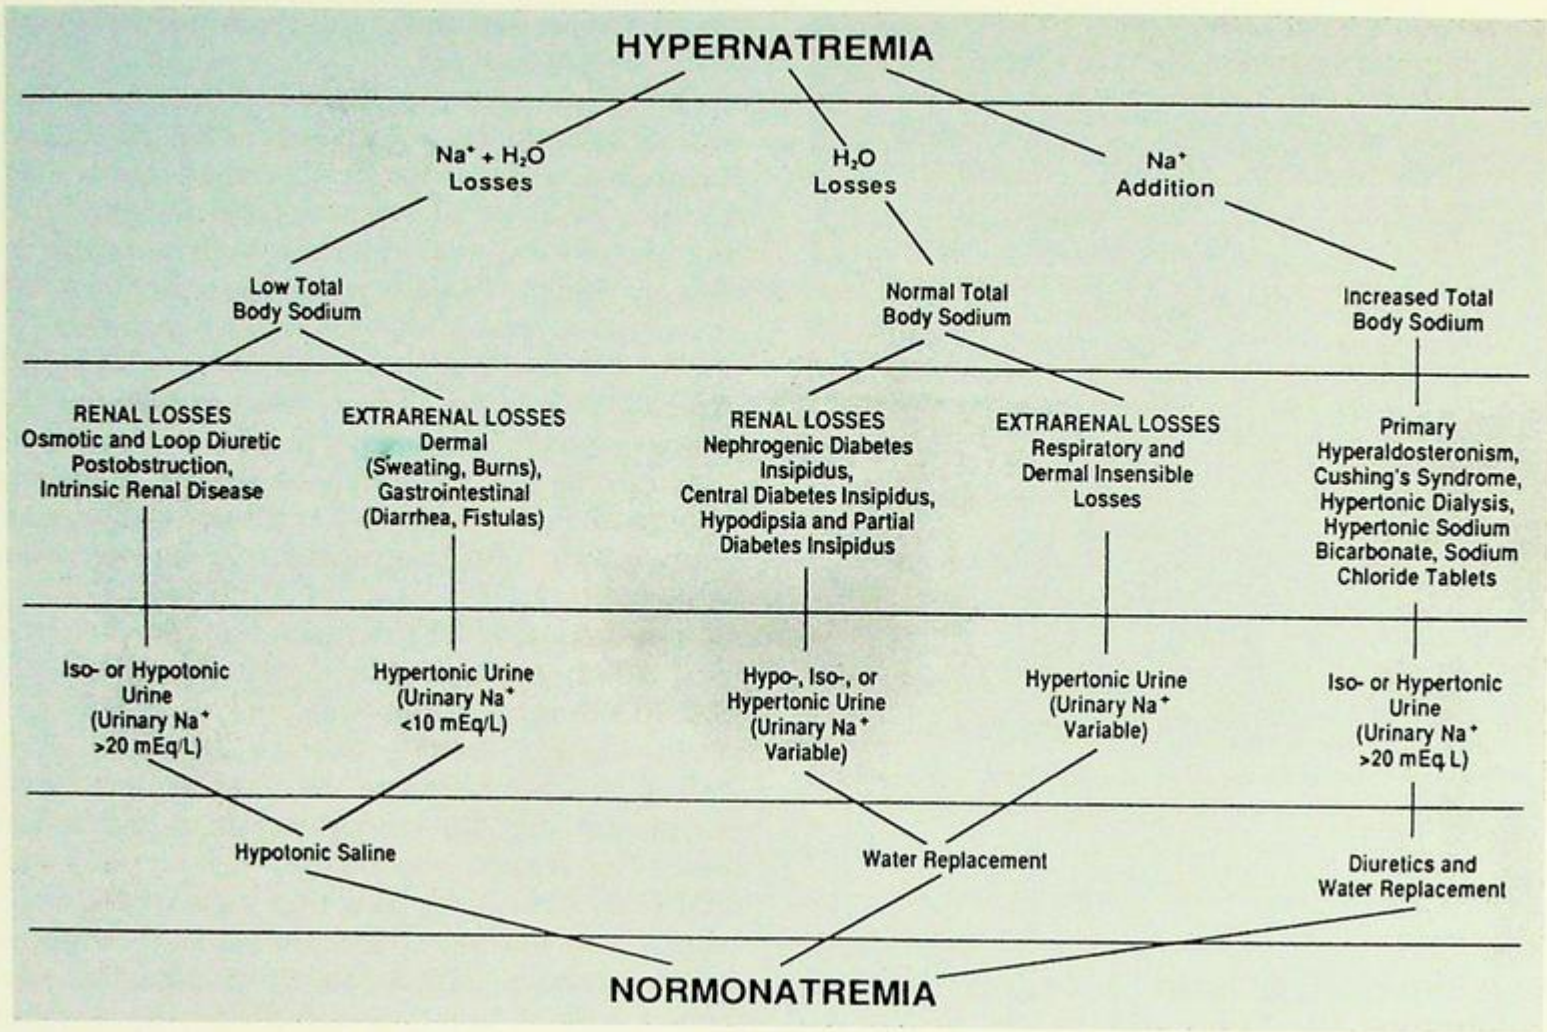

Figure 35–21. Clinical approach to patient with hypernatremia. (From Berl T, Anderson RJ, McDonald KM, Schrier RW: Clinical disorders of water metabolism. Kidney Int 1976;10:117-132.)

KEY POINTS: SODIUM AND WATER IMBALANCES

- Serum sodium represents sodium concentration, *not* total body sodium.
- The best tools to determine the cause of a sodium disorder are the history, volume status, and urinary sodium.
- Severe sodium deficit or excess must be corrected slowly.

Potassium Imbalances

Potassium is primarily an intracellular ion, and serum levels do not represent total body content in disease states. Because neuromuscular excitability is closely linked to serum potassium levels, extremes of low or high values can lead to cardiac arrhythmias and death. The body responds to changes in potassium intake and levels by controlling urinary excretion and by changing the balance between intracellular and extracellular stores. **Urinary excretion can be increased in the kidney through increased aldosterone, a high sodium load in the distal tubule, and acidosis. Potassium is driven into the cells by insulin, bicarbonate, and β-agonists.**

Hypokalemia

The most common causes of hypokalemia are increased losses through the gastrointestinal (GI) tract or urine and increased intracellular shift of potassium in response to alkalosis (mnemonic: aLKalosis = low K^+). The most common iatrogenic causes are diuretics, laxatives, amphotericin, theophylline, and postobstructive diuresis. Metabolic causes include conditions associated with elevated aldosterone such as adrenal adenoma, Cushing's syndrome, and adrenal carcinoma. The patient may have no symptoms or present with signs and symptoms of the underlying condition (e.g., hypertension). Severe hypokalemia may produce tachycardia, heart block, and ST depression. Therapy is directed at correction of the underlying cause and oral or parenteral potassium supplementation. In general, intravenous potassium replacement should not exceed 40 mEq per hour.

Hyperkalemia

Hyperkalemia usually reflects decreased renal excretion of potassium or a shift out of cells into the extracellular space (usually by acidosis). A compromised excretory capacity can be further exacerbated by GI bleeding or hemolysis. The most common causes (Table 35–4) are renal failure, drugs (potassium-sparing diuretics, lithium, digoxin, angiotensin-converting enzyme inhibitors), chronic acidosis (e.g., renal tubular acidosis type 4), and hypoaldosteronism. Hemolysis of the [illegible] blood sample can falsely elevate serum potassium [illegible] fore an unexpectedly high value in a patient

Table 35–4. Etiology of Hyperkalemia

Factitious
Laboratory error
Pseudohyperkalemia: in vitro hemolysis, thrombocytosis, leukocytosis
Increased Input
Exogenous: diet, salt substitutes
Endogenous: hemolysis, GI bleeding, catabolic states, crush injury, tumor lysis
Renal Failure
Acute: especially tubulointerstitial disease
Chronic: GFR <15-20 mL/min
Impaired Renin-Aldosterone Axis
Addison's disease
Congenital adrenal enzyme deficiencies (e.g., corticosterone methyl oxidase deficiency)
Drug induced: heparin, prostaglandin inhibitors, ACE inhibitors, pentamidine, β blockers
Hyporeninemic hypoaldosteronism
Primary hypoaldosteronism (normal renin)
Primary Renal Tubular Potassium Secretory Defect
Sickle-cell disease
Systemic lupus erythematosus
Postrenal transplantation
Obstructive uropathy
Tubulointerstitial renal disease
Pseudohypoaldosteronism
Hyperkalemic distal renal tubular acidosis
Inhibitors of Tubular Secretion
Diuretics: amiloride, spironolactone, triamterene
Cyclosporine
Lithium
Digitalis
Abnormal Potassium Distribution
Metabolic acidosis
Insulin deficiency
Hypertonicity (e.g., hyerglycemia)
Aldosterone deficiency
β-Adrenergic receptor blockade
α-Adrenergic receptor agonist
Exercise
Periodic paralysis
Digitalis
Succinylcholine

ACE, angiotensin-converting enzyme; GFR, glomerular filtration rate; GI, gastrointestinal.

Adapted from Rastegar A, DeFronzo RA: Disorders of potassium metabolism associated with renal disease. In Schrier RW, Gottschalk CW (eds): Diseases of the Kidney, 5th ed. Boston, Little, Brown, 1992, pp 1645-2661.

with no symptoms, risk factors, or electrocardiographic (ECG) changes should be checked with a redrawn sample pending aggressive therapy. The classical ECG changes include a short QT interval, peaked T waves, and ultimately ventricular arrhythmias.

Need for therapy is determined by the degree of elevation of potassium, the acuteness of elevation, and the presence of ECG changes. Mild hyperkalemia without ECG changes requires only dietary restriction and reversal of underlying causes. ECG changes require emergency therapy: intravenous calcium gluconate (to protect the heart) and a cocktail of drugs to drive the potassium into the cell including sodium bicarbonate, insulin (given with glucose to avoid hypoglycemia), and nebulized albuterol (especially if there is a delay in gaining intravenous access). Therapy to increase intracellular potassium must be coupled with therapy to remove potassium stores, or the hyperkalemia will recur when infusions stop. Potassium-binding exchange resins (sodium polystyrene sulfonate [Kayexalate], calcium polystyrene sulfonate [Resonium]) can be used for this purpose orally or by enema. Finally, hemodialysis can remove extracellular potassium most quickly and completely.

KEY POINTS: POTASSIUM IMBALANCES

- Potassium is primarily intracellular.
- Serum potassium levels reflect total body potassium as well as the equilibrium between intra- and extracellular potassium.
- Alkalosis produces a low serum potassium.

Acid-Base Metabolism

Although the hydrogen ion (H^+) is present in miniscule concentrations in the extracellular fluid compared with other common ions in the body, its primary importance is reflected by the multiple mechanisms that exist to control its concentration within a tight range. The reason is that small alterations in H^+ concentration have large effects on the relative concentrations of other conjugate bases and acids of all the weak electrolytes. At neutral body pH, most biologically active molecules are in their charged state and can be trapped more effectively within cells to perform their functions. Furthermore, pH determines the net charge of proteins, which influences protein conformation and enzyme binding characteristics. Outside normal blood pH (7.35 to 7.46), severe metabolic problems occur.

In order to maintain pH, the body has to deal with the daily production of acid. There is a large production of acid by the metabolism of carbohydrates and fats, largely in the form of carbon dioxide, approximately 15,000 mmol/day. CO_2 is not an acid in the classical sense of the Brønsted-Lowry theory (Kildeberg, 1983) because it is not capable of donating an H^+ to a base. CO_2 can be considered a "volatile" acid because it is easily converted into H_2CO_3, carbonic acid:

$$H^+ + HCO_3^- \rightleftharpoons H_2CO_3 \rightleftharpoons H_2O + CO_2$$

Each molecule of CO_2 excreted by the lungs results from the reaction of one molecule of bicarbonate with one molecule of H^+. The H^+ remains in the body as H_2O. The metabolism of ingested proteins into amino acids is another source of acid production, estimated as between 50 and 100 mEq of H^+ per day (sulfate from the three sulfur-containing amino acids, phosphate from phosphoproteins). Because these acids cannot be excreted by the lungs, they are considered "fixed" and must be excreted by the kidneys.

The body therefore has three primary mechanisms to handle physiologic and pathophysiologic acid loads: buffers in the blood, CO_2 excretion by the lungs, and H^+ excretion by

HCO_3 metabolism in the kidneys (Vasuvattakul et al, 1992). The immediate response to an acid load is buffering. A buffer is simply a mixture of a weak acid and its conjugate base or a weak base and its conjugate acid that resists changes in pH when another acid or base is added. The key buffers in the blood are HCO_3 for metabolic acids and hemoglobin for CO_2. Within the cell, proteins and phosphates, which are found in higher concentrations than in the blood, become important as well. In the extracellular fluid, HCO_3 is responsible for about 80% of buffering. Changes in pH are governed by the Henderson-Hasselbalch equation, which generally is

$$pH = pKa + \log \text{base/acid}$$

When specifically formulated for the bicarbonate system, it becomes

$$pH = 6.1 + \log HCO_3^-/0.03 \times pCO_2$$

In general, optimal buffering occurs within 1.0 pH unit of the pKa. Therefore, the pKa value of 6.1 of bicarbonate buffer does not appear to be the most efficient for maintaining the pH 7.4 that is required for normal homeostasis. **The bicarbonate buffer system is effective despite having a low pKa because the body also controls pCO_2.**

Excretion of CO_2 by the lungs can occur rapidly and change both blood and intracellular pH. Elevated pCO_2 is detected by central and peripheral chemoreceptors which increase respiratory rate, leading to increased alveolar ventilation. Respiratory compensation in response to a pure metabolic acidosis cannot reduce CO_2 to below 10 mm Hg and is therefore unable to maintain pH in the setting of a large acid load.

Although most of the daily acid production is volatile and therefore excreted by the lungs, the kidneys must excrete the fixed acid and in doing so also reabsorb most of the filtered bicarbonate so that efficient extracellular buffering can be maintained. A healthy individual, with a GFR of 180 L/day and a plasma [HCO_3^-] of 24 mEq/L, filters 4300 mEq of HCO_3^- daily from the glomerulus into the proximal tubule. Of this filtered load, less than 0.1% normally appears in the urine. **The bulk of the filtered bicarbonate is reclaimed in the proximal nephron, with approximately 80% of the filtered HCO_3^- reabsorbed within the proximal convoluted tubule.** In the tubular urine, H^+ and HCO_3^- are formed from CO_2 and H_2O in a reaction catalyzed by carbonic anhydrase (Kaunisto et al, 2002). The H^+ is returned to the tubular urine through two mechanisms: an Na^+-H^+ pump (antiporter) and a direct H^+-ATPase proton pump. The net result is reabsorption of $NaHCO_3$ into the interstitial fluid and secretion of H^+ into the proximal collecting duct urine. Note that the use of a carbonic anhydrase inhibitor such as acetazolamide reduces HCO_3 reabsorption and increases excretion of Na^+ and water, resulting in a weak diuretic effect (Puscas et al, 1999). The reabsorption of HCO_3 does not result in net excretion of H^+ from the body; however, the proximal tubular reabsorption of HCO_3 is essential to preserving acid-base balance. The primary factors that increase HCO_3 reabsorption are arterial pCO_2, HCO_3 concentration in the lumen, luminal flow rate, and angiotensin II (de Mello-Aires and Malnic, 2002).

The remainder of the filtered bicarbonate is reabsorbed in the distal nephron by a mechanism independent of carbonic anhydrase. In the distal tubule, further H^+ is secreted through the production of titratable acid, usually by buffering with phosphate. The term *titratable acidity* refers to the quantity of NaOH required to titrate urine back to a pH of 7.40, which is similar to that of blood. Other buffers, such as uric acid (pKa, 5.75) and creatinine (pKa, 4.97), contribute to the titratable acidity but only to a minor extent. H^+ is also secreted through the production of ammonium ion (NH_4^+). NH_4 is produced from glutamine, primarily by proximal tubular cells (Michoudet et al, 1994). Because of its high pKa (about 9.2), it is present almost exclusively as the NH_4^+ ion. Ammonium excretion can increase significantly during systemic acidosis (Nagami, 2004), which is the key mechanism for secreting excess H^+ because at very low urinary pH titratable acid cannot increase much (unless other ions such as ketoanions are being produced).

Regulation of H^+ secretion occurs through multiple biochemical and hormonal actions upon the preceding system. **Volume depletion** leads to Na retention and enhanced HCO_3 absorption, with a net loss of H^+. **Elevated pCO_2** as seen in chronic respiratory acidosis (see later) leads to a renal response of increased H^+ secretion. **Reduced GFR** reduces the amount of filtered HCO_3, leading to increased H^+ excretion. **High aldosterone levels** indirectly increase H^+ excretion by increasing Na^+ absorption. **Low potassium and low chloride** increase HCO_3 reabsorption and can maintain chronic metabolic alkalosis.

Acid-Base Disorders

Those of us outside the fields of nephrology and anesthesia encounter acid-base disorders less commonly and are often intimidated by the process of working through the appropriate diagnosis. Nevertheless, when the terminology and basic equations are understood, the process is simple and, in many ways, mechanical (Corey, 2005). Common misconceptions begin with definition of terms. **The actual pH disturbance is an "emia" and the disease causing it is an "osis." Acidemia** refers strictly to a low arterial blood pH, less than 7.36. **Alkalemia** is a blood pH greater than 7.44. **Acidosis** is an abnormal condition or process that would lower arterial pH if no other condition was present, and **alkalosis** is a condition that would raise pH. **The basic information required to diagnose an acid-base disturbance is a history, physical, serum electrolytes, and arterial blood gas.** If the acid-base disorder is caused by a respiratory problem, the pCO_2 moves in the opposite direction to the pH (Madias and Adrogue, 2003). If caused by a metabolic (renal) disorder, the HCO_3 moves in the same direction as the pH. In every disorder, there should be an attempt by the other acid-handling mechanism to compensate for the change. For instance, chronic loss of bicarbonate from the kidney causing a metabolic acidosis (low pH and low HCO_3) should lead to increased ventilation to try to excrete the excess acid through the lung, leading to a lower pCO_2 (respiratory compensation). In **simple** acid-base disorders, there is one mechanism causing the acid disturbance with an appropriate compensation. In **mixed** disorders, the clue to multiple mechanisms comes from significant under- or overcompensation. Although formulas have been developed to predict appropriate compensation for each disorder, visual nomograms are typically used at the bedside.

Metabolic Acidosis

In metabolic acidosis, loss of bicarbonate leads to systemic acidemia, which produces a low arterial pH and low serum HCO_3. The appropriate compensation is increased respiration leading to a reduced pCO_2. In general, the expected degree of pCO_2 reduction is calculated as

$$\text{Expected } pCO_2 = 1.5 \times [HCO_3^-] + 8 \pm 2$$

This bicarbonate loss can be direct or from secondary effects of other ions. The presence of active ions that are not measured in routine blood work can be detected by the anion gap. The anion gap is defined as the difference between the levels of routinely measured cations (Na^+) and anions (Cl^- and CO_2) in blood:

$$\text{Anion gap} = Na^+ - (Cl^- + HCO_3^-) = 140 - (105 + 24) = 11$$

The normal range is 9 to 14 mEq/L. The predominant unmeasured anions include albumin and phosphate. The major unmeasured cations include calcium, magnesium, and gamma globulins. If the anion gap is elevated in a patient with metabolic acidosis, the condition occurs because acids that do not contain chloride are present in the blood. The most common are ketones (diabetic ketoacidosis), lactate (lactic acidosis), and drug intoxication (methanol, aspirin) (Levraut and Grimaud, 2003).

Metabolic acidosis with a normal anion gap is caused by direct bicarbonate loss through the gut or kidney or by the addition of exogenous acid that is buffered by bicarbonate (Table 35–5). The patient's history can give major clues to the diagnosis, involving either GI loss (vomiting, diarrhea, fistula), drug use (acetazolamide), or previous surgery (ileal conduit). Serum potassium can be a further clue to etiology. Low potassium is associated with loss through the GI tract or renal tubular acidosis because renin is stimulated from the volume contraction. In acidosis associated with severe renal dysfunction, potassium is often elevated.

Renal Tubular Acidosis

Renal tubular acidosis (RTA) is a family of syndromes of metabolic acidosis resulting from defects in tubular H secretion and urinary acidification. They are classified according to the mechanism of the defect, and each type has different clinical manifestations. RTA type 1 is the most common form and the most clinically significant to the urologist. It has also been called classical RTA and distal RTA. The old classification of RTA type 3 is now recognized as a type 1 variant. The underlying problem is failure of H^+ secretion in the distal nephron, which can be congenital or acquired. Associated disorders include autoimmune diseases (thyroiditis), toxic nephropathy, and chronic ureteral obstruction. **The hallmark is a hyperchloremic metabolic acidosis with a high urinary pH (>5.5) in the presence of persistently low serum HCO_3.** If no metabolic acidosis is present but the condition is still suspected, acid loading with ammonium chloride decreases the serum HCO_3 while maintaining a high urine pH. Volume contraction from sodium loss is common, which leads to secondary hyperaldosteronism and hypokalemia. These patients often develop recurrent renal stones composed of calcium phosphate. The most likely contributing factor is low urinary citrate coupled with a high urinary pH and hypercalciuria. Treatment with sodium bicarbonate can alkalinize the urine, correct the sodium defect, lower aldosterone, and raise the potassium. Potassium citrate can augment the urinary citrate levels and inhibit stone formation (Domrongkitchaiporn et al, 2002).

Type 2 RTA, also called proximal, is caused by failure of bicarbonate reabsorption in the proximal tubule (Igarashi et al, 2002). The mechanisms of H^+ secretion in the distal tubule are overwhelmed, resulting in HCO_3 loss in the urine. The bicarbonate is replaced in the circulation by Cl^-, resulting in hyperchloremia. Increased sodium delivery to the distal tubule increases aldosterone secretion, resulting in hypokalemia. Ultimately, a new steady state is reached in which serum HCO_3^- is decreased, and, hence, the filtered load, distal delivery, and urinary excretion of HCO_3^- are all reduced. **The acidosis is self-limited because acid production and excretion are equivalent at this reduced pH; the plasma HCO_3^- remains at 15 to 20 mEq/L.** Because urinary citrate levels are not reduced, stone formation does not occur despite increased urinary calcium. This condition is more common in children, and it can lead to growth retardation and metabolic bone disease (Roth and Chan, 2001). Oral supplementation with $NaHCO_3$ can correct the condition but can lead to further hypokalemia, and potassium supplements may also be required. As an interesting aside (and possible memory aid), it was suggested that Dickens' character of Tiny Tim was based on a child with type 2 RTA (growth retardation, osteomalacia), which was reversed when Mr. Scrooge paid for his therapy (sodium bicarbonate).

Type 4 RTA is due to impairment of cation exchange in the distal tubule with reduced secretion of both H^+ and K^+. It is due to aldosterone deficiency or resistance. **The unique feature compared with other RTAs is hyperkalemia.** Patients often have associated azotemia and hypertension. Because the distal tubule H^+ pump functions normally, patients are able to

Table 35–6. Differential Diagnosis of Metabolic Alkalosis

Measurement	*Saline Responsive*	*Normotensive: Saline Unresponsive*	*Hypertensive: Saline Unresponsive*
Urinary [Cl^-]	<15 mEq/L	>15 mEq/L	>15 mEq/L

Adapted from Alpern RJ, Emmett M, Seldin DW: Metabolic alkalosis. In Seldin DW, Giebisch G (eds): The Kidney: Physiology and Pathophysiology, 2nd ed. New York, Raven, 1992, pp 2733-2758.

decrease urine pH to less than 5.5 in response to the acidosis. Urinary citrate may be normal or low, but renal dysfunction reduces secretion of calcium and uric acid, and stones do not form (Uribarri et al, 1994). Therapy is typically directed at controlling the hyperkalemia.

Metabolic Alkalosis

In metabolic alkalosis, the pH is high (alkalemia) and the HCO_3 high (mirrors pH in primary metabolic disorder) (Khanna and Kurtzman, 2001). The appropriate respiratory compensation is reduced ventilation with increased pCO_2. The expected degree of respiratory compensation can be estimated by

Expected pCO_2 = 6 mm Hg per 10 mEq/L increase in HCO_3

An exogenous alkali load is usually rapidly excreted into the urine by the kidney, and other mechanisms are required to maintain the disorder. Maintenance of the alkalosis requires a process that greatly impairs the kidney's ability to excrete bicarbonate and prevent the return of the elevated plasma level to normal. Chloride deficiency leads to the kidney reabsorbing more bicarbonate anion than usual because there is not sufficient chloride anion present to maintain electroneutrality. This condition is reversed with fluid and chloride. Consequently, metabolic alkalosis is most conveniently classified as chloride responsive and chloride resistant.

The most common chloride-responsive conditions are GI loss (vomiting, nasogastric drainage, laxative abuse) and kidney loss (diuretics). These make up over 90% of clinical cases of metabolic alkalosis (Table 35–6). Volume contraction in these conditions stimulates aldosterone production and distal secretion of H^+ and K^+. **Thus, there may be a paradoxical aciduria, which persists until volume is replaced.** Chloride-resistant metabolic alkalosis is associated with potassium loss resulting from mineralocorticoid excess. It is associated with volume expansion and high urinary chloride levels, which can aid in the diagnosis. Common causes are hyperaldosteronism (primary or secondary), Cushing's syndrome, diuretics, and congenital conditions such Bartter's syndrome (hyperplasia of the juxtaglomerular apparatus).

Respiratory Acidosis

In respiratory acidosis, pH is low (acidemia) and pCO_2 is high because of inadequate respiration (Epstein and Singh, 2001). The anticipated compensatory response is increased HCO_3:

Acute: Expected HCO_3 = 1 mEq/L for each 10 mm Hg pCO_2

Chronic: Expected HCO_3 = 3.5 mEq/L for each 10 mm Hg pCO_2

Elevated pCO_2 can be caused by increased production of CO_2, decreased ventilation, and increased CO_2 in the inspired air. Because increased production is usually handled quickly by increased respiration and CO_2 does not vary except in ventilated patients, the most common cause is decreased ventilation. This can be due to central depression of respiration (e.g., opiates, trauma, cervical cord trauma), chest cavity problems (e.g., pneumothorax, pulmonary edema), upper airway obstruction, or an iatrogenic cause (insufficient ventilation). Because CO_2 readily diffuses across all cellular membranes, marked elevation can severely interfere with intracellular metabolism. Clinical effects of elevated pCO_2, which are separate from acidosis per se, include elevated intracranial pressure, tachycardia, central depression, and eventually coma and death.

Respiratory Alkalosis

In respiratory alkalosis, pH is high (alkalemia) because of a low pCO_2. This is due to hyperventilation (Foster et al, 2001). The appropriate compensatory response is a lowering of HCO_3 by the following expected amounts:

Acute: Expected HCO_3 = 2 mEq/L for each 10 mm Hg pCO_2

Chronic: Expected HCO_3 = 5 mEq/L for each 10 mm Hg pCO_2

Common causes of hyperventilation that can lead to respiratory alkalosis are fever, pain, anxiety, septicemia, head trauma, pulmonary embolism, and iatrogenic (excessive mechanical ventilation). Neurologic symptoms such as paresthesia and tetany may occur. Therapy is directed at improving oxygenation and ventilation.

KEY POINTS: ACID-BASE

- Physiologic chemical reactions require a narrow range of serum pH.
- Acid is excreted through the lungs and the kidney.
- Type 1 RTA (distal) is the only type associated with renal stones.
- In acid-base disorders, determine first whether the kidney (HCO_3) or lungs (pCO_2) are responsible for the primary disorder, then determine whether the compensatory response is appropriate.

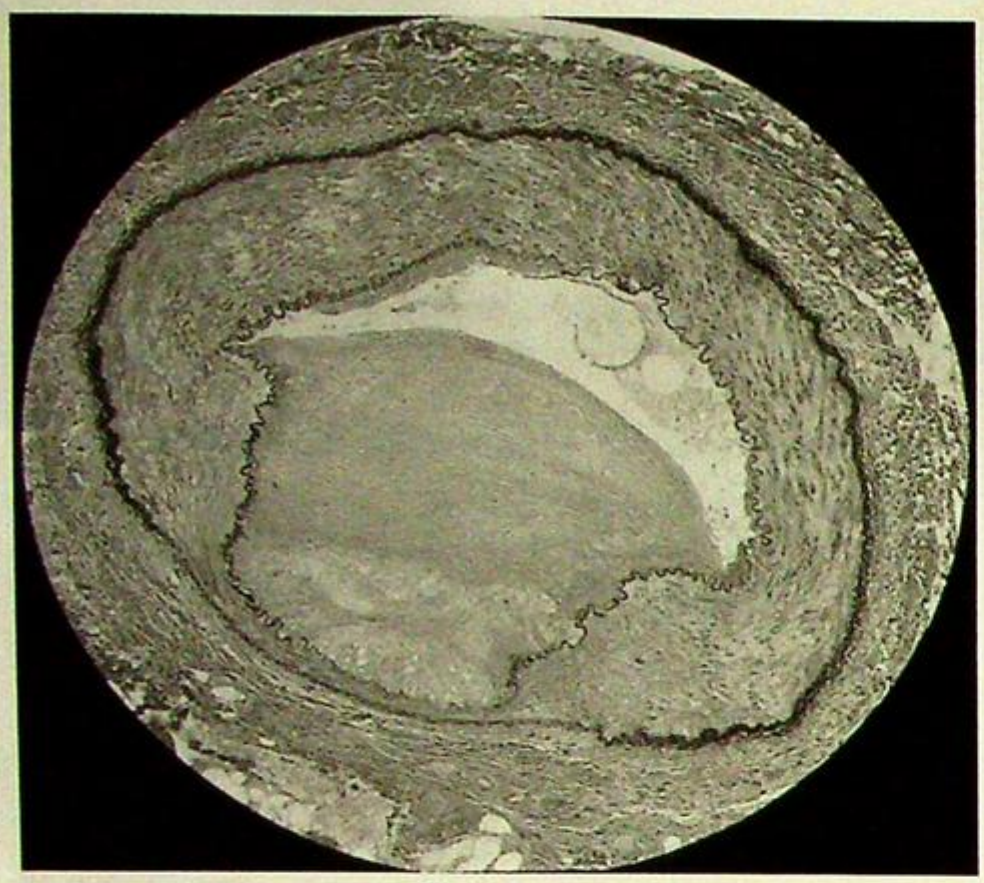

Figure 36–1. Histopathologic appearance of eccentric atherosclerotic plaque causing renal artery stenosis.

plaque (Fig. 36–1); in the remainder, the vessel is circumferentially involved, with narrowing of the lumen and destruction of the intima. Dissecting hematomas frequently complicate this disease, sometimes resulting in thrombosis of the entire vessel.

The natural history of atherosclerotic renal artery disease has been studied by obtaining sequential abdominal aortography or duplex ultrasound scanning in patients with documented renal artery lesions who have been treated medically (Table 36–2). The largest of these studies have shown that **progressive arterial obstruction occurs in 42% to 53% of patients with atherosclerotic renal artery disease, often within the first 2 years of radiographic follow-up. The incidence of progression to complete renal artery occlusion in these studies has ranged from 9% to 16%, and this has occurred more often in arteries that initially showed high degrees of stenosis.**

In a study at the Cleveland Clinic (Schreiber et al, 1984), we reviewed the natural history of atherosclerotic renal artery stenosis (ARAS) in 85 patients who were observed with sequential renal angiograms obtained 3 to 172 months after an initial diagnostic angiogram. Progressive obstruction of the renal artery related to ASO occurred in 37 patients (44%), including 14 (16%) in whom such progression eventuated in complete occlusion of the involved renal artery. In patients in whom progressive disease developed, it occurred primarily within the first 2 years of angiographic follow-up. The rate of progression of ARAS correlated directly with the degree of stenosis on the initial angiogram. The majority of renal arteries with mild (50%) or moderate (50% to 75%) stenosis on the initial angiogram were unchanged on follow-up angiograms. In contrast, 39% of renal arteries with more than 75% stenosis on the initial angiogram progressed to complete occlusion. Other studies have since validated this observation that **progression to [illegible] occurs more often and more rapidly in renal arteries that are initially involved with a high degree (>75%) of stenosis** (Tollefson and Ernst, 1991; Zierler et al, 1994).

Table 36–2. **Natural History of Atherosclerotic Renal Artery Sclerosis**

Clinical follow-up of patients in our study also revealed that significantly more patients with progressive disease developed deterioration of overall renal function compared with patients with stable disease. Interestingly, **serial blood pressure control** was equivalent in these two groups, indicating that blood pressure is not a useful clinical marker for progressive ARAS.

These natural history data clearly show that **atherosclerotic renal artery disease progresses in many patients and that loss of functioning renal parenchyma is a common sequela of such progression.** It is now further appreciated that progressive atherosclerotic renal artery obstruction can eventuate in end-stage renal disease (ESRD). The typical occurrence of ESRD is in older patients with generalized ASO who are not candidates for transplantation and whose prognosis on chronic dialysis is poor in terms of both the quality of life and longevity. In an early study, we identified 25 patients in whom ESRD was clearly a consequence of advanced atherosclerotic renal artery disease (Novick, 1994b). Seventeen of these patients were maintained with chronic dialysis, and of these, 13 died within 1 year (mean survival 8.7 months). The causes of death on dialysis were myocardial infarction (6), infection (2), gastrointestinal bleeding (1), ruptured aortic aneurysm (1), mesenteric infarct (1), cardiogenic shock (1), and cerebrovascular accident (1). In a subsequent study, Mailloux and colleagues (1988) analyzed the survival of patients started on dialysis from 1970 to 1985 according to the primary renal diagnosis. Patients with renovascular disease as the cause of ESRD had the poorest survival, with a 27-month median survival time and a 12% 5-year survival rate. In another study in which 51 patients with bilateral ARAS were observed for 52 months, 12% of the patients progressed to ESRD, and an average rate of decline of GFR of 4 mL/min/yr was noted (Baboolal et al, 1998). A crude mortality rate of 45% was reported. These data further highlight that ESRD from atherosclerotic renal artery disease does not respond well to renal replacement therapy.

The exact incidence of ESRD caused by atherosclerotic renal artery disease in the United States is not known. Fatica and coauthors (2001) reported an increase in incidence of renovascular disease (RVD) as a cause for ESRD in patients starting dialysis treatment. This increase was from 1.4% to 2.1%, with an annual increase of 12%. This information was

derived from the recorded diagnosis of these patients in the U.S. Renal Data System database, and the disease was not specifically searched for. No increase in mortality on dialysis was found in these patients when compared with other etiologies of ESRD.

van Ampting and associates (2003) reported a 27% incidence of significant renal artery stenosis (RAS) in 49 patients older than 45 years starting dialysis when investigated using computed tomography angiography (CTA).

Uzu and coworkers (2002) reported a higher (50%) incidence in 44 patients with ESRD studied by magnetic resonance angiography when additional vascular disease (cerebral, coronary, or peripheral) was also diagnosed.

In a report from England, Scoble and colleagues (1989) prospectively performed renal arteriography in all new patients with ESRD during an 18-month period. Atherosclerotic renal artery disease was the cause of ESRD in 6% of all patients and in 14% of patients older than 50 years. Approximately 300,000 patients in the United States are currently being maintained with chronic dialysis. Their median age is older than 60 years, and a majority have evidence of generalized ASO obliterans. **Although the exact number of patients with ESRD caused by atherosclerotic renal artery disease is not known, based on the data previously described, there appear to be several thousand patients in this category.**

Intimal Fibroplasia

Primary intimal fibroplasia occurs in children and in young adults and constitutes approximately 10% of the total number of fibrous lesions. This lesion is characterized by a circumferential accumulation of collagen inside the internal elastic lamina (Fig. 36–2). Disruption and duplication of the elastica interna occur more often in younger patients, with dissecting hematomas as a complication in many patients. The possibility of ASO as a cause of renal artery disease in this group can be excluded histologically by the absence of lipid demonstrable with special staining techniques. Intimal fibroplasia with complicating medial dissection is characterized pathologically by large dissecting channels in the outer half of the media. These lesions are thought to develop because of defects in the internal elastica with resultant medial dissection and aneurysmal dilatation.

Angiography in primary intimal fibroplasia reveals a smooth, fairly focal stenosis, usually involving the proximal or midportion of the vessel or its branches (Fig. 36–3). Dissecting hematomas may distort the area of the stenosis. With nonoperative management, progressive renal artery obstruction and ischemic atrophy of the involved kidney invariably occur. Severe intimal fibroplasia may subsequently develop de novo in the contralateral renal artery. Although primary intimal fibroplasia most commonly affects the renal arteries, it may also occur as a generalized disorder with concomitant involvement of carotid, upper and lower extremity, and mesenteric vessels.

Medial Fibroplasia

Medial fibroplasia is the most common of the fibrous lesions, constituting 75% to 80% of the total number. It tends to occur in women between the ages of 25 and 50 years

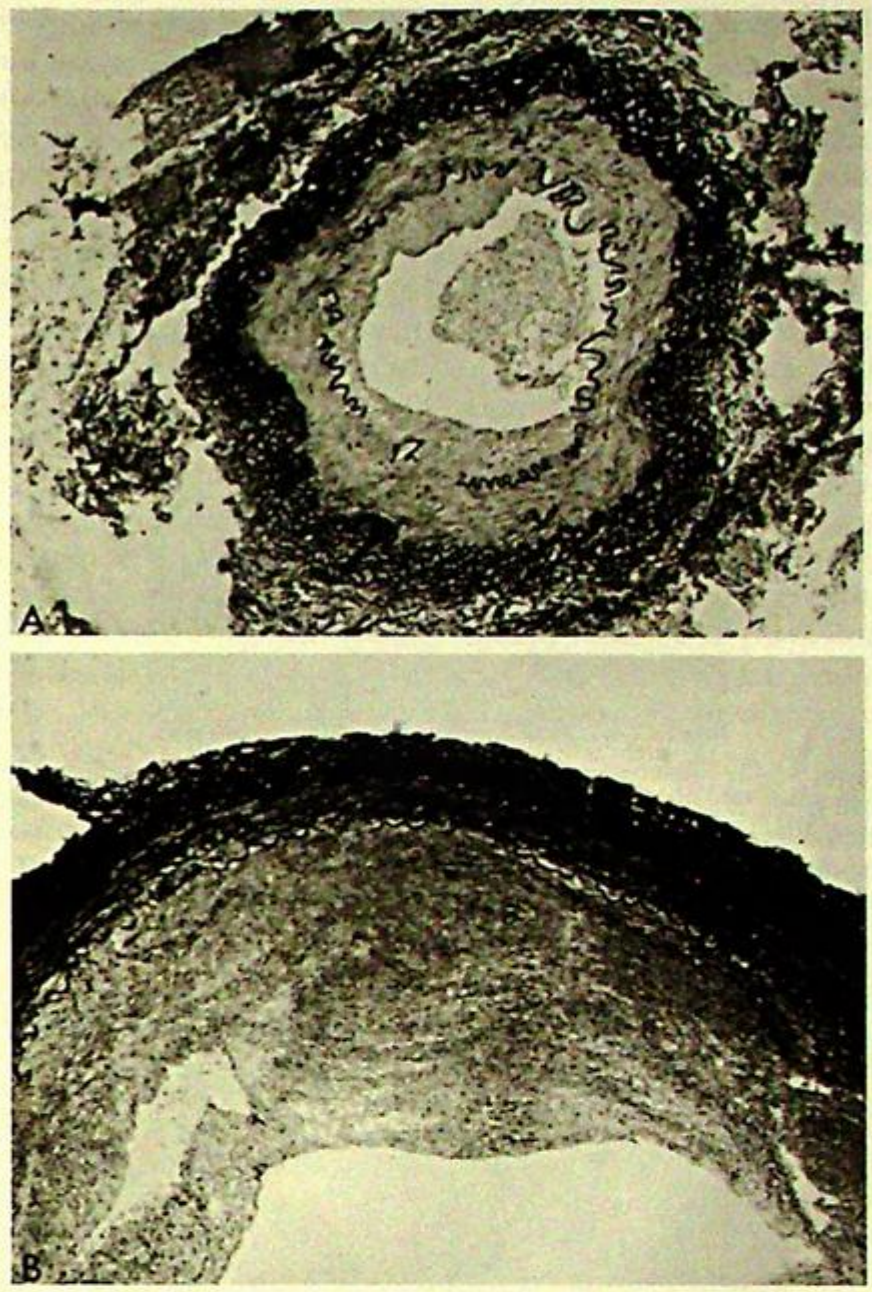

Figure 36–2. **A,** Photomicrograph of a cross section demonstrates intimal fibroplasia with focal fragmentation and partial absence of the elastica interna. **B,** Photomicrograph of a cross section demonstrates severe renal arterial intimal fibroplasia with a dense cuff of intimal collagen apposed to the luminal surface of a partially disrupted elastica interna. A small recannulized channel is noted in the lower left. (From Novick AC: Renal vascular hypertension in children. In Kelalis PP, King LR, Belman AB [eds]: Clinical Pediatric Urology. Philadelphia, WB Saunders, 1984.)

and often involves both renal arteries. It may involve other vessels in the body, most notably the carotid, mesenteric, and iliac arteries. Microscopically, the internal elastic membrane is focally and variably thinned and lost. Within the alternating thickened areas, much of the muscle is replaced by collagen, hence the term *medial fibroplasia*. In other areas, thinning of the media occurs to the point of complete loss, and microaneurysms can be seen as saccules lined by only the external elastica. In extreme cases, giant aneurysms may be found in association with medial fibroplasia.

Angiographically, medial fibroplasia demonstrates a typical "string of beads" appearance involving the distal two thirds of the main renal artery and branches (Fig. 36–4). The areas of stenosis are often overshadowed by contrast medium in the microaneurysms, making the degree of actual stenosis difficult to assess. The aneurysms themselves are greater in diameter than the normal renal artery proximal to the disease, and extreme collateral circulation is absent. These are

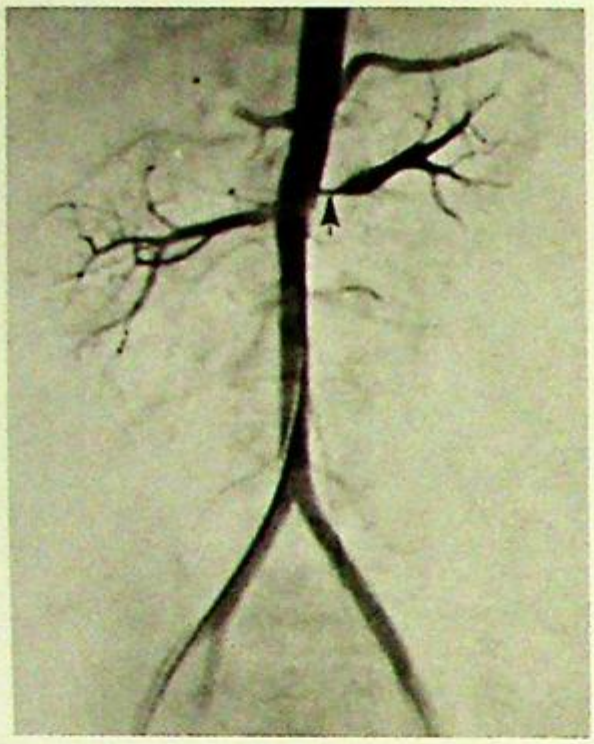

Figure 36–3. Aortogram of a 6-year-old boy demonstrates proximal left renal artery stenosis *(arrow)* from intimal fibroplasia. (From Novick AC: Renal vascular hypertension in children. In Kelalis PP, King LR, Belman AB [eds]: Clinical Pediatric Urology. Philadelphia, WB Saunders, 1984.)

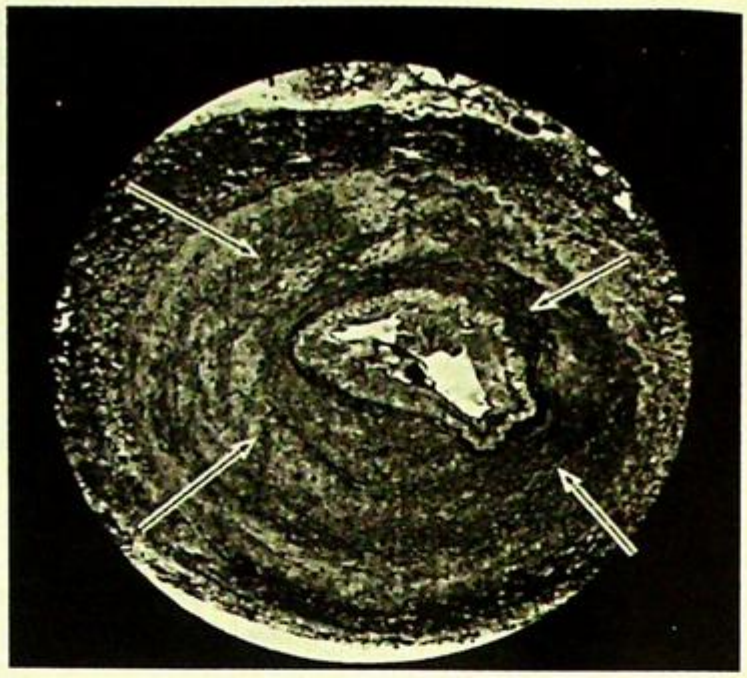

Figure 36–5. Cross section of the main renal artery in a girl with perimedial fibroplasia demonstrates a dense collagenous collar *(arrows)* involving the outer media of the vessel, which causes a severe progressive stenosis. (From Novick AC: Renal vascular hypertension in children. In Kelalis PP, King LR, Belman AB [eds]: Clinical Pediatric Urology. Philadelphia, WB Saunders, 1984.)

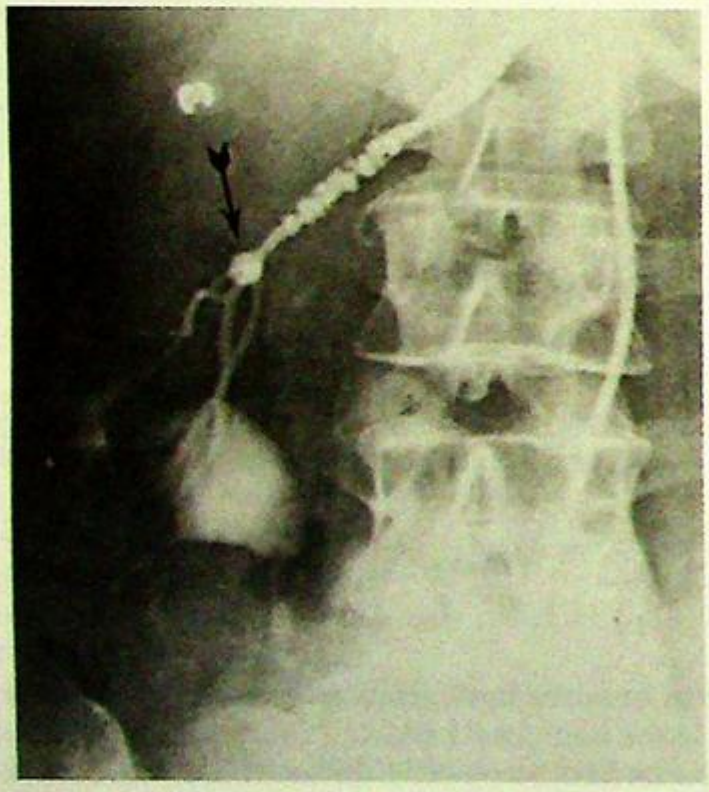

Figure 36–4. Selective right renal arteriogram reveals medial fibroplasia involving the main renal artery with typical "string of beads" appearance. (From Novick AC: Renal vascular hypertension in children. In Kelalis PP, King LR, Belman AB [eds]: Clinical Pediatric Urology. Philadelphia, WB Saunders, 1984.)

important features in differentiating the lesion from perimedial fibroplasia. Schreiber and colleagues (1984) studied the natural history of renal artery disease related to medial fibroplasia in 66 patients who were observed with serial angiography. Progressive RAS occurred in 22 patients (33%), and, contrary to an earlier report, this occurrence was no different whether patients were older or younger than 40 years. Significantly, there were no cases of progression to total arterial occlusion in this group. Also, clinical follow-up revealed that serial decreases in either overall renal function or the size of the involved kidney seldom occurred in patients with progressive medial fibroplasia, suggesting that the risk of losing renal function is relatively small in patients with this disease who are managed medically.

Perimedial Fibroplasia

Perimedial fibroplasia occurs predominantly in young women between the ages of 15 and 30 years and has therefore been referred to, rather crudely, as *girlie disease*. It constitutes about 10% to 15% of the total number of fibrous lesions and occurs only in the renal artery. This is a tightly stenotic lesion that, pathologically, consists of a collar of dense collagen enveloping the renal artery for variable lengths and thicknesses. The collagen is deposited in the outer border of the media, usually replaces a considerable portion of the media, and may replace it completely in some areas (Fig. 36–5). Islands of smooth muscle are occasionally seen trapped within the collagenous ring. Special stains show that the lesion is confined within the external elastic lamina and contained in all cases by intact adventitial connective tissue. The arterial lumen may be further compromised by a process of secondary intimal fibroplasia. It has been suggested that this secondary thickening of the intima is related to slowing of blood flow through a narrowed arterial segment, with resultant platelet and fibrin deposition and subsequent fibrous organization.

The arteriogram in perimedial fibroplasia may give the appearance of arterial beading, but careful observation shows that the caliber of the normal segment of the vessel is not exceeded by the "bead" (Fig. 36–6). This fact, along with the frequent occurrence of extensive collateral circulation, differentiates this lesion angiographically from that of medial fibroplasia. Perimedial fibroplasia produces severe stenosis, and, unless complicating thrombosis or dissection is

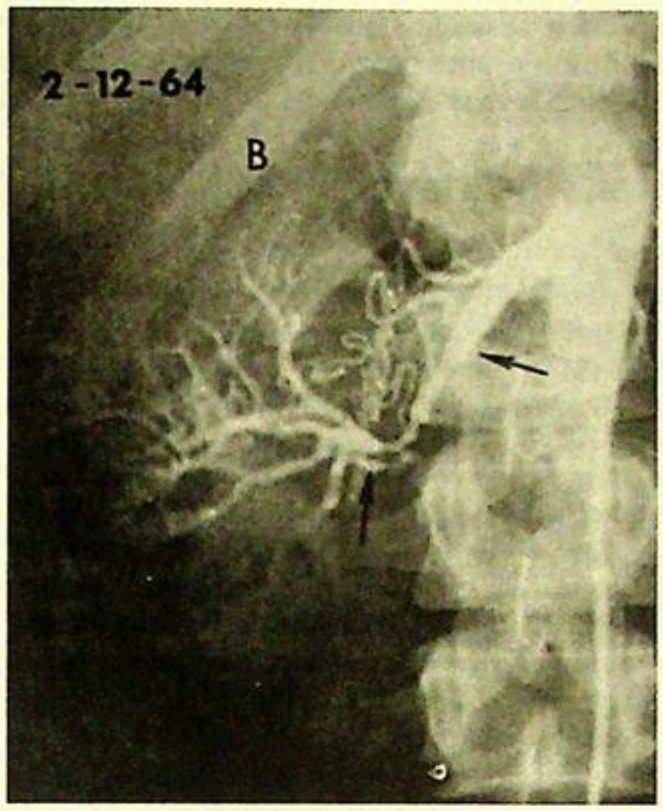

Figure 36–6. Renal arteriogram in a patient with perimedial fibroplasia shows slightly irregular yet severe stenosis of the midrenal artery *(arrows)* associated with extensive collateral circulation to the kidney. The small size of the arterial irregularities and the presence of collateral circulation distinguish this lesion radiographically from medial fibroplasia. (From Novick AC: Renal vascular hypertension in children. In Kelalis PP, King LR, Belman AB [eds]: Clinical Pediatric Urology. Philadelphia, WB Saunders, 1984.)

relatively uncommon, progressive obstruction with ischemic renal atrophy occurs in almost all patients managed nonoperatively.

Fibromuscular Hyperplasia

Fibromuscular hyperplasia is an extremely rare disease, constituting only 2% to 3% of fibrous lesions, and tends to occur in children and young adults. This is the only renal arterial disease in which true hyperplasia of the smooth muscle cells is present. The renal artery shows a concentric thickening of its wall with a mixture of proliferating smooth muscle and fibrous tissue in variable quantity. Angiographically, fibromuscular hyperplasia arises as a smooth stenosis of the renal artery or its branches and, from a radiographic standpoint, may be indistinguishable from intimal fibroplasia. Most patients with this disease have developed progressive vascular obstruction when observed with serial angiographic studies.

PHYSIOLOGY OF THE RENIN-ANGIOTENSIN-ALDOSTERONE SYSTEM

The RAAS plays a fundamental role in maintaining arterial blood pressure as well as extracellular volume. The system is composed of a series of proteins and peptides that react in a cascade, ultimately resulting in a widespread series of actions. Local renin-angiotensin systems are widely present in several organ systems and exert numerous local actions. **The main components of the system are angiotensinogen, renin, ACE, and various angiotensins, most important among which is angiotensin II (AII). AII is a powerful vasoconstrictor that increases peripheral vascular resistance to raise blood pressure. In addition, AII stimulates sodium reabsorption directly and through stimulation of aldosterone synthesis. The primary role of the RAAS is to maintain tissue perfusion, especially in cases of hypovolemia.**

The basic cascade involves conversion of angiotensinogen to angiotensin I (AI) through the action of renin. This is the rate-limiting step for the entire system, and, accordingly, control of renin release regulates the activity of the whole system. ACE then acts on AI to produce AII, which exerts a wide variety of immediate and delayed actions on the vascular system and kidneys as well as stimulates production of aldosterone from the adrenal cortex. In healthy subjects with normal dietary sodium intake, the RAAS probably plays little role in day-to-day blood pressure control. Several disease states, however, activate the RAAS. True hypovolemia or hypotension is the physiologic stimulus for AII secretion. Inappropriate activation of the RAAS occurs in cases of perceived hypovolemia such as RAS, congestive heart failure, or advanced hepatic disease, leading to hypertension, inappropriate salt and fluid retention, or both.

Angiotensinogen

Angiotensinogen is a 452-amino-acid protein and is the source of all angiotensins (Kageyama et al, 1984). It is formed as preangiotensinogen and loses the signal peptide as it becomes secreted from the cell as angiotensinogen. It functions as a serine protease inhibitor (serpin) similar to α_1-antitrypsin and antithrombin III, with which it shares some structural homology (Carrell et al, 1987). It is present in plasma in two forms, a smaller (52- to 60-kD) predominant molecule and a larger (450- to 500-kD) molecule that increases in pregnancy and after estrogen treatment (Tewksbury and Dart, 1982). The larger form is probably composed of the smaller molecule bound to other plasma proteins. Renin acts on the smaller form of angiotensinogen preferentially, cleaving AI off the larger molecule. Renin reacts with much less affinity with the larger form, also forming AI.

The liver is the primary site of synthesis of angiotensinogen, which is not stored but secreted directly after production. Angiotensinogen messenger RNA (mRNA) is widely present in several tissues that are regulated by local renin-angiotensin systems, including the central nervous system (CNS), kidney, adrenal, heart, and leukocytes (Dzau et al, 1987). Several hormones stimulate angiotensinogen synthesis by the liver, including estrogens and glucocorticoids. Stressful stimuli such as infection or tissue injury also increase plasma angiotensinogen levels (Hoj Nielsen and Knudsen, 1987). Feedback control through the RAAS is also present, with AII increasing and renin decreasing plasma levels of angiotensinogen.

Renin

Renin is a single-polypeptide-chain aspartyl protease that is secreted from the juxtaglomerular cells of the afferent

arteriole. **The kidney is the major site of renin production,** although renin mRNA is found in several other tissues where a local renin-angiotensin system functions. It is produced as pre-prorenin, and both active renin and prorenin are secreted (Atlas et al, 1980). The function of circulating prorenin is not clear, and it does not appear that prorenin is transformed to active renin in the circulation (Sealey et al, 1977). The action of renin is very specific, restricted to cleavage of a single bond, separating AI from angiotensinogen. Because renin controls the rate-limiting step of the RAAS, control of renin secretion regulates the activity of the RAAS. Several mechanisms affect the secretion of renin, as described in the following sections:

A–Macula Densa Mechanism

The macula densa region of the thick ascending loop of Henle comes in close proximity to the juxtaglomerular cells and influences renin release. **Reduction of distal tubule salt delivery stimulates renin secretion and vice versa.** Although sodium was initially thought to be responsible for this action, it now appears that the signal for macula densa–controlled renin release is the alteration of tubular chloride concentration (Lorenz et al, 1990).

B–Baroreceptor Mechanism

The juxtaglomerular cells of the afferent arteriole act as their own baroreceptors by responding directly to stretch of the afferent arteriole (Tobian et al, 1959). **Diminished cell stretch as a result of renal hypoperfusion hyperpolarizes the juxtaglomerular cells, resulting in decreased intracellular calcium and increased renin release.**

C–Neural Mechanism

The juxtaglomerular cells are richly innervated by β-adrenergic sympathetic nerve fibers. Stimulation of these β-adrenergic nerves leads to increased renin secretion (Keeton and Campbell, 1980). Dopamine is also stimulatory to renin release, although the limited number of dopaminergic nerve endings results in a much smaller role (Mizoguchi et al, 1983). Renal nerve stimulation is the mechanism through which renin release is increased as a result of exercise and tilting.

D–Endocrine and Paracrine Mechanisms

Several local and systemic hormones affect the rate of renin secretion. Foremost among these are prostaglandins. **Prostaglandin E_2** and I_2 (prostacyclin) as well as exogenously administered arachidonic acid stimulate renin secretion (Franco-Saenz et al, 1980; Whorton et al, 1980). This prostaglandin effect is independent of the other mechanisms controlling renin release. AII inhibits renin release as a feedback mechanism. Other inhibitors of renin release include endothelin, vasopressin, and atrial natriuretic peptide.

E–Intracellular Mechanisms

Agents that increase adenylate cyclase activity increase the secretion of renin, including β-adrenergic agonists, prostaglandin E_2, prostaglandin I_2, dopamine, histamine, and parathyroid hormone. This is because cyclic AMP is an important second messenger in renin release. Intracellular calcium concentrations are also important in controlling renin release. AII, vasopressin, and adenosine increase intracellular calcium levels and inhibit renin secretion through their effect on intracellular calcium levels.

Angiotensin-Converting Enzyme

ACE is a zinc-containing single-chain glycoprotein enzyme. It is also known as *kininase II* and is a dipeptidyl carboxypeptidase (Ehlers and Riordan, 1989). It splits two amino acids off the carboxy terminus of AI to form AII and, at the same time, functions in the kallikrein-kinin system by inactivating bradykinin. ACE is found in a wide variety of organs, where it is primarily expressed on endothelial, epithelial, and neuroepithelial cells. A high concentration of ACE is found in the kidney, ileum, duodenum, and uterus (Lieberman and Sastre, 1983). **Although pulmonary endothelial ACE was presumed to be the major site of ACE activity for the systemic RAAS, it is now believed that peripheral sites might play an equal role.** The majority of circulating ACE originates from endothelial cells and macrophages.

ACE is expressed in several tissues where local renin-angiotensin systems function. Renal ACE is localized to the glomerular endothelial cells and the proximal tubule brush border, where it might play a role in cleaving filtered protein for reabsorption (Danilov et al, 1987). Within the CNS, ACE is found in several locations, where it functions in the local renin-angiotensin system. This local CNS renin-angiotensin system is thought to have dipsogenic and hypertensive effects as well as to stimulate vasopressin secretion (Strittmatter and Snyder, 1987). Adrenal ACE is found predominantly in the medulla, where it is thought to stimulate catecholamine secretion (Peach et al, 1971). ACE is abundantly found in the testes and prostate, in the Leydig cells, as well as in cytoplasmic droplets in sperm (Pandey et al, 1984; Yotsumoto et al, 1984). In the female reproductive tract, ACE is found in follicular and fallopian tube oocytes (Brentjens et al, 1986). The precise role of ACE in the reproductive system has not been elucidated. Several hormones and disease states affect the level and activity of ACE. Corticosteroids as well as thyroid hormones stimulate ACE activity (Friedland et al, 1978; Smallridge et al, 1983). The serum ACE level is increased in silicosis, primary biliary cirrhosis, and sarcoidosis (Studdy et al, 1983). As mentioned previously, **ACE is not the rate-limiting step in the RAAS cascade, so changes in serum ACE levels do not directly affect the activity of the systemic RAAS (circulating AII levels).**

In addition to ACE, several angiotensinases act in the RAAS to lesser degrees. The physiologic contribution of these enzymes to the function of the RAAS is not clear. Most of these enzymes are present in body tissues such as the kidney. Among these are aminopeptidase A and angiotensinase A, B, and C. Nonspecific angiotensinases hydrolyze AII and angiotensin III (AIII), inactivating them rapidly.

Angiotensin II

The role of the RAAS in the control of blood pressure and extracellular volume is carried out through the integration of a variety of actions performed by AII. Vasoconstriction and the release of aldosterone occur immediately and are of short duration, supporting the role of AII in maintaining tissue

perfusion in hypovolemia. Other actions such as vascular growth and ventricular hypertrophy are slower in onset and longer in duration, lasting for several days or weeks.

Effect of Angiotensin II on Glomerular Circulation

One of the most important actions of AII is the autoregulation of the GFR in response to changes in renal perfusion. These are effected through changes in vascular resistance as well as mesangial cell tone. AII causes a marked increase in efferent arteriolar resistance in cases of renal hypoperfusion but does not affect afferent arteriolar resistance unless there is an increase in renal perfusion pressure. The result of this disproportionate increase in efferent over afferent resistance is an increase in capillary hydraulic pressure, and subsequently in filtration pressure, maintaining the GFR in the presence of decreased renal perfusion (Hall et al, 1977). It is through inhibition of this action that ACE inhibitors result in a decrease in GFR in cases of RAS. This effect of AII on the glomerular circulation is thought to be mediated through differential induction of vasodilatory prostaglandins from the afferent and efferent vessels (Hura and Kunau, 1988).

In addition to its effects on the glomerular vessels, AII directly results in mesangial cell contraction, leading to a decrease in the filtration coefficient of the glomerulus (Blantz et al, 1976).

Tubular Effects of Angiotensin II

AII-induced increases in the filtration fraction lead to an increase in the oncotic pressure in the postglomerular vessels. This leads to an increase in fluid reabsorption in the proximal tubules. AII receptors are also present on the proximal tubule brush border and basolateral sides, and AII is produced in large amounts locally within the proximal tubules. AII is present within the proximal renal tubule in much higher concentration than in the plasma (Seikaly et al, 1990). **The effect of AII on sodium reabsorption is bimodal; physiologic concentrations of AII stimulate sodium reabsorption in the proximal tubule, whereas higher concentrations inhibit sodium transport** (Harris and Young, 1977).

Medullary Effects

AII decreases medullary blood flow, leading to increased medullary hypertonicity and concentration of urine (Arendshorst and Finn, 1977).

Vascular Effects

AII raises blood pressure by increasing peripheral vascular resistance through a direct effect on vascular smooth muscle cells, causing them to contract. Medium-sized and small arteries are more responsive to AII than large vessels. Contraction occurs mainly in the vessels of the kidney, skin, mesentery, coronary arteries, and brain. Vessels of the lung and skeletal muscle are less responsive to AII. In addition to vasoconstriction, AII stimulates vascular smooth muscle cell growth, leading to a hypertrophic response (Geisterfer et al, 1988).

Adrenal Effects

AII acts directly on the adrenal glomerulosa cells to stimulate aldosterone secretion. This is accomplished through increased desmolase activity and increased conversion of corticosterone to aldosterone (Aguilera, 1993). This augments the salt reabsorptive actions of AII to conserve sodium.

Central Nervous System Renin-Angiotensin-Aldosterone System

The CNS is affected mainly by the local renin-angiotensin system, but high circulating levels of AII may also affect CNS function. Central AII results in an increase in blood pressure as well as increased drinking and salt appetite (Sweet et al, 1971; Fitzsimons, 1980). Central AII also leads to increased secretion of corticotropin, prolactin, luteinizing hormone, oxytocin, and vasopressin (Unger et al, 1988).

Gonadal Renin-Angiotensin-Aldosterone System

Gonadal RAAS is present in both the testis and the ovary. The function of testicular RAAS is not clear; in the ovary, RAAS may play a role in oocyte maturation.

Angiotensin II Receptor Subtypes

Nonpeptide receptor antagonists have provided definite proof of at least two major angiotensin receptor subtypes, named AT1 and AT2. Both receptors are polypeptides containing 360 amino acids spanning the cell membrane several times. They are functionally distinct with a sequence homology of 30%. The gene for the AT1 receptor is located on chromosome 3, and the gene for the AT2 receptor is located on the X chromosome (Goodfriend et al, 1996). AT1 receptors are blocked by DuP 753 (losartan), and AT2 receptors are blocked by tetrahydroimidazopyridines such as PD 123177. AT1 receptors have a higher affinity for AII than AIII, but AT2 receptors bind both AII and AIII equally. AT1 receptors have been further subtyped into two isoforms, AT1A and AT1B, although the function of the subtypes is not clear.

The AT1A receptor is expressed in the liver, kidney, aorta, uterus, adrenals, ovary, spleen, and lung as well as in the hypothalamus. The AT1B receptor is expressed in the pituitary, adrenal, kidney, uterus, and liver and is absent in the heart, brain, and spleen. In fetal life, the AT2 receptor is widely present in the adrenal, kidney, liver, skin, tongue, and brain. In the adult, this distribution becomes restricted to the adrenals, uterus, ovary, heart, and some nuclei in the brain.

In the kidneys, AT1 receptors are located predominantly in the glomeruli and tubulointerstitium, whereas AT2 receptors are located in the large cortical blood vessels (Goldfarb et al, 1994).

Almost all the vascular effects of AII, including vasoconstriction, aldosterone release, and β-adrenergic stimulation, are mediated by the AT1 receptor (Timmermans et al, 1992). The development of AT1 receptor antagonists (e.g., losartan) has produced a new class of drugs as well as an effective tool for blocking the RAAS in a variety of disease states including

hypertension as well as modulating cardiac and renal injury responses to disease.

The function of the AT2 receptor has not been fully defined; however, it may act in a manner antagonistic to the AT1 receptor, especially in the cardiovascular system, where it exerts antiproliferative, antihypertrophic, and proapoptotic functions (Horiuchi et al, 1999). AT2 receptors are also believed to play a crucial role during gestational growth and development, mainly because of the widespread distribution of these receptors in most body tissues during fetal life. Reexpression of these receptors in adult life occurs as a response to vascular injury or inflammation (Horiuchi et al, 1999).

The signal transduction mechanism initiated by binding of AII to the AT1 receptor has been well described; however, the signal transduction mechanism for the AT2 receptor is not yet known. Binding of AII to the AT1 receptor leads to the dissociation of subunits of a guanine nucleotide–binding protein, which activates phospholipase C to generate diacylglycerol and inositol triphosphate. Inositol triphosphate releases calcium from the endoplasmic reticulum, and AII also increases calcium entry through the cell membrane. The intracellular calcium as well as diacylglycerol activate protein kinase C and other enzymes that phosphorylate protein and ultimately regulate the specific cellular function induced by AII (Goodfriend et al, 1996).

Other Angiotensins

The parent peptide of the angiotensin family is the decapeptide AI. Several other peptides are formed within the RAAS, some of which have weak activity compared with AII and some of which have undetermined activity. As previously mentioned, AII (also called angiotensin 1-8) is the major active peptide in the system; it is an octapeptide formed by the removal of terminal histidine and leucine from the carboxy terminus of AI. AIII (or angiotensin 2-8) is similar to AII but lacks the aspartyl amino acid at the amino end of the polypeptide chain. It can be formed from AII or directly from AI. Angiotensin 1-7 lacks the three amino acids at the carboxy terminus of AI and has undetermined receptor activity. AIV is a hexapeptide lacking the two terminal amino acids at both ends of the AI polypeptide chain (Goodfriend et al, 1996).

The actions of angiotensin 1-7 have been defined. It appears to be formed from AI directly by a different enzyme than ACE, called neprilysin. ACE inhibitors thus increase the levels of circulating angiotensin 1-7. It acts in an opposing fashion to AII, producing vasodilatation and natriuresis, and also has antiproliferative effects on vascular smooth muscle (Chappell and Ferrario, 1999).

PATHOPHYSIOLOGY OF RENOVASCULAR HYPERTENSION

The classical experiments on RVH were performed by Goldblatt and colleagues (1934), who demonstrated that hypertension could be produced by constricting the renal artery in the dog. Two models of experimental Goldblatt hypertension are described: the two-kidney, one-clip (2K,1C) model, in which one renal artery is clipped and the contralateral kidney is in place and normal, and the one-kidney, one-clip (1K,1C) model, in which one renal artery is clipped and the contralateral kidney is removed. RVH results in both models, but the evolution and the pathophysiologic mechanisms are different. These models provide the basis for understanding the mechanism and evolution of RVH in humans.

Two-Kidney, One-Clip Model

In the two-kidney, one-clip model, the renal artery to one kidney is clipped, resulting in ischemia of the clipped kidney. The RAAS is activated as a result of renal hypoperfusion, resulting in generalized vasoconstriction and systemic hypertension. The adrenal cortex is also stimulated, resulting in secondary hyperaldosteronism and promoting sodium retention by the stenotic kidney. This is the early phase of RVH and is totally mediated by high circulating levels of AII. The normal contralateral kidney is subjected to higher than normal perfusion pressure and reacts by suppression of renin secretion as well as "pressure" natriuresis, excreting higher than normal levels of sodium and water. Renal vein renin (RVR) from the normal kidney is equal to the arterial value, indicating no secretion by the kidney. In this manner, both kidneys work against each other, with the normal kidney preventing the systemic blood pressure and sodium content from reaching levels high enough to suppress renin release from the stenotic kidney.

In brief, the two-kidney, one-clip model is characterized by the unilateral release of renin from the ischemic kidney accompanied by contralateral suppression of renin release from the normal kidney, sodium retention by the stenotic kidney, and excretion by the contralateral kidney; euvolemia; and hypertension dependent on AII-induced vasoconstriction. Accordingly, unclipping of the ischemic kidney, ACE inhibitors, or AII antagonists result in a marked decrease in blood pressure.

One-Kidney, One-Clip Model

In the one-kidney, one-clip model, one renal artery is clipped and the contralateral kidney is removed. The solitary ischemic kidney secretes renin, activating the RAAS and resulting in systemic hypertension. Owing to the absence of the normal contralateral kidney, pressure natriuresis does not occur, and the stenotic kidney avidly conserves sodium and fluid, producing volume expansion. The elevation of blood pressure, sodium retention, and volume expansion gradually suppress renin release from the ischemic kidney. Accordingly, although the *generating* mechanism of hypertension is similar in both models, **hypertension in the one-kidney, one-clip model is largely *maintained*** by volume and sodium excess, in the presence of normal circulating AII levels. ACE inhibitors or AII antagonists do not result in a marked decrease of blood pressure. Under conditions of sodium depletion, hypertension once again becomes dependent on AII, with a marked response to ACE inhibition.

In addition, both models do not remain static but rather pass through an acute phase, a transitional phase, and then a final chronic phase (Table 36–3). In cases of two-kidney, one-clip hypertension, after several days or weeks a chronic phase is eventually reached in which unclipping of the stenotic kidney fails to normalize blood pressure. In this chronic phase,

Table 36–3. Phases of Experimental Renovascular Hypertension

Acute Phase
Renin dependence
Transitional Phase
Progressive volume and sodium retention
Gradual onset of secondary hyperaldosteronism
Thirst
Progressive suppression of renin secretion
Progressive decline of contralateral natriuresis
Chronic Phase
Volume expansion
Suppressed renin secretion
Systemic vasoconstriction
Increased sensitivity to angiotensin II
Increased vasopressin secretion
Increased sympathetic activity
Structural vessel wall changes
Development of contralateral nephrosclerosis

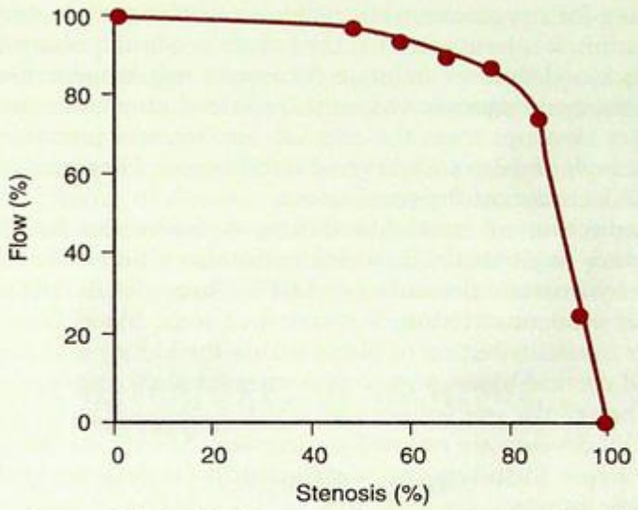

Figure 36–7. Relationship between renal artery stenosis and renal blood flow.

the elevated perfusion pressure as well as high levels of AII have resulted in widespread arteriolar damage to the contralateral kidney. The excretory function (natriuresis) of the contralateral kidney declines, resulting in extracellular volume expansion, a decrease in circulating AII levels, and the gradual development of a "volume-dependent" type of hypertension. ACE inhibition or removal of the stenotic kidney fails to cure the hypertension in this phase of the disease unless sodium depletion is instituted. Systemic vasoconstriction continues to play a role in maintaining hypertension in the chronic phase, with increased sensitivity to AII, increased vasopressin secretion, and increased sympathetic nervous system activity.

HUMAN CORRELATES OF EXPERIMENTAL RENOVASCULAR HYPERTENSION

The situation in cases of human RVH is not as simple as the experimental models, but **in most cases human unilateral RAS resembles the two-kidney, one-clip model.** A similar sequence of events ensues, with activation of the RAAS resulting in hypertension and secondary hyperaldosteronism, sometimes resulting in hypokalemia. Relief of the stenotic lesion by revascularization or nephrectomy has a higher chance of amelioration of hypertension if carried out before the development of a chronic phase in which parenchymal damage in the contralateral kidney maintains the blood pressure elevation.

Bilateral renal artery stenosis in humans does not clearly follow either experimental model but rather is a mixed picture with some characteristics of each. In this respect, a beneficial blood pressure response is seen with ACE inhibition, indicating overactivity of the RAAS, and there is also evidence of volume expansion with frequent pulmonary edema as well as diuresis after revascularization. Different reasons for this mixed picture are possible, mainly owing to the asymmetrical development of RAS, starting with unilateral disease and progressing to bilateral disease. Undetermined renal parenchymal damage may occur to the contralateral normal kidney before the onset of bilateral disease as well. Volume overload would then be exacerbated by the development of bilateral disease.

The one-kidney, one-clip model clinically resembles cases of stenosis to a solitary functioning kidney, unilateral renal artery stenosis with parenchymal damage to the contralateral kidney (nephrosclerosis or atheroembolism), and transplant renal artery stenosis.

PATHOPHYSIOLOGY OF ISCHEMIC NEPHROPATHY

In addition to RVH, a second, equally important phenomenon resulting from renal artery stenosis is deterioration of renal function, termed *ischemic nephropathy* (IN). This is a clinical syndrome that occurs through different pathophysiologic mechanisms, is distinct from RVH, and can occur in the absence of elevated blood pressure.

IN is the result of chronic hypoperfusion of the total functioning renal mass. This occurs in the setting of bilateral severe stenosis or stenosis to a functionally or anatomically solitary kidney. The pathophysiology of renal injury as a result of chronic ischemia is poorly understood. This injury is not simply cell death related to a lack of oxygen and nutrients because the oxygen demand of the kidney never exceeds the supply. Experiments studying the effects of acute renal ischemia do not lend themselves to the explanation of chronic ischemic injury. For ischemic injury to occur, the reduction in renal blood flow needs to exceed the compensatory ability of the kidneys. Renal autoregulation fails to maintain the GFR when renal perfusion decreases below 70 to 80 mm Hg. This occurs when the luminal diameter of the renal artery is stenosed by more than 70% of the original size. At this point, the stenosis becomes hemodynamically significant, resulting in a gradual deterioration of the GFR with an accompanying rise in the serum creatinine level (Fig. 36–7).

Critical reduction of renal blood flow results in IN without affecting renal viability because renal blood flow is severalfold higher than blood flow to other organs such as the liver or heart. This flow rate far exceeds the needs of the

kidney for oxygenation but is necessary to drive glomerular filtration. It is estimated that the kidney needs only about 10% of its blood flow to maintain its oxygen requirement. Under conditions of chronic ischemia, collateral circulation to the kidney develops from the adrenal, lumbar, and ureteric vascular beds and can sustain renal viability even in cases of complete occlusion of the renal artery.

Reduction of renal blood flow activates the RAAS to produce angiotensin II, which maintains glomerular capillary hydrostatic pressure (and GFR) through efferent arteriolar vasoconstriction. Reduction of renal blood flow also leads to redistribution of blood within the kidney and diminished cortical blood flow to prevent medullary anoxia.

The cellular mechanisms by which a decrease in renal size and IN develop are not well understood. Several mechanisms play a role, including vascular mediators (endothelin, thromboxane, prostacyclin, and nitric oxide), calcium accumulation in or ATP depletion of the ischemic cells, production of oxygen free radicals, or disruption of cellular membrane polarity (Textor, 1994). The exact role played by each of these mechanisms is not well defined. The action of repetitive cycles of hypoperfusion may allow renal injury to continue before repair is complete, whereas a disturbance in cellular repair processes may hinder recovery between these episodes (Textor, 1996). The point at (or mechanism through) which these changes become irreversible after relief of renal ischemia is even more poorly understood.

Although the exact mechanisms through which chronic ischemic injury of the kidneys occur are not clear, the resulting structural changes within the chronically ischemic kidney have been well identified. Tubular changes are usually most prominent, in the form of patchy tubular necrosis and atrophy. Glomeruli decrease in size with wrinkling of the glomerular tuft and thickening of Bowman's capsule. Localized or global glomerular sclerosis is also seen. Hypercellularity of the juxtaglomerular apparatus is commonly seen. Blood vessels show the effects of comorbid conditions, such as essential hypertension, diabetes, and hyperlipidemia, with arteriolar thickening and hyalinosis.

Atheroembolism (Cholesterol Embolism)

Renal cholesterol embolism occurs most commonly in older hypertensive patients, with severe abdominal aortic ASO as the most common associated underlying cause, and contributes significantly to renal dysfunction in cases of IN (Vidt et al, 1989). Atheroembolism can occur spontaneously but more commonly follows manipulation of the atherosclerotic aorta by surgery, angiography, or the use of thrombolytic agents. In a review of 221 cases of cholesterol embolism, 69% were spontaneous, and an inciting event precipitated embolism in 31%. Renal manifestations were present in 50% of cases, and the mortality rate was 81% (Fine et al, 1987).

Atheromatous fragments lodged in blood vessels are highly thrombogenic, leading to occlusion of the vessels in which they lodge, and at the same time an inflammatory reaction and fibrosis are incited. Cholesterol crystals can remain histologically detectable in blood vessels for up to 9 months after the event. Diagnosis of atheroembolism is made by examination of biopsy samples from the affected tissue, most commonly skin, muscle, or kidney. Cholesterol microemboli are seen within the renal vasculature (needle-shaped cholesterol crystals, which appear birefringent on frozen section and are dissolved by the solvents used in permanent sections leaving empty cholesterol clefts) and generally portend a poorer prognosis. In a study of 44 patients from the Cleveland Clinic, findings reflective of atheroembolism were identified on intraoperative biopsy of 16 patients (36%) at the time of open surgical renal revascularization. Patients with atheroembolism had a significantly decreased 5-year survival (54% versus 85%) compared with patients who did not exhibit histologic evidence of atheroembolism. Patients with atheroembolism had a significantly higher incidence of postoperative atherosclerotic complications as well as renal and renovascular complications (Krishnamurthi et al, 1999).

The organs most commonly affected by atheroembolism are the kidney, spleen, pancreas, and gastrointestinal tract. Virtually all organs can be affected, however, leading to multisystem organ disease. Cutaneous manifestations are the most common extrarenal manifestation, in the form of livedo reticularis (lacy bluish discoloration affecting the lower extremities), digital cyanosis or gangrene, ulceration, or subcutaneous nodules. Retinal emboli (Hollenhorst's plaque) can occur, leading to visual symptoms, or can be silent.

Renal affection takes the form of deteriorating renal function, usually after a precipitating event. Decline of renal function can vary in severity from mild to rapid acute renal failure. Gradual improvement in renal function occurs after the event, but recurrent episodes lead to progressive loss of renal function with time (Siemons et al, 1987). Symptoms of renal involvement are usually absent, but new-onset hypertension or worsening of preexisting hypertension may occur.

A preventive approach to atheroembolism entails avoiding unnecessary or rough manipulation of atherosclerotic vessels as well as avoiding prolonged anticoagulation in patients at risk for developing atheroemboli. **Management of cholesterol embolism is supportive, with removal of the inciting trauma if present, cessation of anticoagulation, control of hypertension, and institution of renal replacement therapy as needed.** Increased awareness of this condition has led to early diagnosis and institution of aggressive supportive care, resulting in a decline in mortality from the disease. A 1999 study of intensive multiorgan support for 67 patients reported a mortality rate of only 16%, with 32% of the survivors requiring long-term dialysis therapy (Belenfant et al, 1999).

CLINICAL FEATURES OF RENOVASCULAR HYPERTENSION

Although RVH is the most common correctable cause of secondary hypertension (with the exception of hypertension related to oral contraceptive use), the prevalence of RVH is probably less than 1% for patients with mild or moderate hypertension (Lewin et al, 1985). For this reason, before subjecting patients to numerous diagnostic procedures that are potentially invasive and costly, enough clinical suspicion needs to be generated to prevent unnecessary investigations of patients with essential hypertension. Patients with RAS may

also present with renal impairment (IN) in the presence or absence of RVH.

Clinical Clues

Symptoms suggestive of RVH are rare, with the exception of flank pain related to segmental infarction or arterial dissection and generalized nonspecific symptoms in cases of Takayasu's arteritis. The clinical course of hypertension, however, may be suggestive of a renovascular cause.

The age at presentation is a clue. The onset of hypertension before the age of 30 years or after the age of 55 years is more commonly associated with renovascular disease, typically FD in young patients and ASO in those older than 55 years. In the Cooperative Study for Renovascular Hypertension, the average age at the onset of essential hypertension was 35 years; for hypertension secondary to FD, the average age of onset was 33 years, and for atherosclerotic renal artery stenosis (ASO-RAS), the average age of onset was 46 years (Maxwell et al, 1972).

A family history of hypertension suggests essential hypertension, although there are reports of familial fibromuscular disease of the renal arteries, especially in females (Major et al, 1977; Pannier-Moreau et al, 1997).

Sudden onset and shorter duration of hypertension are usually associated with RVH; they may also be associated with a better chance of cure after treatment.

Hypertension that is difficult to control with two or three medications is more likely to be associated with renovascular disease. A sudden increase in severity or difficulty of control of previous mild or well-controlled hypertension is also suggestive of the development of RVH on top of preexisting essential hypertension.

Accelerated, malignant hypertension or hypertensive crises are more frequently associated with RVH than essential hypertension (Simon et al, 1972).

Hypertension associated with episodes of pulmonary edema, evidence of generalized atherosclerotic disease, or gradual impairment of renal function is also suggestive of RVH.

Smoking is a risk factor for developing atherosclerotic disease. In a retrospective study comparing patients with documented RVH with patients with essential hypertension, 88% of patients with ASO-RAS were smokers, compared with 42% of patients with essential hypertension. Patients with FD also showed a higher incidence of smoking (71%) (Nicholson et al, 1983).

On physical examination, clues suggestive of RVH include severe hypertension, the presence of an upper abdominal or epigastric bruit (with both systolic and diastolic components), severe hypertensive retinopathy (grade III or IV), and evidence of generalized ASO.

Laboratory Investigations

The presence of mild *proteinuria* is not uncommon in RVH; however, nephrotic-range proteinuria has also been described with RVH (Kumar and Shapiro, 1980; Chen et al, 1995) and has been reversed by renal revascularization (Zimbler et al, 1987). Apart from renal artery disease, proteinuria may be the result of coexisting disease such as diabetes or glomerulosclerosis.

Azotemia in the presence of generalized ASO with or without the presence of hypertension is strongly suggestive of a renal arterial cause.

Hypokalemia (serum potassium level 3.4 mEq/L) especially in the absence of diuretic use is strongly suggestive of RVH resulting in secondary hyperaldosteronism. In the Cooperative Study for Renovascular Hypertension, 16% of patients with RVH were found to have hypokalemia (Maxwell et al, 1972).

CLINICAL FEATURES OF ISCHEMIC NEPHROPATHY

Epidemiologic Considerations

Epidemiologic studies indicate that atherosclerotic renal artery disease is quite common in patients with generalized atherosclerosis obliterans, regardless of whether RVH is present. These studies have involved renal angiography in patients with a documented abdominal aortic aneurysm, aorto-occlusive disease, or lower extremity occlusive disease. In such patients, the overall incidence of ARAS has ranged from 31% to 61%, with significant (>50%) ARAS present in 14% to 42% of patients (Table 36–4). In a detailed study by Olin and colleagues (1990), significant ARAS was present in 41 of 108 patients (38%) with an abdominal aortic aneurysm, 7 of 21 patients (33%) with aorto-occlusive disease, and 74 of 189 patients (39%) with lower extremity occlusive disease.

Other studies have evaluated the prevalence of atherosclerotic renal artery disease in patients with coronary artery disease by obtaining abdominal aortography at the time of coronary angiography. Vetrovec and colleagues (1989) noted significant (>50%) ARAS in 22 of 76 patients (29%) with coronary artery disease. In a much larger study, Harding and associates (1992) found significant (>50%) ARAS in 164 of 817 patients (20%) with coronary artery disease. In the latter study, the prevalence of significant ARAS was greater in patients with more severe coronary artery disease; significant ARAS was present in 29% of patients with three-vessel disease and in 39% of patients with left-main disease. More recently, the Mayo Clinic group (Rihal et al, 2002) reported a 19% incidence of greater than 50% stenosis, 7% greater than 70% stenosis, and 3.7% bilateral stenosis in 297 hypertensive

Table 36–4. **Prevalence of Atherosclerotic Renal Artery Stenosis in Patients with Peripheral Vascular Disease**

Study	Patients (N)	No. with 50% ARAS	No. with >50% ARAS
Choudhri et al, 1990	100	17(17%)	42 (42%)
Wilms et al, 1990	100	NA	22 (22%)
Olin et al, 1990	318	71 (22%)	122 (38%)
Salmon & Brown, 1990	374	64 (17%)	52 (14%)
Swartbol et al, 1992	450	117 (26%)	104 (23%)

ARAS, atherosclerotic renal artery stenosis; NA, not available.

patients undergoing coronary angiography. Similar results were reported by Aqel and colleagues (2003) in a smaller group of 90 veterans with hypertension. A 16% incidence of severe stenosis and 6% incidence of bilateral disease was reported in this study. None of these studies reported an increase in complications related to the addition of abdominal angiography to coronary angiography. This would present a logical rationale for screening the renal arteries in patients with risk factors such as peripheral vascular disease, renal insufficiency, and hypertension.

In a large population-based study of nonselected subjects, Hansen and colleagues (2002) screened 870 patients for RAS using duplex ultrasonography. An overall prevalence of 6.8% was noted, with 12% having bilateral disease, and stenosis was associated with hypertension, advancing age, and elevated low-density lipoprotein.

Another study has shown an increased prevalence of ARAS in patients with diabetes mellitus. Sawicki and colleagues (1991) evaluated 5194 consecutive autopsy protocols from patients who died between 1980 and 1988. Significant (>50%) ARAS was present in 4.3% of all patients but in 8.3% of all diabetic patients; all but one of the latter had type 2 diabetes mellitus. Bilateral ARAS was found in 30% of the nondiabetic patients with ARAS but in 43% of diabetic patients with ARAS. These data suggest that the presence of type 2 diabetes increases the risk of ARAS and that the latter is more likely to involve both kidneys.

These studies show that **ARAS is commonly present in patients with generalized atherosclerosis, particularly those with peripheral vascular disease or coronary artery disease. Although hypertension is also commonly present in such older patients with ARAS, it is far more likely to be idiopathic (essential) than renovascular in origin. Therefore, the prevalence of anatomic ARAS is much greater than that of atherosclerotic RVH.**

Screening and Diagnosis

The screening of patients for atherosclerotic renal artery disease is based in part on an early study by Gifford and associates (1965). These investigators found that in 53 of 75 older patients (71%) with unilateral renal atrophy, the renal atrophy was caused by stenosing atherosclerotic renal artery disease. Of equal importance was the finding that 22 of these 53 patients (42%) also had unsuspected atherosclerotic renal artery disease involving the opposite, normal-sized kidney. Subsequently, Lawrie and associates (1980) reviewed 40 patients with renal atrophy caused by total arterial occlusion and noted contralateral ARAS in 31 patients (78%). **These observations underscore the high incidence of renal artery disease, often bilateral, in patients with generalized atherosclerosis and diminished renal size. The additional finding of even mild azotemia in this setting further enhances the likelihood that underlying large vessel occlusive disease is present.**

Harding and associates (1992) evaluated clinical variables associated with ARAS in a study of 1235 patients undergoing simultaneous cardiac catheterization and abdominal aortography. **A multivariate logistic-regression analysis identified the following five risk factors as strongly predictive of significant ARAS: higher age, coronary artery disease, a history of congestive heart failure, female gender, and peripheral vascular disease. An elevated serum creatinine level was also predictive of ARAS** by univariate logistic-regression analysis. Hypertension was not helpful in identifying patients with ARAS.

Another important clinical clue to the presence of significant ARAS is the development of progressive azotemia after medical control of the blood pressure in patients with significant hypertension. This problem strongly suggests the presence of perfusion-dependent renal function related to significant underlying renal artery obstruction (Textor et al, 1983). In addition to reducing flow across a stenotic renal artery by lowering the systemic blood pressure, antihypertensive medications can impair renal function in such patients through other mechanisms. β-Adrenergic blockers produce a fall in cardiac output, which may occasionally diminish effective renal plasma flow and the GFR. ACE inhibitors can lead to deterioration of renal function through loss of efferent arteriolar vasoconstrictor tone in the kidney (Hricik et al, 1983).

Finally, **atherosclerotic renal artery disease should also be suspected in older patients with renal insufficiency and no obvious cause for the latter.** Corradi and associates (1993) obtained renal angiography in 51 consecutive patients with the following criteria: age older than 60 years, creatinine clearance less than 50 mL/min, no analgesic abuse, proteinuria less than 1 g/day, clinical signs of generalized ASO, and no biochemical or radiographic findings indicative of glomerulopathy, diabetic nephropathy, polycystic disease, obstructive nephropathy, or pyelonephritis. Angiographic studies revealed significant RAS in 29 patients (56.8%); RAS was present bilaterally in 10 patients (19.6%) and unilaterally in 19 patients (37.2%).

The studies described indicate that clinical screening for atherosclerotic renal artery disease is appropriate in older patients with most or all of the following features: (1) evidence of generalized ASO; (2) a decrease in the size of one or both kidneys; (3) renal insufficiency, even of a mild extent, particularly in patients with no obvious underlying cause; (4) the development of progressive azotemia after restoration of normotension with medical antihypertensive therapy; (5) coronary artery disease; (6) a history of congestive heart failure; and (7) peripheral vascular disease. It should be emphasized that **patients with atherosclerotic renal artery disease may or may not have significant hypertension, and this should not influence the decision to investigate the patient for this disease.**

DIAGNOSTIC EVALUATION

Several noninvasive studies are available to diagnose RAS. Most of these studies are intended for hypertensive patients, aiming to identify patients with a renovascular cause of hypertension. Among these studies are rapid-sequence intravenous (IV) urography, ultrasonography, peripheral renin activity assays, captopril testing, and radionuclide renal scanning (with and without ACE inhibition). A variety of modern noninvasive tests have become available and have largely superseded the previously mentioned tests; these are duplex ultrasonography (DUS), magnetic resonance angiography (MRA), and computed tomography angiography (CTA). These tests offer anatomic information only, with no

functional information. **The definitive diagnosis of RAS, however, is documented by angiographic study of the aorta and renal vessels, which remains the "gold standard" against which all other diagnostic modalities are compared.**

Diagnostic evaluation for patients presenting with suspected RVH differs from that for patients presenting with suspected IN. **For patients with suspected RVH, a number of tests are available for functional diagnosis of RVH. These tests (plasma renin activity [PRA], captopril test, captopril renography, and RVR assays) diagnose hyperactivity of the RAAS but provide no anatomic information regarding the offending arterial lesion.** Captopril renography and RVR assays can localize the ischemic kidney as well. Anatomic delineation of the arterial lesion guides the treatment decisions and is obtained by intra-arterial angiography. A variety of noninvasive anatomic studies (DUS, MRA, and spiral CTA) can be used before angiography in cases in which clinical suspicion of RVH is not confirmed by functional tests.

The pathophysiology of RVH is different and distinct from that of IN. The diagnostic evaluation of patients with suspected IN is hampered by the lack of functional tests and the inability to determine conclusively that an anatomic lesion in the renal artery is responsible for impairment of renal function. Noninvasive anatomic testing is used to confirm a clinical suspicion of RAS, which is definitively diagnosed by intra-arterial angiography. Stabilization or improvement of renal function after revascularization remains the final proof of the cause, provided that ischemic damage to the kidney has not become irreversible.

Intravenous Urogram

Until better methods were developed, a modification of the standard IV urogram, called the hypertensive, rapid-sequence, or minute-sequence urogram, was used as a screening test for RVH. Several findings are suggestive of RVH, including a delayed appearance of contrast material in the calyces of the affected kidney (most important), disparity of renal size of more than 1.5 cm (most common finding), delayed hyperconcentration of contrast material within the affected collecting system, retention of contrast material in a nonobstructed collecting system, and notching of the pelvicalyceal system by collateral vessels.

The poor sensitivity and specificity of the rapid-sequence urogram and the development of multiple other more sensitive diagnostic tests have led to the discontinuation of its use for diagnosing renovascular disease.

Peripheral Plasma Renin Activity

Measurement of peripheral PRA is a functional test designed to diagnose overactivity of the RAAS. Originally intended as a screening test for RVH, it provides no anatomic information and has no value for diagnosing IN. In order to obtain meaningful results from this test, all antihypertensive medications should be discontinued for 2 weeks, and the PRA should be indexed to the sodium intake. Blood should be collected at noon after 4 hours of the patient's ambulation. When the test is standardized as mentioned, a sensitivity and specificity of 80% and 84%, respectively, can be expected (Pickering et al, 1984).

Important limitations of this test have restricted its general use. Sixteen percent of patients with essential hypertension have elevated PRA, whereas up to 20% of patients with RVH have normal PRA (Brunner et al, 1972). In addition, discontinuation of all antihypertensive medication in a population of patients with severe, sometimes life-threatening hypertension is not generally feasible.

Captopril Test

Measurement of peripheral PRA before and after an oral dose of captopril is called the *captopril test*. This is a functional test of RVH that does not provide anatomic information. The test is based on the observation that after the administration of ACE inhibitors, patients with RVH show a higher reactionary rise of PRA than patients with essential hypertension (Case and Laragh, 1979). Patients may continue to take β blockers, but all diuretics and ACE inhibitors need to be discontinued for at least 1 week before the test. A normal- or high-salt diet is needed. Blood should be drawn with the patient in the same position before and after captopril administration, after measurements of blood pressure are stable. An oral dose of 25 mg of captopril is used, and blood is drawn again 1 hour after the dose.

Criteria for a positive test are the presence of all the following: postcaptopril PRA greater than 12 ng/mL/hr, an absolute increase in PRA greater than 10 ng/mL/hr, and a 400% increase in baseline PRA (150% increase if the baseline PRA was more than 3 ng/mL/hr) (Muller et al, 1986). The test is generally safe, with the main risk being an excessive fall of blood pressure in hyperreninemic patients who are also volume depleted. Overall sensitivity is about 74% and specificity is around 89% (Pickering et al, 1996). **The test is not reliable in patients who are azotemic, nor is it sufficiently accurate for use in children** (Gauthier et al, 1991).

The low sensitivity of the captopril test makes it not suitable for use as a general screening test for RVH. The major strength of the captopril test is its accuracy in excluding RVH, especially in patients with low clinical suspicion. The high negative predictive value (approximately 95%) of captopril testing has been confirmed in several studies (Gosse et al, 1989; Svetkey et al, 1989; Frederickson et al, 1990).

Renal Vein Renins

The primary criterion for the functional diagnosis of RVH is hypersecretion of renin from the ischemic kidney combined with contralateral suppression of renin secretion. Calculation of net renin secretion from any kidney is performed by subtracting the renin value in the arterial blood to the kidney (inflow) from the renin value in the venous blood from the kidney (outflow). Because renin values in both the aorta and the inferior vena cava (IVC) are the same, IVC renin is used instead of aortic renin (Sealey et al, 1973). RVR assays are useful for localizing the ischemic kidney in unilateral RAS as well as the more ischemic kidney in bilateral cases. A moderate sodium intake should be maintained at the time of the sampling, which is usually performed with the patient in the supine position. Blood samples from both renal veins as well as from the IVC are obtained.

Hypersecretion of renin from the ischemic kidney (>50% of PRA) confirms the diagnosis of RVH. Contralateral suppression of renin secretion (renal vein – IVC renin = 0) indicates an appropriate response of the normal contralateral kidney to the elevated blood pressure and predicts a cure of hypertension after revascularization. Increasing severity of stenosis reduces blood flow to the ischemic kidney, resulting in an increased RVR increment (after subtracting IVC renin) higher than 50% of the total peripheral PRA (Vaughan et al, 1973). In patients with high PRA and RVR failing to show an increment above 50% from both kidneys, sampling from segmental renal veins may be performed to localize the segment of kidney responsible for hypersecretion of renin (Schambelan et al, 1974). Administration of captopril results in accentuation of renin secretion from the ischemic kidney (similar to the captopril test), resulting in increased accuracy in diagnosing RVH (Simon and Coleman, 1994). This is particularly useful when RVR values are equivocal, in cases of branch stenosis, and in cases of coexisting hypertension or renal disease.

Captopril Renography

Radionuclide renography without ACE inhibition has limited use for the functional or anatomic diagnosis of renovascular disease. The physiologic principle of captopril renography is the loss of preferential vasoconstriction of the efferent arteriole that is mediated by AII and maintains the glomerular pressure gradient in cases of RAS. This loss of postglomerular pressure results in a decreased GFR of the kidney distal to the stenosis, which is measured noninvasively by radionuclide renography.

The study is performed in well-hydrated patients with liberal salt intake. ACE inhibitors are discontinued for 3 to 5 days before the study, but other antihypertensives may be continued (Setaro et al, 1991). Oral hydration is continued on the day of the procedure. Oral captopril (25 to 50 mg) is usually used, although IV enalapril (0.04 mg/kg) can be used as well (Sfakianakis and Sfakianakis, 1988). The captopril renogram is obtained 1 hour after the captopril dose. The use of furosemide has also been suggested to improve the accuracy of ACE renography (Erbsloh-Moller et al, 1991).

Considerable debate continues around the optimal radionuclide agent to use for captopril renography. The most commonly used agents are technetium 99m (^{99m}Tc) diethylenetriaminepentaacetic acid (DTPA) and orthoiodohippurate (OIH) I 131, with the addition of ^{99m}Tc mercaptoacetyltriglycine (MAG3). The imaging characteristics of ^{99m}Tc compounds are better than those of iodine 131 (^{131}I) compounds. On the other hand, OIH and MAG3 are excreted by both glomerular filtration and tubular secretion, whereas DTPA is excreted by glomerular filtration only, making it less optimal for patients with renal dysfunction. To date, ^{99m}Tc-MAG3 has shown the best results for captopril renography, especially in patients with impaired renal function (Dondi, 1991). Studies have shown that ^{99m}Tc ethylenedicysteine (EC) can be used as an imaging agent for captopril renography to diagnose RVH and predict the outcome of revascularization (Ugur et al, 1999).

Captopril renographic diagnostic criteria have not been well standardized. The following are the criteria suggested by the Consensus Panel on Captopril Renography (Nally et al, 1991). Two categories of information are used: asymmetry of renal size and function, as suggested by the scintigraphic images, and specific captopril-induced changes in the renogram. These changes on the postcaptopril renogram include a delayed time to maximal activity (>11 minutes), significant asymmetry of peak activity of each kidney, marked cortical retention of radionuclide, and a marked decrease in the GFR of the ipsilateral kidney. For radionuclides with tubular excretion (^{131}I-OIH and ^{99m}Tc-MAG3), the ratio of 20-minute counts to peak counts can also be used. Normally less than 0.3, a 0.15 change is considered significant. A small poorly functioning (30%) kidney that shows no change after ACE inhibition, as well as bilateral symmetrical change after ACE inhibition, is considered to be moderately indicative of RVH (Taylor et al, 1998).

The use of AT1 receptor antagonists for hypertension does not preclude the use of captopril renography as a diagnostic test. In a study comparing captopril renography in patients using AT1 receptor antagonists and hypertensive control subjects, Picciotto and colleagues (2003) found equally accurate results in both groups.

Overall, the sensitivity of captopril renography appears to be approximately 90% to 93%, and the specificity approximately 93% to 98% (if the test is used in patients with a strong clinical suspicion). More important, captopril renography is predictive of a cure or improvement in blood pressure after revascularization in 80% to 90% of cases (Nally, 1996). The presence of bilateral RAS, RAS to a solitary kidney, or impaired renal function (serum creatinine level >2.5 to 3 mg/dL) decreases the accuracy of captopril renography.

Duplex Ultrasonography

DUS of the renal arteries is a noninvasive anatomic study that has shown an excellent ability to diagnose RAS. It combines the use of real-time B-mode renal ultrasonography with color-coded pulsed Doppler to obtain blood flow velocities within the major abdominal vessels. Flow velocity at the renal hilum and inside the renal parenchyma can be measured as well. **The basis for diagnosing renal artery stenosis is the altered flow pattern distal to the stenosis, with a turbulent jet during systole and a decrease in diastolic flow.** Measurements are obtained at the proximal main renal artery using a standardized angle of incidence, and several indices as well as waveform analysis are used to diagnose stenosis. More than 180 cm/sec **peak systolic velocity (PSV) in the renal artery** is indicative of RAS (normal renal PSV averages 100 ± 25 cm/sec). PSV has been found to be the most important single indicator of RAS (Miralles et al, 1996). The ratio of the renal PSV to the aortic PSV (renal PSV/aortic PSV) is called the *renal aortic ratio* (RAR). A ratio of 3.5 or more indicates severe (>60%) stenosis. The use of the RAR is not possible in cases of aortic occlusive or aneurysmal disease because of the abnormal aortic flow patterns in these situations. Measurement of the flow patterns within the distal hilar renal artery branches as well as within the parenchyma can be analyzed to provide indices indicative of arterial stenosis or increased renovascular resistance (Nazzal et al, 1997; Riehl et al, 1997). These indices (acceleration time, acceleration index, resistive index) have not proved as universally reliable as the afore-

mentioned (PSV, RAR) measurement. Intraluminal ultrasonography has also been used to measure flow rate directly within the renal artery (van der Hulst et al, 1996; Chavan et al, 1998), and this has been useful to evaluate the flow rate before and after angioplasty (Savader et al, 1998).

Diagnostic categories obtained by DUS include normal, mild stenosis (60%), severe stenosis (>60%), and technically unsatisfactory study (unable to visualize the renal arteries). Renal artery occlusion is indirectly diagnosed by the findings of a small kidney and the inability to detect a renal artery flow pattern.

DUS offers significant advantages as a diagnostic tool for RAS. It is noninvasive, uses portable equipment that is relatively inexpensive and widely available, does not use iodinated contrast material, and has no effect on renal function. Azotemia does not affect the results of the study, and no discontinuation of antihypertensive medications is required.

The main disadvantage of DUS is its dependence on operator skill, with less reliable results obtained from less experienced vascular laboratories. In obese patients and patients with a great deal of bowel gas, the renal arteries may be difficult to visualize. Accessory renal arteries are difficult to visualize, and occluded renal arteries cannot be diagnosed with certainty. Finally, DUS offers anatomic data with no indication of the functional significance of the lesion.

In a prospective study comparing DUS with angiography in 102 patients, DUS was found to have a sensitivity and specificity of 98%, correctly identifying the lesions in 182 of 187 arteries with different degrees of stenosis (Olin et al, 1995). In another prospective study involving 41 patients, DUS (compared with angiography) revealed a sensitivity of 95% and a specificity of 90% (Strandness, 1994). In a more recent prospective study evaluating 53 patients with both DUS and angiography, a DUS sensitivity of only 75% was reported, with 103 (of 112) arteries and 12 (of 16) stenoses detected by DUS. Specificity for detecting RAS was 100% (Mollo et al, 1997).

In a study using slightly different diagnostic criteria (PSV > 210 cm/sec) and evaluating 46 patients, the sensitivity and specificity of DUS were 89.5% and 90.7%, respectively. Of note is that in the same study, only 23 patients were hypertensive, and captopril renography was positive in only 5 cases (Miralles et al, 1993). The superior utility of DUS over captopril renography reported in this study was not validated in a later study prospectively comparing both DUS and captopril renography with angiography in 28 patients. After 11 (of 45) renal arteries were excluded from the study because no Doppler signal could be obtained, the accuracy of both diagnostic modalities was comparable, with a sensitivity and specificity for DUS and captopril renography of 78% and 81%, and 83% and 81%, respectively (Kaplan-Pavlovcic and Nadja, 1998).

Continuous developments in equipment and techniques of DUS are occurring and promise increased accuracy and utility. Among these developments are the use of power Doppler imaging, three-dimensional imaging, harmonic imaging, and ultrasonic contrast agents. Power Doppler imaging is more sensitive, especially in the detection of low flow rates (Murphy and Rubin, 1997). Three-dimensional imaging uses computer technology to produce a three-dimensional image of the region of interest. Harmonic imaging also improves the imaging of structures that might be moving, such as the proximal renal arteries. The use of biodegradable microbubbles in the circulation increases the echogenicity and enhances the visualization of the renal vessels (Missouris et al, 1996).

Magnetic Resonance Angiography

MRA is a modern noninvasive anatomic diagnostic modality that has become available for diagnosing RAS. The techniques used for MRA are time of flight and phase contrast. Gadolinium DTPA enhances the blood signal, resulting in improved images of the aorta and the proximal renal arteries. **MRA has the advantage of being noninvasive, not using radiation, having a low technical failure rate, and not using iodinated contrast material, which latter factor makes the technique suitable for use in patients with renal insufficiency** (Ghantous et al, 1999). Multiple projections can be obtained, and the morphology of the kidney can be evaluated as well. Functional information, including individual renal blood flow and GFR, can also be obtained (Grist, 1994).

MRA provides an image quality that is inferior to that of angiographic images. Only the proximal parts of the main renal arteries are visualized without the ability to image the distal arterial tree. MRA is contraindicated in patients with magnetic implants and claustrophobia, and it uses sophisticated, expensive equipment that might not be widely available.

MRA was compared with intra-arterial angiography in 103 patients, all of whom had both studies performed. When MRA was used, all main renal arteries and 31 of 33 accessory renal arteries were visualized, and 61 of 65 stenoses were diagnosed and graded correctly. The overall sensitivity was 93% and the specificity was 90% (Hany et al, 1998). Another study evaluated 62 patients with both MRA and angiography (Thornton et al, 1999). MRA had a sensitivity of 88% and a specificity of 98% and visualized 93% of all the arteries seen on angiography. The reproducibility of interpretation and interobserver variability of MRA were found to be comparable to those of conventional angiography in 54 patients who underwent both diagnostic procedures (Gilfeather et al, 1999).

A prospective study compared gadolinium-enhanced MRA with color DUS in 45 patients, and the results of both examinations were referenced to angiography in all cases (De Cobelli et al, 2000). Of 13 accessory renal arteries detected by digital subtraction angiography (DSA), 12 were detected by MRA and only 3 were detected by DUS. The sensitivity and specificity of MRA were 94% and 91% for diagnosing all degrees of stenosis, whereas the sensitivity and specificity of DUS were 71% and 76%. For the detection of stenoses of more than 50%, the corresponding values were 93% and 95% for MRA, compared with 93% and 89% for DUS. Another group (Leung et al, 1999) compared the two modalities (and referenced results to DSA studies) and reported similar results, with slightly better sensitivity and specificity for MRA (90% and 86%) compared with DUS (81% and 87%). This study also confirmed the superior ability of MRA over DUS in detecting accessory renal arteries (96% versus 5%). MRA was more sensitive in detecting RAS related to ASO than in detecting RAS caused by FD, according to this study; this could be related to the more distal nature of most FD lesions. MRA can also diagnose renal artery aneurysms, and is useful to follow the size of renal artery aneurysms over time, although

aneurysms distal to the primary branches of the renal artery are not well visualized on MRA (Browne et al, 2004).

Improving techniques and increasing experience with MRA continue to increase its accuracy and utility. The use of time-resolved imaging to decrease artifacts, decrease venous overlap, and improve spatial resolution and contrast enhancement has been reported (van Hoe et al, 2000). Gadolinium has been administered intra-arterially in vitro in an attempt to improve visualization of blood vessels (Omary et al, 1999). The multiecho gradient echo technique for three-dimensional MRA has been reported to produce high vessel-to-background contrast with decreased bowel-related artifact (Papachristopoulos et al, 1999).

Computed Tomography Angiography

The availability of spiral CT technology with rapid acquisition time has made possible imaging of the renal arteries. Scanning through the area of the renal arteries using thin (2-mm) slices during the arterial phase of contrast material injection is performed while the patient holds a single breath. Three-dimensional reconstruction of the axial image is then carried out, showing the abdominal aorta with its main branches. Atherosclerotic disease affecting the aorta and the renal arteries can be visualized, as well as renal morphology and parenchymal lesions. **Spiral CTA lacks the ability to define disease distal to the main stem renal artery, and a relatively large volume of IV iodinated contrast material is required to perform the study;** however, CTA might offer the advantages over MRA of cost, convenience, and widespread availability (Prokop, 1998).

Comparison between CTA and DSA in 82 patients revealed a sensitivity and specificity of 96% and 99%, respectively, for hemodynamically significant stenosis, with only 1 stenosis (of 34) missed on CTA. Thirty-three accessory renal arteries were visualized in this study, as well as 5 adrenal masses (Wittenberg et al, 1999). In another study evaluating 50 patients with suspected RAS, CTA showed a sensitivity of 90% and a specificity of 97% and demonstrated 27 of 28 accessory renal arteries (Kim et al, 1998). Modern CT technology can also be utilized to perform virtual endoscopy, which can be helpful for evaluating renal artery stenoses and positioning arterial stents (Neri et al, 2000). Multiple detector-row CTA is a new method of CTA that also promises more accurate depiction of the renal and other visceral arteries (Pannu and Fishman, 2002; Fleischmann, 2003).

In order to clarify the various limitations of noninvasive imaging modalities in respect to accessory renal arteries as well as proximal branches of the renal artery, a study compared DUS, CTA, and MRA with angiography. The points of comparison were the ability to evaluate accessory renal arteries and proximal branches. Fifty-six patients underwent angiography; of those patients, 45 underwent DUS, 52 underwent CTA, and 28 underwent MRA. When angiography was used, 28 accessory renal arteries as well as 21 proximal (>2 cm from the aorta) renal artery branches were visualized. DUS depicted 21% of the accessory arteries and 0% of the proximal branches. MRA depicted 73% of the accessory arteries (and four additional arteries not seen on angiography) and 0% of the proximal branches. CTA depicted 92% of the accessory arteries and 76% of the proximal branches. Although experience with modalities differs among institutions, this study offers an interesting comparison of the limitations of these techniques (Halpern et al, 1999).

In a more recent study comparing MRA against CTA with intra-arterial DSA as the reference standard, there was no significant difference in the accuracy of both MRA and CTA, with sensitivity around 92% and specificity around 99% for both modalities. Acceptance by patients was also measured and estimated to be best for CTA, although the time consumed for reconstruction of the images was most in CTA (Willmann et al, 2003).

Contrast Arteriography

Intra-arterial angiography remains the gold standard for diagnosing renal artery disease, and it is the test against which the results of other tests are compared. The availability of modern interventional techniques (angioplasty and arterial stents) has allowed angiography to become a combined diagnostic and therapeutic procedure. However, for several reasons, angiography is not suitable for use as a preliminary screening tool for all patients suspected of having RAS. It is an expensive test that cannot be done on an outpatient basis. It is also an invasive test utilizing ionizing radiation and requiring arterial puncture, manipulation of arterial catheters, and injection of iodinated contrast material.

Complications of arterial puncture and manipulation include bleeding, hematoma, dissection, thrombosis, and distal embolization of atherosclerotic plaque as well as cholesterol embolization. The use of iodinated contrast material carries the risk of allergic reaction and volume overload. The contrast load also leads to a transient impairment of renal function, especially in patients with preexisting renal insufficiency and in diabetic patients. Several advances in the field of angiography have been directed at decreasing side effects from iodinated contrast material. These advances include decreasing the contrast load through digital postprocessing as well as the use of contrast agents with decreased nephrotoxicity such as carbon dioxide or gadodiamide (Spinosa et al, 1999).

Conventional angiography uses conventional cut film and large volumes of contrast material as well as larger catheters to deliver the contrast volume. The advent of DSA has allowed reduction of the contrast load with a concomitant reduction in catheter size. Although the spatial resolution of DSA is lower than that of conventional angiography, the contrast resolution of DSA is superior. The ability to subtract bone and soft tissue with DSA is an important advantage, making DSA the most commonly used technique today.

Early in the development of digital techniques, it was suggested that IV studies (IV-DSA) would be accurate and supersede the arterial approach (Wilms et al, 1986). The attraction of visualizing the renal arteries angiographically with an outpatient procedure was not realized, however. Several disadvantages led to the gradual abandonment of IV-DSA in favor of intra-arterial studies. These disadvantages include the need for a large contrast material volume, the frequent need for central venous catheters to deliver this large volume, poor image quality owing to overlying visceral arteries, frequent uninterpretable studies, and poor opacification, especially in elderly patients or those with cardiac dysfunction (Buonocore et al, 1981; Smith et al, 1982).

Carbon dioxide has been introduced as a contrast agent for intra-arterial injection in an effort to reduce contrast nephrotoxicity from iodinated contrast material. An injected bolus of carbon dioxide displaces blood from the vessels to be imaged and provides sufficient contrast for adequate imaging using DSA technology and postprocessing enhancement. The injected carbon dioxide is cleared by the lungs without deleterious effects. Carbon dioxide has no effect on renal function, making it an ideal agent for use in patients with renal insufficiency. It is nonallergenic, is cheap, and presents no problems with fluid overload. Smaller, softer arterial catheters can be used for injection, minimizing trauma to the arterial walls. This technique can also provide information that is not visualized using standard iodinated contrast material, including small arteriovenous shunts, small tumor vessels, and minute amounts of arterial bleeding (Hawkins et al, 1994).

In a prospective study comparing carbon dioxide angiography with standard contrast arteriography in 100 patients, the overall accuracy of carbon dioxide DSA was 97% (Schreier et al, 1996). Carbon dioxide DSA was successfully used for guiding angioplasty and renal artery stenting in 17 patients in another study with only one transient rise in the serum creatinine level (Caridi et al, 1999). Similarly, no cases of contrast nephropathy were reported in a study employing carbon dioxide DSA as the main imaging technique for patients with renal impairment (Fitridge et al, 1999). Carbon dioxide renal angiography has been used safely in children (Kriss et al, 1997). Although carbon dioxide is generally regarded as a benign contrast medium, a case of fatal complications (rhabdomyolysis and intestinal infarction) after carbon dioxide angiography has been reported (Rundback et al, 1997).

Ailawadi and colleagues (2003) evaluated the use of gadolinium as a contrast agent for intra-arterial angiography in patients with renal insufficiency and found it to be safe and adequate for imaging the renal arteries as well as first- and second-order branches. No comparison with conventional contrast angiography was performed, but this might be an option to decrease nephrotoxic side effects of angiography.

COST-EFFECTIVE APPROACH FOR DIAGNOSIS

The diagnostic approach for patients with RAS should be tailored according to the predominant clinical picture; that is, patients with IN should be worked up differently from patients with hypertension as the presenting clinical problem. As mentioned previously, **patients with IN constitute the majority of patients presenting for treatment today, may not have hypertension as part of the clinical picture, and cannot be diagnosed by functional testing. In these patients, an anatomic diagnosis is pursued directly.** Patients with a strong suspicion of renal arterial disease should probably undergo intra-arterial angiography (iodinated contrast material or carbon dioxide) directly. Patients with mild or moderate suspicion of having RAS should undergo a noninvasive anatomic test (DUS, MRA, or CTA). The choice of diagnostic procedure depends on the patient's level of renal function (azotemic patients more suitable for DUS than CTA) as well as the experience with the various modalities at different centers. Positive findings on noninvasive testing should lead to definitive confirmation of the lesion and therapeutic planning through intra-arterial angiography. Negative findings on these tests should be interpreted with understanding of the limitations of each technique and should lead to further noninvasive testing if technical factors are suspected or to no further testing if a technically perfect study is clearly negative in a patient with minimal clinical suspicion.

Patients with suspected RVH present a different diagnostic challenge. Functional evaluation of the RAAS is possible and is usually performed as a first step in the diagnosis before anatomic diagnosis. The steps used to screen and select patients for further study differ according to different centers and have changed over the years, mainly owing to the introduction of reliable noninvasive anatomic imaging techniques.

Patients should be stratified according to the clinical findings suspicious for RVH into patients with low, moderate, and high suspicion. Like patients with IN, patients with a high suspicion for RVH are probably best served by performing angiography directly. Negative findings on other studies would not prevent these patients from progressing to angiography in any case. In bilateral cases, RVR assays can be used to localize the more ischemic side.

Patients with low or moderate suspicion of RVH are more problematic. In these cases, it is probably reasonable to perform captopril renography as a preliminary test. A positive test should be followed by further testing, preferably definitive diagnosis through angiography. Patients with low clinical suspicion and a technically satisfactory negative study should not be subjected to further testing. Technically unsatisfactory studies should probably be followed by a noninvasive test of a different type (e.g., DUS). These tests (DUS, MRA, or CTA) provide no functional information or prediction of cure after intervention. To date, anatomic confirmation of the disease and treatment planning still require intra-arterial angiography.

The role of renin assays has decreased significantly since the 1980s. Few centers use the captopril test to exclude patients from having RVH because of its consistently high negative predictive value. RVR assays are rarely used to diagnose RVH before a noninvasive test indicates the anatomic presence of stenosis; their role has focused on localizing the more ischemic kidney in bilateral cases.

SELECTION OF PATIENTS FOR SURGICAL OR ENDOVASCULAR THERAPY

Renovascular Hypertension

In patients with RVH secondary to FD, the decision for intervention (surgery or angioplasty) is guided by the specific type of disease as determined by angiographic findings and the associated natural history (Novick et al, 1996). **Medical management of hypertension is the preferred initial treatment for patients with medial fibroplasia because loss of renal function from progressive obstruction is uncommon with this disease. Interventive treatment** in the latter category is reserved for patients whose blood pressure is difficult to control with multiple drugs. Conversely, RAS secondary to

intimal or perimedial fibroplasia generally progresses and often eventuates in ischemic renal atrophy. Furthermore, these lesions tend to occur in younger patients and to cause hypertension that is extremely difficult to control. Early interventional therapy in these patients is therefore indicated both to preserve renal function and to minimize the need for long-term antihypertensive medication.

In selecting patients with FD for surgical renal revascularization, the efficacy of percutaneous transluminal angioplasty (PTA) must also be considered. **The results of angioplasty for FD of the main renal artery have been excellent** and equal to those obtained with surgical revascularization; therefore, angioplasty is the initial treatment of choice in such cases. However, as many as 30% of patients with FD have branch renal arterial involvement, which increases the technical difficulty of, and often precludes, angioplasty. Therefore, surgical renal revascularization is the primary interventional treatment in this category.

In patients with atherosclerotic RVH, more vigorous attempts at medical management are warranted because these patients are older and often have extrarenal vascular disease. Therefore, multiple-drug regimens that control the blood pressure are often the preferred approach. Indeed, the advent of new β-blocking agents and converting enzyme inhibitors has enhanced the efficacy of medical antihypertensive therapy. Intervention with surgery or endovascular therapy is best reserved for patients whose hypertension cannot be adequately controlled or when renal function is threatened by advanced vascular disease (Novick et al, 1996).

Ischemic Nephropathy

Anatomic Severity and Extent of Renal Artery Disease

After angiographic diagnosis of ARAS, and with knowledge of the natural history of this disease, one can identify the patients in whom such disease poses a significant threat to overall renal function. This designation applies to patients with high-grade (>75%) arterial stenosis affecting their entire renal mass, namely, where such stenosis is present bilaterally or involves a solitary kidney (Fig. 36–8). In these patients, the risk of complete renal arterial occlusion is significant, and if this occurs, the clinical outcome is a critical decrease in functioning renal mass with resulting renal failure. Intervention to restore normal renal arterial blood flow is indicated in such patients for the purpose of preserving renal function. In a study from the Cleveland Clinic (Novick et al, 1987), surgical revascularization for preservation of renal function was performed in 161 patients with ARAS bilaterally or in a solitary kidney. Postoperatively, renal function was improved in 93 patients (58%), stable in 50 patients (31%), and deteriorated in only 18 patients (11%).

The benefit of undertaking revascularization for the preservation of renal function in patients with unilateral ARAS and an unobstructed contralateral renal artery is not established. If the contralateral kidney is anatomically and functionally normal, revascularization for this purpose is clearly not warranted. If the opposite kidney is functioning but involved with some type of parenchymal disorder, revascularization of the ischemic kidney may benefit some

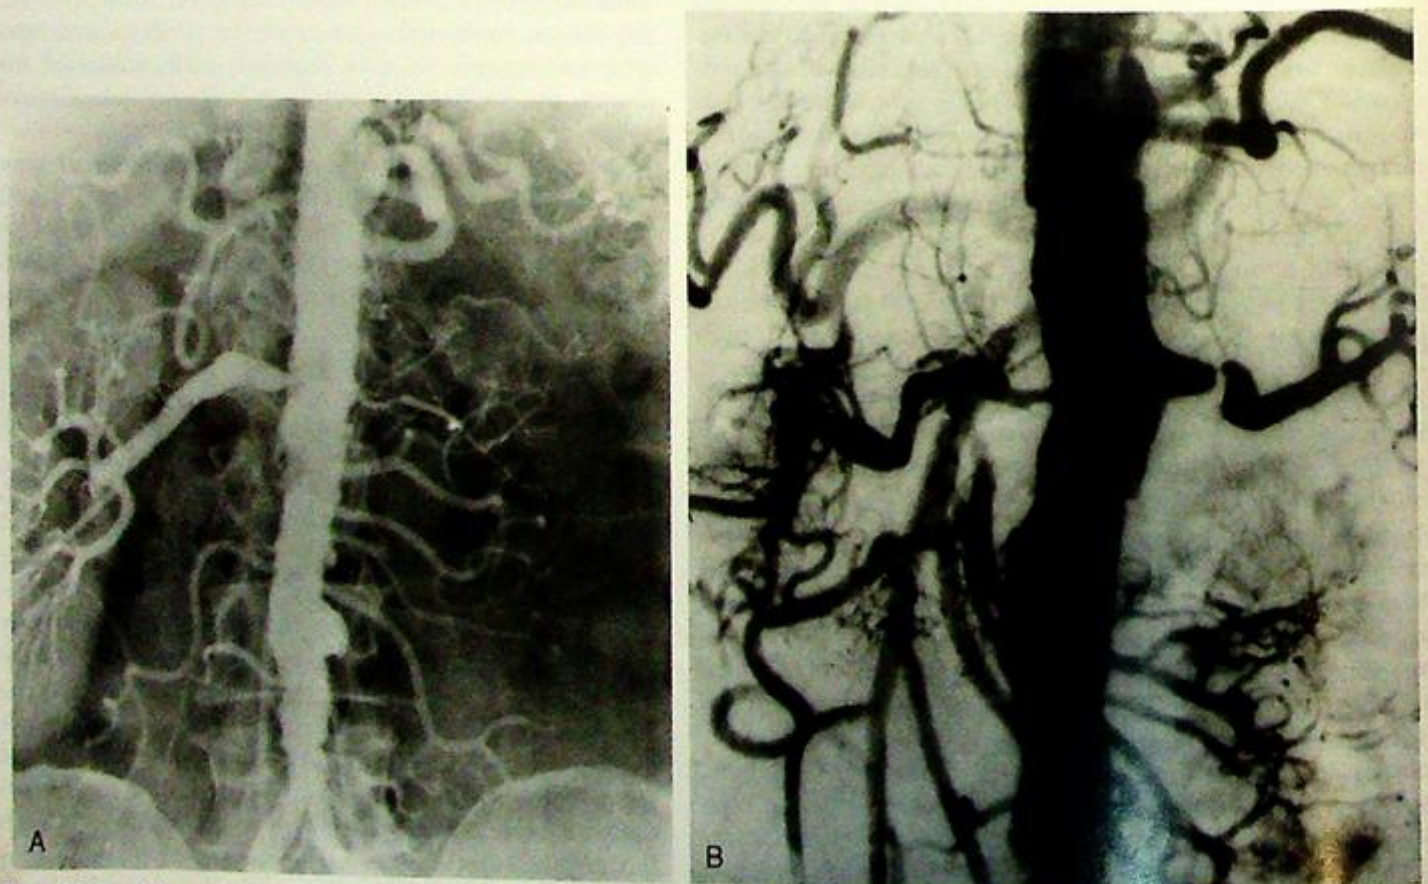

Figure 36–8. Atherosclerotic renal artery disease poses the greatest threat to overall renal function in patients with high-grade arterial stenosis to a solitary (right) kidney (**A**) and bilateral high-grade renal artery stenosis (**B**), as demonstrated on these abdominal aortograms.

patients, but specific indications for this approach are not well defined. Dean and associates (1991) reviewed the renal functional outcome after surgical revascularization in 53 patients with IN. The postoperative estimated GFR was improved significantly in 41 patients treated for bilateral ARAS but was unaltered in 12 patients with unilateral ARAS.

Complete occlusion of the renal artery most often eventuates in irreversible ischemic damage of the involved kidney. However, in some patients with gradual arterial occlusion, the viability of the kidney can be maintained through the development of a collateral arterial supply (Morris et al, 1956; Zinman and Libertino, 1977; Schefft et al, 1980). Helpful clinical clues suggesting renal salvability in such cases include (1) angiographic demonstration of retrograde filling of the distal renal arterial tree by collateral vessels on the side of total arterial occlusion (Fig. 36–9), (2) a renal biopsy showing well-preserved glomeruli, (3) kidney size greater than 9 cm, and (4) function of the involved kidney on isotope renography or IV pyelography. When such criteria are present, restoration of normal renal arterial flow can lead to recovery of renal function.

Level of Renal Function

In general, revascularization to preserve renal function in patients with ARAS is most likely to be beneficial in those who have not yet sustained severe, permanent impairment of overall renal function. In a study from the Cleveland Clinic (Bedoya et al, 1989), we evaluated the effect of baseline renal function on the outcome of surgical revascularization in elderly patients with ARAS. The majority of these patients had preoperative serum creatinine levels of less than 3 mg/dL; postoperative renal function was stable or improved in 89% of patients in this category.

Revascularization to preserve renal function is generally not worthwhile in patients with severe azotemia (serum creatinine level >4 mg/dL) because advanced underlying renal parenchymal disease is inevitably present and obviates improvement in renal function with restored perfusion. This observation has been recorded by several groups including our own (Mercier et al, 1990; Chaikof et al, 1994). Severe nephrosclerosis is the most common form of renal parenchymal disease in such patients; however, renal cholesterol embolization may be an additional complicating feature (Fig. 36–10) (Vidt et al, 1989). In patients with atherosclerotic ischemic renal disease and a serum creatinine level greater than 4 mg/dL, our policy is to perform a renal biopsy to evaluate the severity of renal parenchymal involvement from one or both of these disorders.

Some patients present with severe impairment of overall renal function that has developed acutely after the initiation of medical antihypertensive therapy (Hricik et al, 1983; Textor et al, 1983). Such rapidly progressive renal insufficiency may be a manifestation of perfusion-dependent renal function related to underlying ARAS. If this problem is detected promptly, renal function often improves after discontinuation of the offending antihypertensive medications. Intervention to relieve renal arterial obstruction can prevent permanent renal damage in patients with this type of severe acute renal insufficiency.

In addition to the absolute level of renal function, the rate of decline in overall renal function is an important determinant of the outcome after intervention in atherosclerotic ischemic renal disease. In a study by Dean and associates (1991), patients with a rapid rate of deterioration in estimated GFR during the 6 months preceding surgical revascularization achieved the greatest benefit in terms of postoperative improvement of estimated GFR. Unfortunately, their data precluded definition of a critical rate of decline in estimated GFR that would predict retrieval of renal function by revascularization. Nevertheless, rapid deterioration of overall renal function in association with ARAS suggests a strong possibility of retrieval of function by intervention to restore normal renal arterial flow.

Occasional patients with ESRD from IN have been encountered in whom renal function has been salvable with revascularization (Wasser et al, 1981; Kaylor et al, 1989). The basis for this has been the presence of chronic bilateral total renal arterial occlusion in which, fortuitously, the viability of one or both kidneys has been maintained through collateral vascular supply. In such cases, revascularization can yield dramatic recovery of renal function (Fig. 36–11). Unfortunately, this clinical presentation is rare, and a less favorable outcome

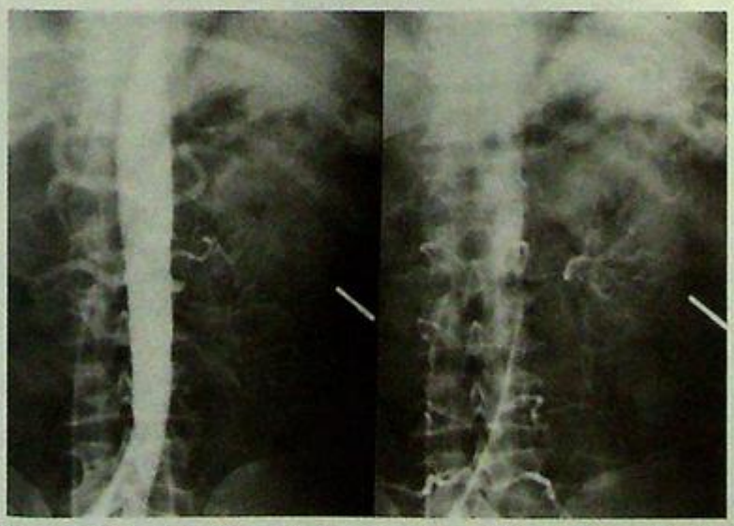

Figure 36–9. Abdominal aortograms reveal complete occlusion of the left renal artery *(left)* with filling of the distal renal artery branches from an extensive collateral supply on delayed film *(right)*.

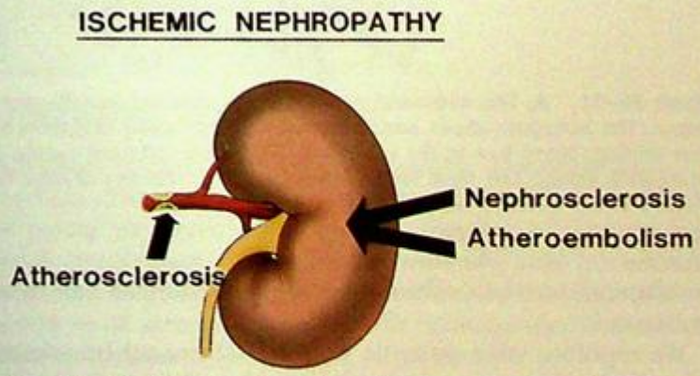

Figure 36–10. Patients with atherosclerotic renal artery disease often have renal parenchymal involvement with varied degrees of nephrosclerosis or atheroembolic disease.

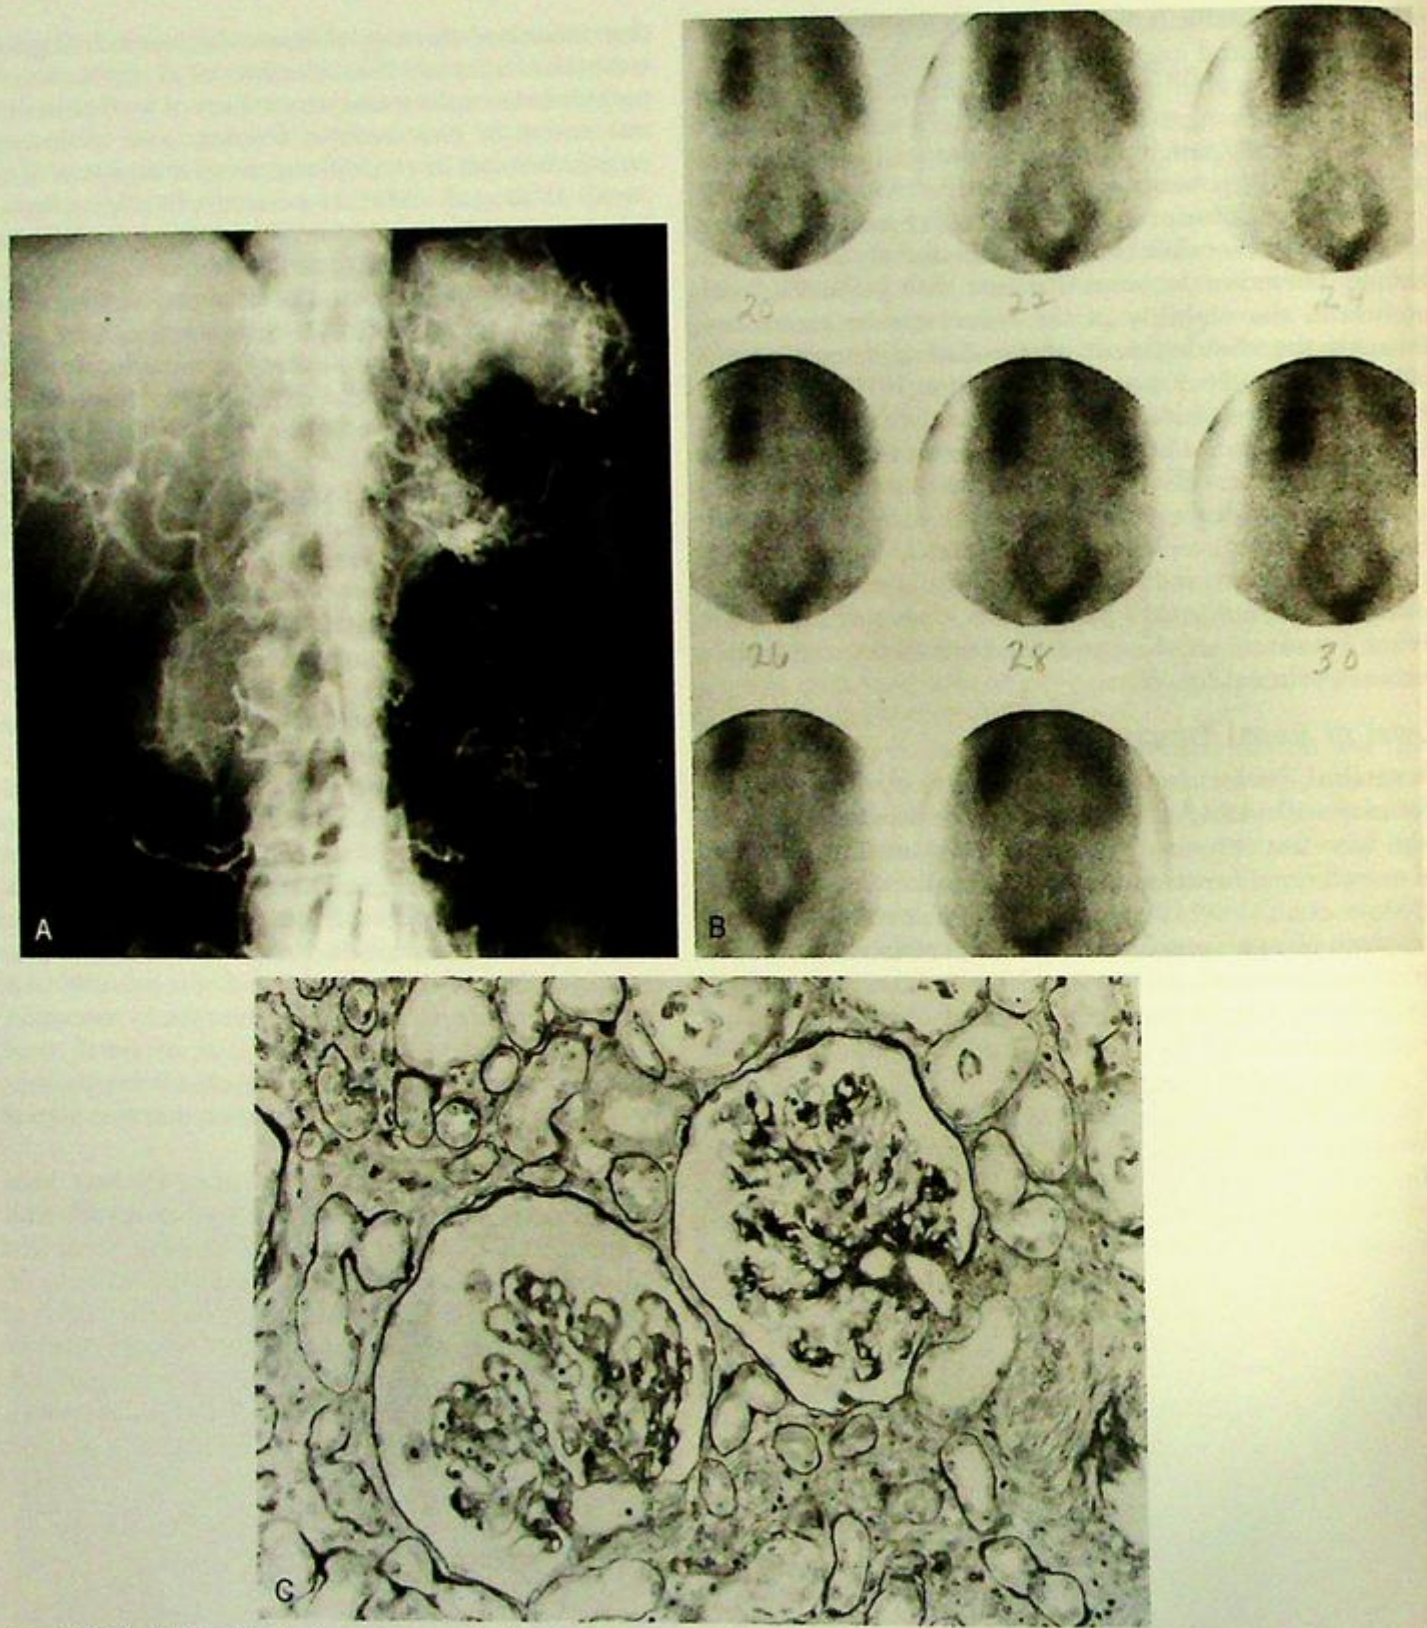

Figure 36–11. **A,** This abdominal aortogram was obtained in a 60-year-old woman who had been undergoing chronic dialysis for 9 months with no urine output. The aortogram shows complete bilateral renal artery occlusion with evidence of collateral vascular supply to the left kidney. **B,** Technetium renal scan confirms blood flow to the left kidney *(left)* from collateral supply. **C,** Left renal biopsy shows hypoperfused but viable glomerular tissue, indicating a salvageable kidney. Left renal revascularization led to recovery of renal function and discontinuation of dialysis in this patient.

of bilateral arterial occlusion on renal viability is far more common.

We reported nine patients with ESRD caused by atherosclerotic renal artery occlusion who underwent surgical revascularization with subsequent recovery of renal function (Kaylor et al, 1989). The duration of dialysis preoperatively ranged from 1 to 13 months. In all cases, renal viability was being maintained by collateral vascular supply. Postoperatively, renal function improved immediately, and no patient required subsequent dialysis. Excellent overall rehabilitation was achieved in all patients. Six patients were alive at a mean interval of 4 years postoperatively and with satisfactory renal

function (mean serum creatinine level of 2.7 mg/dL). Three patients died at a mean interval of 6.8 years postoperatively, and they all maintained satisfactory renal function (mean serum creatinine level of 3 mg/dL) until death. Although some patients with ESRD caused by atherosclerotic arterial occlusion can be salvaged in this manner, in most such cases irreversible loss of renal function has occurred. Therefore, the most effective approach is to relieve arterial obstruction before the development of ESRD.

Finally, it is important to emphasize that **patients with ESRD and ARAS without complete occlusion are not appropriate candidates for revascularization to restore function.** In such cases, main renal arterial blood flow is preserved, albeit at a reduced level, yet the supplied renal parenchyma is without function. The basis for this is the presence of severe unalterable parenchymal damage that precludes recovery of renal function with improved perfusion.

Renal Histopathology

Evaluation of renal histopathology can help to determine the presence of salvable renal function in selected patients with atherosclerotic renal ischemic disease. **In patients with ARAS and severe existing impairment of overall renal function (serum creatinine level >4 mg/dL)**, renal biopsy findings can help to predict whether revascularization is likely to forestall further progressive renal insufficiency. In patients with atherosclerotic renal artery occlusion, renal biopsy findings can indicate whether the involved kidney is viable and functionally salvable on the basis of collateral vascular supply. The two predominant morphologic lesions in such patients are arteriolar nephrosclerosis and atheroembolic renal disease, with the former more often encountered. Both these diagnoses can be established on a frozen section histopathologic examination, and, therefore, the renal biopsy can be done at the same time as surgical revascularization, if the biopsy findings are favorable. In patients with arteriolar nephrosclerosis, the most important favorable criterion is histologic evidence that a majority of examined glomeruli are intact and viable (Zinman et al, 1977; Schefft et al, 1980). Histologic findings of tubular atrophy, interstitial fibrosis, and arteriolar sclerosis are of lesser importance and do not necessarily preclude recovery of renal function; these findings may merely reflect the histologic changes of chronic reversible renal ischemia. However, the finding of widespread glomerular hyalinization indicates irreversible ischemic renal injury that obviates any benefit from relief of renal arterial obstruction (Fig. 36–12A). The finding of extensive atheroembolic disease would also preclude renal revascularization (see Fig. 36–12B). With respect to the technique for renal biopsy in such patients, a more representative specimen of renal tissue is obtained with an open surgical wedge biopsy than with a closed needle biopsy.

SURGICAL REVASCULARIZATION

Preoperative Preparation

When surgical revascularization is indicated for renal artery disease, it is important to define accurately the general medical condition of the patient because this will determine the risk of undertaking a major vascular operation. Most patients with renal arterial FD are young and otherwise healthy, and the operative risk is minimal in this group (Novick, 1994a). **In patients with atherosclerotic renovascular disease, the preoperative evaluation should include a thorough search for coronary artery disease because this has been the leading cause of operative death after surgical revascularization.** In our program, in addition to a careful history, a physical examination, and an ECG, a thallium cardiac stress test is done on all operative candidates in this category. If any of these assessments suggest the presence of coronary artery disease, our policy is to perform coronary cineangiography and left-sided ventriculography. Myocardial revascularization is recommended for patients with significant correctable coronary artery disease before renal revascularization (Novick et al, 1981).

Cerebrovascular accident has also been a significant cause of death after renal revascularization in patients with atherosclerosis, albeit a less common complication than myocardial infarction. The approach to patients whose history or examination suggests extracranial cerebrovascular disease is analogous to that employed for patients with suspected coronary artery disease. In such patients, carotid arteriography is obtained preoperatively, and if significant occlusive disease is found, endarterectomy is recommended before renal revascularization (Novick et al, 1981).

In patients with generalized ASO and renal artery disease, cardiac function is often compromised to various degrees. In these patients, hypertension increases the workload on the left ventricle, which decreases cardiac reserve and renders the heart less efficient. In addition to having an impaired myocardium, these patients often have a decreased intravascular volume because of prior treatment with diuretic agents. These patients can benefit from a careful hemodynamic assessment in an intensive care unit for 12 to 24 hours before surgical revascularization. In the intensive care unit, Swan-Ganz arterial and urethral catheters are placed for measurement of blood pressure, pulmonary capillary wedge pressure, pulmonary artery pressure, cardiac output, total peripheral resistance, and urinary output. While these parameters are being monitored, IV vasodilators can be administered to control the blood pressure and decrease the cardiac afterload while the intravascular space is carefully expanded with isotonic fluid. Afterload reduction and fluid repletion in this manner optimize perioperative cardiac function by increasing cardiac output and decreasing cardiac work. This approach can enhance the safety of surgical renal revascularization in patients with generalized ASO.

Operative Techniques

Advances in both surgical renovascular reconstruction and medical antihypertensive therapy have limited the role of total or partial nephrectomy in the management of patients with renal artery disease. These operations are only occasionally indicated in patients with severe arteriolar nephrosclerosis, severe renal atrophy, uncorrectable renovascular lesions, and renal infarction.

A variety of surgical revascularization techniques are available for treating patients with significant renal artery disease. **Aortorenal bypass with a free graft of autogenous**

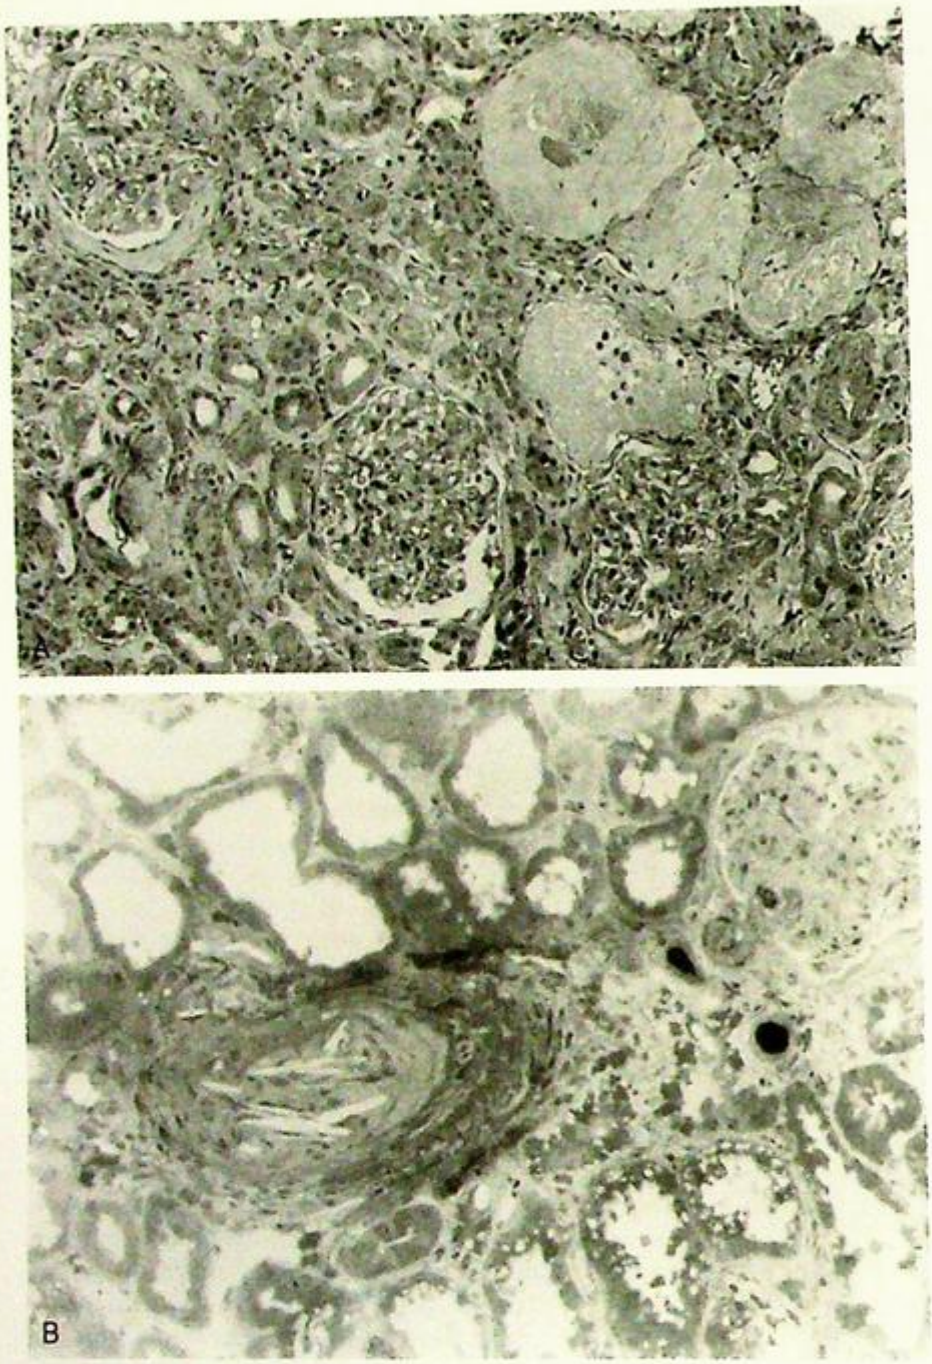

Figure 36–12. **A,** Light microscopic findings on biopsy of a kidney with total arterial occlusion demonstrate extensive glomerular hyalinization, which precludes any benefit from revascularization. **B,** Biopsy of a kidney in another patient demonstrates atheroembolic disease.

hypogastric artery or saphenous vein remains a popular method in patients with a healthy abdominal aorta. Polytetrafluoroethylene aortorenal bypass grafts have been successfully employed by some authors, usually when an autogenous graft is not available. Renal endarterectomy also continues to be utilized occasionally to treat atherosclerotic renal artery disease. Patients with complex branch renal artery lesions are managed with extracorporeal microvascular reconstruction and autotransplantation.

In older patients, severe atherosclerosis of the abdominal aorta may render an aortorenal bypass or endarterectomy technically difficult and potentially hazardous to perform. In such cases, several authors prefer alternative surgical approaches that allow renal revascularization to be safely and effectively accomplished while avoiding operation on a badly diseased aorta. The most effective alternative bypass techniques have been a splenorenal bypass for left renal revascularization and a hepatorenal bypass for right renal revascularization. The absence of occlusive disease involving the origin of the celiac artery is an important prerequisite for these operations. A 1995 study indicated the presence of significant celiac artery stenosis in 50% or more of patients with ARAS (Fergany et al, 1995). This information underscores the importance of obtaining preoperative lateral aortography to evaluate the celiac artery origin in patients who are being considered for hepatorenal or splenorenal bypass.

Use of the supraceliac or lower thoracic aorta for renal revascularization is a more recent surgical alternative in patients with significant atherosclerosis of the abdominal aorta and its major visceral branches. The supraceliac aorta is often relatively disease free in such patients and can be used to achieve renovascular reconstruction with an interposition saphenous vein graft. Simultaneous aortic replacement and renal revascularization have been associated with an increased

risk of operative mortality, and this approach is best reserved for patients with a fixed indication for aortic replacement such as a significant aortic aneurysm or symptomatic aortoiliac occlusive disease.

Results

Reports from several centers indicate that the techniques described previously for surgical renovascular reconstruction can be safely performed with a high technical success rate. **Patients with FD are usually otherwise healthy, and operative morbidity and mortality after revascularization in this group have been minimal** (Novick et al, 1987; Hansen et al, 1992). Operative mortality rates of 2.1% (Novick et al, 1987), 3.1% (Hansen et al, 1992), 3.4% (Bredenberg et al, 1992), and 6.1% (Libertino et al, 1992) have been reported after surgical revascularization in patients with atherosclerotic renal artery disease. An increased risk of operative mortality has been observed with bilateral simultaneous renal revascularization (Hallett et al, 1987) or when renal revascularization is performed in conjunction with another major vascular operation such as aortic replacement (Lawrie et al, 1989). Most studies have indicated a high technical success rate for surgical vascular reconstruction with postoperative thrombosis or stenosis rates of less than 10% (Novick et al, 1987; Van Bockel et al, 1987; Libertino et al, 1992).

In a retrospective study from the Cleveland Clinic, Tsoukas and colleagues (2001) evaluated the results of simultaneous aortic and renal revascularization and reported a 13% postoperative mortality rate for bilateral renal revascularization versus 7% for patients with unilateral renal revascularization when both are performed simultaneously with aortic replacement. The 5-year survival rate for patients with preoperative serum creatinine greater than 2 mg/dL was 53% compared with 85% for patients with lower creatinine. The authors recommend adjunctive use of endovascular techniques to decrease the magnitude of the surgical procedure for patients with concomitant aortic and bilateral renal artery atherosclerotic disease.

In evaluating the results of surgical revascularization for RVH, most studies have considered patients to be cured if the blood pressure is 140/90 mm Hg or less postoperatively. Patients have been considered to be improved if they have either shown a reduction in diastolic pressure of 10 to 15 mm Hg or more or become normotensive with medication. Failures have been those who have not qualified for either of the aforementioned categories. The results of surgical treatment for RVH vary according to the underlying pathologic diagnosis. In patients with FD, 50% to 60% are cured, 30% to 40% are improved, and the failure rate is less than 10% (Novick et al, 1987; Hansen et al, 1992). In patients undergoing revascularization for atherosclerotic RVH (Table 36–5), the failure rate is approximately the same; however, fewer patients are cured and more patients are improved postoperatively. The explanation for this is that RVH is often superimposed on existing essential hypertension in older patients. A study by Van Bockel and colleagues (1987) highlighted the excellent long-term results after reconstructive surgery for atherosclerotic RVH; with a mean follow-up of 8.9 years, postoperative hypertension was cured or improved in 83 of 105 patients (79%).

Table 36–5. Results of Surgical Revascularization for Atherosclerotic Renovascular Hypertension

Series	Patients (N)	No. Cured	No. Improved	No. Failed
Van Bockel et al, 1987	105	19 (18%)	64 (61%)	22 (21%)
Novick et al, 1987	180	55 (31%)	110 (61%)	15 (8%)
Libertino et al, 1988	86	38 (44%)	44 (51%)	4 (5%)

Bredenberg et al, 1992	40	22 (55%)	10 (25%)	8 (20%)
Libertino et al, 1992	91	45 (49%)	31 (35%)	15 (16%)

During the past 15 years, **more centers have been performing surgical revascularization to preserve renal function in patients with high-grade atherosclerotic arterial occlusive disease affecting both kidneys or a solitary kidney.** These are generally older patients with diffuse ASO, ostial renal artery lesions, and varied degrees of renal functional impairment. Studies from several centers (Table 36–6) have indicated improvement or stabilization of renal function postoperatively in 75% to 89% of patients. Considering the significant risks of progressive occlusive disease and renal failure that have been associated with medical management of such patients, these results demonstrate a favorable influence of revascularization on the natural history of untreated atherosclerotic renal artery disease.

We have reviewed the contemporary experience at the Cleveland Clinic with surgical renal revascularization employing an extra-anatomic bypass operation between 1980 and 1992 (Fergany et al, 1995). A total of 175 operations were done including hepatorenal bypass (n = 59), splenorenal bypass (n = 54), iliorenal bypass (n = 37), thoracic aortorenal bypass (n = 23), renal autotransplantation (n = 1), and superior mesenterorenal bypass (n = 1). There were five operative deaths (2.9%) and seven cases of postoperative graft thrombosis (4%). All patients with poorly controlled hypertension were cured or improved postoperatively. Among patients with IN, postoperative renal function improved in 35%, remained stable in 47%, and deteriorated in 18%. These extra-anatomic techniques have become an important component of the surgical armamentarium for ARAS.

In another study, we analyzed long-term clinical outcomes and survival after surgical revascularization for ARAS in 222

patients treated from 1974 to 1987 at the Cleveland Clinic (Steinbach et al, 1997). The indications for surgical revascularization were treatment of hypertension in 60 patients, preservation of renal function in 12 patients, and both control of hypertension and preservation of renal function in 148 patients. The mean postoperative follow-up interval was 7.4 years.

In this study, there were five operative deaths (2.2%) and postoperative thrombosis or stenosis of the repaired renal artery occurred in 16 patients (7.3%). Long-term improvement or stabilization of renal function was achieved in 71.3% of patients. Actuarial 5- and 10-year survivals for the entire series from the time of revascularization were 81% and 53%, respectively. The expected 5- and 10-year survivals for a comparable healthy population are 89% and 77%, respectively. Using a multivariate analysis, factors correlating with diminished long-term survival were age older than 60 years ($P = .002$), coronary artery disease ($P = .031$), and previous vascular operations ($P = .001$). These data support the long-term therapeutic efficacy of surgical revascularization in patients with ARAS. The merits of newer forms of therapy, such as PTA and endovascular stenting, must ultimately be weighed against these results.

Cherr and colleagues (2002) reported on the results of surgical revascularization in 500 patients with atherosclerotic renal artery disease from 1987 to 1999. Unilateral surgery was performed in 40%, bilateral in 60%, and combined aortic and renal surgery in 41%. Mortality rate was 4.6% overall. Hypertension was cured, improved, and unchanged in 12%, 73%, and 15%, respectively. Renal function was improved in 43%, unchanged in 47%, and deteriorated in 10%.

The results of renal autotransplantation for RAS caused by various pathologies (fibromuscular dysplasia [FMD], ASO, and Takayasu's arteritis) were reported by Chiche and coauthors (2003). Results of surgery were better in the FMD patients, with early or delayed nephrectomy performed in five of eight patients with ASO. Hypertension was cured or improved in 96% of patients with FMD and 89% of patients with Takayasu's disease.

Secondary Renal Revascularization

Relatively few reports have addressed the management of patients with recurrent RAS after failed surgical revascularization or PTA. For patients in the latter category, repeated PTA may be attempted; however, ultimately, many of these patients require surgical revascularization. **There has been controversy concerning whether the prior performance of PTA increases the technical difficulty or compromises the outcome of surgical renal revascularization.** A report by Dean and associates (1987) indicated that the task of arterial reconstruction may be rendered more complicated by a perivascular inflammatory response induced by PTA. Reports from McCann and colleagues (1988) and Martinez and coworkers (1990) found that surgical revascularization is not more technically difficult after PTA than when done primarily and that the same satisfactory results can be achieved. The latter study comprised 53 patients treated surgically after failed PTA for RAS. Three patients underwent nephrectomy because of the finding of a nonviable kidney at operation. Successful surgical revascularization was achieved in all the remaining 50 patients. The authors noted no significant fibrosis or inflammation around the previously dilated renal artery. PTA necessitated the performance of a more complicated revascularization operation in only one patient. These data indicate that if the kidney is viable at operation, prior performance of PTA does not increase the technical difficulty of surgical renovascular reconstruction.

Recurrent renal artery stenosis after surgical revascularization is typically a late complication, occurring weeks, months, or even years postoperatively. If the involved kidney is functionally salvable, another attempt to restore normal renal arterial flow is indicated. There has been scant experience with PTA or stenting in this setting; however, this is an appropriate initial approach for focal stenotic lesions. Secondary surgical revascularization has constituted the predominant reported approach, and this may be technically complicated (Stanley et al, 1985; Erturk et al, 1989). Reoperation often entails dissection in a surgical field obliterated by fibrous scar tissue, and it is most efficacious to employ a secondary reconstructive technique that avoids the site of previous surgery. In patients with recurrent RAS after an abdominal aortorenal bypass, alternative approaches that may be used for secondary revascularization include hepatorenal bypass, splenorenal bypass, thoracic aortorenal bypass, iliorenal bypass, and renal autotransplantation.

PERCUTANEOUS TRANSLUMINAL ANGIOPLASTY

Percutaneous dilatation of arterial stenoses (angioplasty) was originally introduced by Dotter and Judkins in 1964; however, their technique of using coaxial catheters of increasing diameter was limited to the femoral and popliteal arteries and did not gain wide acceptance. It was the development of the balloon catheter by Gruntzig and colleagues in 1978 that permitted the widespread use of angioplasty for dilatation of the renal, coronary, and almost all other visceral arteries. Numerous modifications have been made to the original technique since its introduction, and there are currently several approaches to performing renal PTA.

Technique

All angioplasty techniques require a high-quality angiogram before dilatation in order to delineate the lesion accurately and allow assessment of proper equipment needs and approach. A proper-sized balloon should be selected to correspond to the original diameter of the renal artery as measured on the angiogram. Because there is 15% to 20% magnification on the angiogram, the result is the intentional overdilatation of the renal artery by 1 mm. Progress of angioplasty is monitored as the balloon inflates, and a postdilatation angiogram is obtained to assess the results and diagnose complications. PTA should be performed only when a skilled vascular surgeon is immediately available in case inadvertent occlusion or disruption of the renal artery creates a surgical emergency.

The original Gruntzig coaxial technique utilizes a No. 8 or 9 Fr renal guiding catheter through which a No. 4.3 or 4.5 Fr balloon catheter is passed over a guide wire traversing the stenotic segment through a femoral arterial puncture. In

selected circumstances, an axillary approach may be used. Modification of the original technique and balloon catheters have allowed the use of a No. 5 Fr femoral artery puncture through which a No. 5 Fr diagnostic catheter is passed to the renal artery using the Seldinger technique. After the lesion is negotiated with an appropriate guide wire, the diagnostic catheter is exchanged with a No. 5 Fr balloon catheter and the angioplasty is performed (Tegtmeyer et al, 1980).

Mechanism

The principal mechanism through which the increase in arterial diameter after PTA occurs in cases of ASO is fracture of the atherosclerotic plaque. Stretching of the arterial wall with tearing of the media and adventitia also occurs but contributes to a smaller degree in cases of ASO than in FD. This stretching effect probably occurs after the atherosclerotic plaque is fractured and becomes more pronounced with increasing plaque circumference and a decrease in the uninvolved area of the vessel wall.

Complications

Renal angioplasty is a complex and technically demanding procedure that should be performed only by skilled interventional radiologists to prevent the occurrence of potentially serious complications. The complications of PTA include those of standard angiography (complications related to arterial puncture and to the use of iodinated contrast material) as well as specific complications related to manipulation of the renal arteries. **Transient deterioration of renal function is the most frequently occurring complication and is related to the contrast load delivered during the procedure.** Adequate hydration, minimizing the volume of contrast material, separating the diagnostic procedure from the PTA (by several days), and possibly the use of carbon dioxide or nonnephrotoxic contrast agents may decrease the incidence of this complication.

Technical mishaps during PTA may lead to an intimal dissection or even thrombosis of the renal artery. A small intimal flap is usually inconsequential, healing without sequelae. A larger flap compromising blood flow is usually managed by placing an arterial stent across the dissection. Thrombosis of the renal artery can be managed by injecting a thrombolytic agent through the renal artery or by emergency surgery. Rupture of the renal artery, a rare complication, is also managed by emergency surgery after reinflation of the balloon catheter to control retroperitoneal hemorrhage. Overall, the complication rate can be expected to be 5% to 10%.

Fibrous Dysplasia

Several studies have reported the results of PTA for blood pressure in cases of FD. Cure of hypertension is usually defined as a diastolic blood pressure of 90 mm Hg or less with no antihypertensive medication. Improvement of hypertension is usually defined as either a decrease in diastolic pressure of 15 mm Hg or a diastolic pressure of 90 mm Hg or less with a decrease in the antihypertensive medication needed to maintain normal blood pressure. Standardization of the results of these studies is difficult for several reasons. Several definitions are not uniform, including *significant stenosis* (varying from >50% to >80% of the original lumen) and technical success (defined as no stenosis or insignificant residual stenosis). Measures of success are also variable, with most studies relying on clinical parameters (blood pressure response) as the measure of success. Follow-up angiographic studies are rarely available. In addition, most studies combine ASO and FD patients, and sometimes results or complication rates are not referred specifically to one of the disease groups. Further complicating the interpretation of results is the reporting of results per patient in some studies and per lesion in others. The results of these studies are summarized in Table 36–7. Data per patient are used and represent primary procedures only.

Overall, PTA is usually performed in cases of FD without stent placement and has become the primary modality of treatment for these lesions. With the use of modern equipment and increasing experience with the technique, technical success has been more than 90% in most modern studies. A beneficial blood pressure response, that is, cure of hypertension or improvement in blood pressure control, can be expected in more than 80% and up to 100% of cases (Fig. 36–13). The incidence of major complications (when reported for FD patients alone) was 6% or less. At short to moderate follow-up intervals, restenosis of the treated artery was reported in up to one third of cases; however, most of these

cases have been successfully redilated. Rare reports describe the use of renal artery stents for resistant fibrous lesions (Joffre et al, 1992; Imamura et al, 1998); however, these are usually not needed for this form of RAS.

Atherosclerotic Renal Artery Stenosis

The pattern of arterial disease in cases of ASO is different from that in FD. **Renal artery stenosis in cases of ASO is usually bilateral and ostial or very proximal in the main renal artery. In most ostial cases, this represents encroachment of the atherosclerotic plaque in the abdominal aorta on the origin of the renal artery rather than primary renal artery disease.** The patients affected by atherosclerotic RAS are also different from patients with FD of the renal arteries. Patients with ASO are generally older and have a number of comorbid medical conditions as well as generalized ASO affecting the coronary or carotid arteries or the peripheral vascular tree. Associated essential hypertension and nephrosclerosis are usually present. All the previously mentioned factors, as well as the propensity for atheroembolism in patients with generalized ASO, make PTA for ASO-RAS less successful and associated with higher morbidity (and some mortality) than in cases of FD. The presence of renal insufficiency or borderline renal function in a significant percentage of patients leads to an increased incidence of contrast nephrotoxicity as well.

The results of PTA for blood pressure in cases of RVH secondary to ASO are summarized in Table 36–8. Because of the previous factors, **the cure rate is lower than that for FD, commonly around 15%, and less in cases with bilateral PTA.** Failure to improve the blood pressure occurs in 15% to 85% in the reported series. Technical success at the time of angioplasty varies from 57% to 92% (Fig. 36–14) and is lower in cases in which separate results for ostial stenosis are reported (62% to 72%). Restenosis rates of 8% to 22%, and as high as 68% in some earlier series, are reported. Restenosis of ostial lesions is higher, reaching 35%, although more recent studies of ostial angioplasty show improved results (Eldrup-Jorgensen et al, 1995; Hoffman et al, 1998). Major complications requiring surgical intervention are reported in 5% to 24% of cases, and a mortality rate of 1% to 2% is also generally reported. More recent reports tend to show higher rates of technical success and lower complication rates (Martin et al, 1986), reflecting improved equipment and increasing expertise (Table 36–9); however, major complications and mortality rates reflect the fact that PTA is a serious procedure with significant attendant risks in this population of patients. Renal artery stents are an adjunct to renal PTA that has been developed to improve the results obtained in ASO patients (see later).

With the advent of newer, more potent antihypertensive medication as well as the increasing awareness of IN as a cause of renal failure, renal revascularization in patients with ASO is increasingly being performed with the intent of preserving or improving renal function rather than the intent of curing RVH. **Several studies have reported the results of PTA for renal function in patients with ASO-RAS** (Table 36–10). Clinical benefit is defined as an improvement in renal

function or a stabilization of renal function, in view of the steadily progressive decline in renal function associated with IN. With technically successful angioplasty, improvement can be expected in 15% to 43% of cases and stabilization of renal function in 26% to 50% of cases. The remaining cases continue to suffer a decline in renal function. Although a mean follow-up of more than 100 months was achieved in one of these studies (Paulsen et al, 1999), follow-up for the rest of the studies is generally short to intermediate, ranging from 1 to 3 years. Percutaneous revascularization has also been reported to be successful in improving blood pressure control and renal function in a diabetic subset of ASO patients (Zuccala et al, 1998).

Inflammatory Renal Artery Stenosis

Takayasu's arteritis is one of the causes of RAS in children and accounts for a majority of cases of RAS in South and East Asian countries. In the absence of active disease or inflammation, angioplasty has been performed to relieve RVH as well as to prevent renal loss. In a series of 24 patients aged 5 to 16 years, all with inactive disease, technically successful dilatation was achieved in 92%, with a restenosis rate of 20% after a mean of 33 months of follow-up, and these were successfully redilated. Half the children in this study were cured of hypertension, and the other half were improved. No complications were specifically reported in this study (Sharma et al, 1996). In a slightly larger group of 31 children (age range 5 to 14 years) in which less importance was given to the presence of active disease, technical success was possible in 87% of cases, with a restenosis rate of 26% at a mean follow-up of 23 months. Thirty-one percent of the patients were cured, 61% improved, and 8% failed clinically. One acute occlusion of the renal artery was reported; it was successfully redilated (Tyagi et al, 1997).

These excellent results were not duplicated in a smaller Canadian study of six patients in which only one patient obtained clinical benefit and the remaining five patients proceeded to surgical autotransplantation (D'Souza et al, 1998). All these studies were in agreement that long stenoses starting at the ostium of the renal artery were much less likely to have a successful result with PTA.

Management of RAS secondary to Takayasu's disease in adults with PTA has also been successful (Dong et al, 1987; Deyu et al, 1998; Sharma et al, 1998). Technical success was obtained in more than 80% of patients in these studies, with overall clinical benefit in the range of 85%.

Children

RAS in children is caused by a variety of arterial diseases, including FD, middle aortic syndrome, and neurofibromatosis. In Asian countries, a significant proportion of RAS in children is also caused by aortoarteritis (Takayasu's disease). The main limitation to performing PTA in children was the lack of suitably small-sized equipment. With modern angiographic techniques and digital imaging, PTA has been reported in several studies and is becoming a primary mode of management for children with RVH. The largest series reporting on PTA for treatment of FD in children comprises 16 children, 12 of whom were diagnosed with FD. Three patients required a secondary PTA. Overall, nine patients were cured and two were improved; in five patients, the treatment failed, and four of these were treated surgically. The PTA failed in all three patients with multiple stenoses in this study (none had FD). There were no reports of complications in this study (Courtel et al, 1998).

Reports of smaller studies of PTA in children with FD also demonstrate the technical success and beneficial blood pressure response obtained with this treatment modality (Lund et al, 1984; Millan et al, 1985; Chevalier et al, 1987; Simunic et al, 1990). Angioplasty has been successfully used in very young children, with reports of 18-, 15-, and even 9-month-old children being treated using small coronary angioplasty equipment (Hofbeck et al, 1998; Lee et al, 1999; Liang et al, 1999).

ENDOVASCULAR STENTING

With increasing experience with PTA, limitations of the technique, especially in regard to atherosclerotic lesions, have become well recognized. These limitations involve mainly ostial lesions that represent engulfment of the renal ostium in aortic plaque. These cases represent a significant percentage of ASO-RAS cases, and elastic recoil of the plaque leads to poor initial results and frequent restenosis. **Renal artery stents are an adjunct to PTA that was introduced in an effort to oppose this recoil force and provide better results for angioplasty, especially in ostial lesions. Almost all renal artery stents in the literature have been placed to treat ASO of the renal arteries** (estimated at 97%), with many fewer stents placed in cases of FD, transplant renal arteries, and other miscellaneous renal arterial abnormalities (Rees, 1999).

Arterial stents are radiopaque, expandable metallic wire mesh tubes that have been widely used in the peripheral vascular system. Experience in other parts of the vascular as well as the biliary tree has led to the use of stents in the renal artery, although none are specifically approved by the U.S. Food and Drug Administration for use in the renal artery. Different stents are currently available and include the Palmaz, Strecker, Wallstent, and Nitinol stents. Stent expansion either is spontaneous on extrusion from a delivery catheter (self-expandable) or occurs on inflation of a balloon on which the stent is preloaded (balloon expandable).

Technique

Several techniques for stent placement in the renal artery have been developed. It is essential in all cases to obtain a high-quality angiographic study (immediately before stent placement at the same sitting or separately) in order to delineate the lesion precisely and assess balloon and stent length and diameter. The stent used should be long enough to traverse the entire lesion, taking into consideration shortening of the stent with expansion. Excessive length beyond the lesion is undesirable because the presence of the stent may excite an intimal hyperplastic reaction, placing healthy segments of the vessel at risk. This might also obstruct a site suitable for later bypass surgery. In cases of ostial lesions, the stent should be placed to protrude 1 to 2 mm into the aortic lumen to prevent restenosis caused by recoil of the aortic plaque.

Indications

Current indications for stent placement are poor immediate results during PTA as well as restenosis after PTA. Stents are also used to treat angioplasty complications (artery dissection and intimal flaps) and have markedly reduced the incidence of emergency surgery for these complications. **"Primary" stent placement is becoming increasingly popular in cases of RAS in which PTA alone is unlikely to be successful (ostial lesions).**

Results

The results of several studies reporting on endovascular stent placement in the renal arteries are summarized in Tables 36–11 and 36–12. Most of the published experience in the renal arteries has been described using the Palmaz stent. With the exception of two of the earliest studies using Strecker stents and Wallstents, **the reported technical success for stent placement has consistently been above 95%** and in most studies has been 99% or 100% (Fig. 36–15). With short to moderate follow-up intervals, restenosis of the renal artery after stent placement has ranged from 6% to 38%. A single early study (Wilms et al, 1991) reported a 71% restenosis rate; however, most larger contemporary series average a restenosis rate of 15% to 20%. Restenosis commonly occurs within the stent owing to a hyperplastic intimal reaction. In other cases, an intimal lining about 1 mm thick covers the luminal surface of the stent. Renal arteries that are dilated and stented to a luminal diameter of less than 6 mm are more likely to develop restenosis.

The blood pressure response to renal revascularization by PTA and stenting is shown in Table 36–11. The low cure rates (31% at most) reflect the pathophysiologic nature of atherosclerotic renal artery disease in which anatomic stenosis is frequently associated with concomitant essential hypertension and renal parenchymal damage, precluding a simple pathologic explanation for hypertension. Revascularization for preservation of renal function has become the focus of intervention in cases of ASO-RAS. The result of renal artery stent placement (for renal function preservation or improvement) in various studies is shown in Table 36–12. Because of the progressive nature of renal dysfunction related to ASO, a clinical benefit is defined as improvement or stabilization (halt of decline) of renal function after revascularization. Improvement in renal function was achieved in 13% to 60% of cases, and stabilization was achieved in 24% to 75% of cases, with the remaining cases continuing to have progressive dysfunction.

Perhaps the clearest situation of IN is RAS to a solitary kidney, and it is in these patients that the effect of revascularization on renal function can be most clearly identified. In a study of 21 such patients, an improvement in the serum creatinine level was obtained after stent placement in 42% of cases and stabilization in 29% of cases. Within the group of improved patients were four who were relieved of dialysis dependence. These results were associated with a major complication rate of 19% including a single early (and another late) procedure-related mortality (Shannon et al, 1998).

In the only prospective study comparing PTA alone versus PTA with stenting in ostial ASO, a total of 85 patients were randomly assigned to either treatment group. Technical success was higher in the stented group (88% versus 57%), and

patency at 6 months was 75% for patients in the stent group versus 29% for PTA alone. In patients with successful primary procedures, restenosis occurred in 14% of the patients with stents and in 48% of patients with PTA alone. Stenting for immediate or late failure of PTA was required in 12 (of 42) patients in the PTA group. **This study reflects the overall higher success of PTA with stenting in treating ostial ASO when compared with PTA alone and probably also justifies the increasing trend to perform primary stenting in these cases to avoid exposing patients to a secondary procedure** (Van de Ven et al, 1999).

Several studies addressed the factors affecting outcome after stenting and recommended selecting patients for interventional treatment on the basis of their findings: Kennedy (2003) and Zeller (2003) and their colleagues reported that baseline renal insufficiency correlates with decreased survival and increased adverse events after renal artery stenting. In Zeller's study, the 5-year survival rate was 30% for patients with creatinine more than 2.5 mg/dL versus 95% for patients with creatinine less than 1.2 mg/dL. Major causes of death were cardiac events, cerebral events, and malignancy.

Perkovic and associates (2002) studied several parameters for patients undergoing renal artery stenting and reported baseline renal impairment, older age (>70), and diabetes as predictors of a poor outcome. ACE inhibitor therapy after stenting appeared to improve outcome in this series.

Complications

Complications of renal artery stent placement are similar to those of renal PTA, with the added complications of stent delivery. The incidence of access site complications is higher because of the larger arterial puncture needed. The incidence of intimal injury and dissection is lower than that of PTA because stent placement in itself is a treatment for these complications. A higher incidence of contrast nephrotoxicity owing to a larger contrast load is noted, but the increasing use of carbon dioxide as a contrast agent may decrease the incidence of this complication. The literature has rare reports of endovascular infection from renal artery stents, resolving after conservative therapy with IV antibiotics (Gordon et al, 1996) or progressing to form mycotic aneurysms of the aorta and renal artery necessitating major excision and vascular reconstructive surgery (Deitch et al, 1998).

Major complications (including death) are reported in 0% to 20% of cases (Table 36–13). Minor complications are reported in 0% to 40% of cases. Mortality directly related to

†Procedure-related mortality only.

the procedure is reported in almost all large series, in the range of 3%. This attests to the fact that PTA with stent placement is not a benign procedure and is associated with definite risk. In a review of complications of stent placement in 50 patients, a complication rate of 20% was noted, 10% of patients suffered major complications, and a 10% rate of cholesterol embolism was reported (Beek et al, 1997).

Proper selection of patients for endovascular intervention in cases of ASO-RAS should be a careful process that takes into account the patient's chances of a successful outcome. This process should be as rigorous as selection of patients for open surgery in order to minimize morbidity and poor outcomes from endovascular intervention.

Complications of PTA with stenting were not found to be significantly different from those of PTA alone in a prospective study comparing both procedures. Specifically, bleeding-related complications were 19% in both groups, cholesterol embolism was 10% in both groups, and access site pseudoaneurysm and renal artery injury were slightly higher with stent placement (7% versus 5%). Transient deterioration of renal function from contrast nephrotoxicity was noted in 24% of patients undergoing PTA and 21% of patients undergoing PTA with stent placement (Van de Ven et al, 1999).

OTHER RENAL ARTERY DISEASES

Renal Arterial Aneurysms

A renal arterial aneurysm is a localized dilatation of the main renal artery or its branches or both caused by weakening of the elastic tissue and media of the arterial wall. The estimated incidence of such lesions in the general population ranges from 0.09% to 0.3%. Renal arterial aneurysms may be clinically significant because of a causative relation to hypertension, associated local symptoms, or the risk of catastrophic rupture in certain situations (Novick, 1982). According to the classification of Poutasse (1975), there are four basic types of renal artery aneurysms: saccular, fusiform, dissecting, and intrarenal (Fig. 36–16).

Saccular aneurysms are the most common type and constitute about 75% of renal artery aneurysms. They generally occur at the bifurcation of the renal artery, perhaps owing to an inherent weakness in the wall of the artery at this point. Because of this location, branch arterial involvement is common. The incidence of bilateral or multiple aneurysms or both is approximately 25%. These aneurysms may become involved with secondary atherosclerotic degeneration or intramural calcification or both. Incompletely calcified aneurysms may become soft, thin, and ulcerated between zones of calcification, predisposing to rupture. In addition to rupturing spontaneously, saccular aneurysms may erode into the renal vein or into the renal pelvis. Mural thrombus formation may also occur within saccular aneurysms, occasionally leading to peripheral renal embolization.

Fusiform aneurysms occur as a uniform dilatation of an entire segment of the renal artery to as much as three to four times its normal diameter. These aneurysms range in length from 1 to 3 cm and are generally not calcified. They are typically found in young hypertensive patients with stenosing fibrous renal arterial disease. The fusiform aneurysm is actually a poststenotic dilatation and can involve either the main renal artery or its branches. The major complication of this lesion is thrombosis of the involved arterial segment from progressive proximal stenosing vascular disease.

A dissecting aneurysm results from a tear in the internal elastic membrane of the renal artery, and as blood flows through the opening, the intima is separated from the remainder of the arterial wall. In some patients, the dissection may reenter the lumen distally to preserve renal function. In other cases, arterial thrombosis with renal infarction or rupture with hemorrhage may occur. Dissecting aneurysms are most often complications of renal arterial involvement with ASO, intimal fibroplasia, or perimedial fibroplasia. Less commonly, such an aneurysm may occur as an extension of a dissecting aortic aneurysm.

Intrarenal arterial aneurysms are of mixed origin and may be congenital, post-traumatic, iatrogenic, neoplastic, or associated with polyarteritis nodosa. They are usually saccular or fusiform and may or may not be calcified. Intrarenal aneurysms constitute approximately 17% of all renal arterial aneurysms, and they do have a propensity for rupture. Intrarenal aneurysms that occur after blunt trauma or closed renal biopsy occasionally resolve spontaneously with expectant management.

In general, the diagnosis of renal arterial aneurysm should be considered when ringlike calcification in or near the renal hilum is found on a plain abdominal radiograph. These calcifications occur in about 50% of cases. **The majority of renal arterial aneurysms are small and asymptomatic.** The most common clinical manifestations are hypertension, subcostal or flank pain, hematuria, an abdominal bruit, and, rarely, a palpable pulsating mass. RVH is reported to occur in 15% to 75% of patients and may be due to turbulent flow within an aneurysm, associated arterial stenosis, dissection, arteriovenous fistula formation, thromboembolism, or compression of adjacent arterial branches by a large aneurysm. Complications of renal arterial aneurysms include peripheral dissection, arterial thrombosis with renal infarction, emboli arising from mural thrombus within an aneurysm, obstructive uropathy, erosion into a vein with formation of an arteriovenous fistula, and spontaneous rupture with hemorrhage. Factors that appear to predispose to aneurysmal rupture include absent or incomplete calcification, aneurysmal size greater than 2 cm in diameter, coexisting hypertension, and pregnancy.

A small (2-cm) well-calcified renal arterial aneurysm in an asymptomatic normotensive patient does not require operative intervention. These aneurysms can be followed with serial plain abdominal radiographs to detect any change in size. Surgical removal is indicated for renal arterial aneurysms, regardless of size, in (1) aneurysm causing renal ischemia and hypertension, (2) dissecting aneurysm, (3) aneurysm associated with local symptoms such as flank pain or hematuria, (4) aneurysm occurring in a woman of childbearing age who is likely to conceive, (5) aneurysm occurring with functionally significant renal arterial stenosis, (6) aneurysm with radiographic evidence of expansion on serial radiographs, or (7) aneurysm containing a thrombus detectable on angiography with evidence of distal embolization.

When none of these criteria are present, small (2-cm) asymptomatic noncalcified or incompletely calcified aneurysms can be managed nonoperatively. Such patients should be observed periodically with serial CT or magnetic

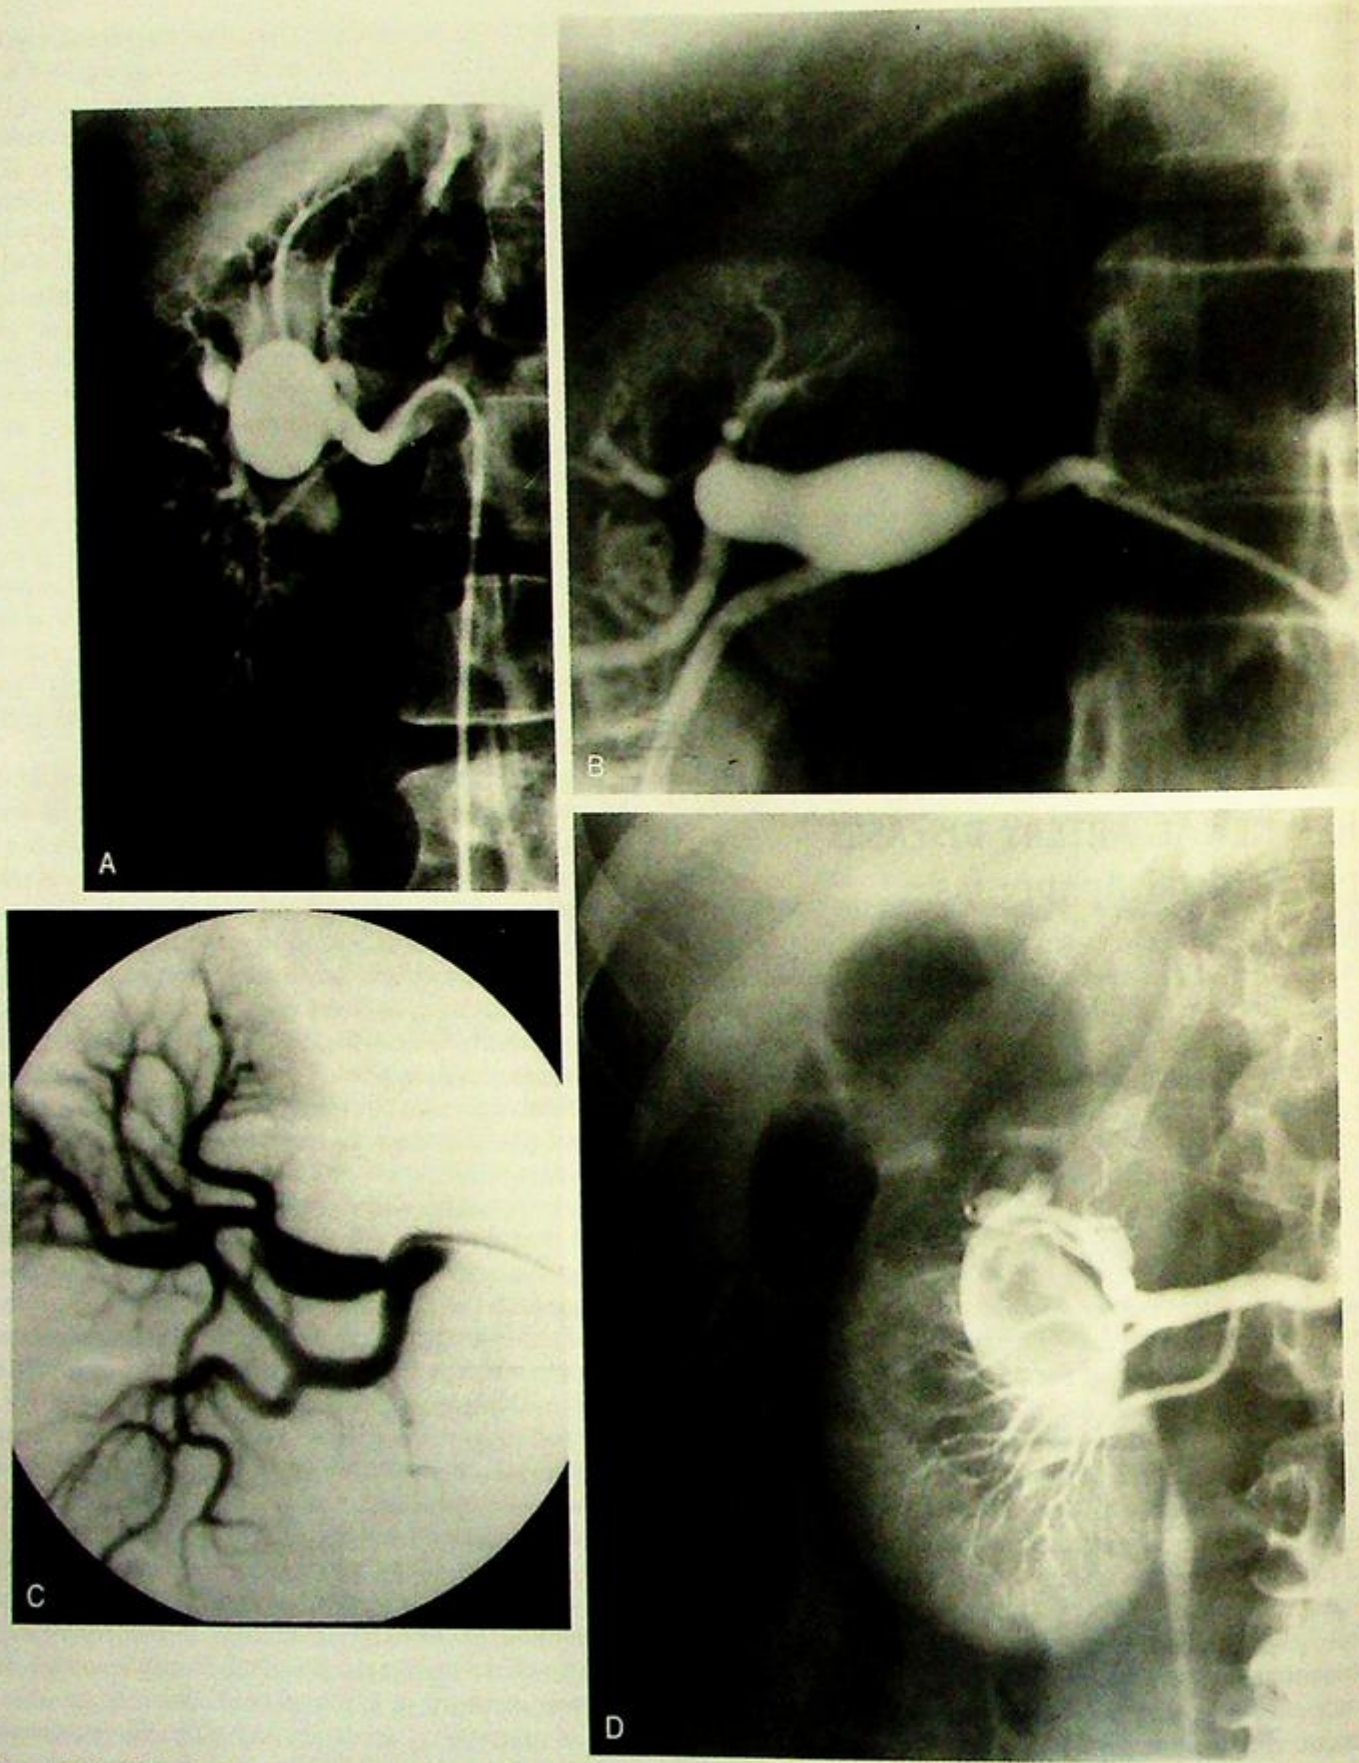

Figure 36–16. Selective renal arteriograms demonstrate the four types of renal artery aneurysms. **A**, Saccular aneurysm located at the bifurcation of the main renal artery. **B**, Fusiform aneurysm distal to a stenotic lesion of the main renal artery. **C**, Dissecting aneurysm involving a renal artery branch. **D**, Intrarenal aneurysm.

resonance imaging (MRI) studies to document the size of the aneurysm. It is not possible to define rigidly indications for operative intervention in asymptomatic patients with aneurysms greater than 2 cm in diameter and with none of the previous criteria. The available data would seem to support surgical excision if these aneurysms are not calcified throughout or are intrarenal because of the increased tendency to rupture in these settings.

In the largest series of renal artery surgery reported in the recent literature (Henke et al, 2001), a total of 121 patients underwent surgical repair. Eight unplanned nephrectomies were necessary resulting in the need for permanent dialysis in one patient, no perioperative mortality was encountered, and all but two reconstructions remained patent at follow-up.

In a retrospective review of surgical repair of renal artery aneurysms in 94 patients, Pfeiffer and colleagues (2003) encountered one postoperative mortality (in an emergency repair secondary to aneurysm rupture), an overall morbidity of 17%, and a primary success rate of 97%.

English and colleagues (2004) reported their results of surgical repair of 72 renal artery aneurysms of varying etiology over a 16-year period. One aneurysm only was deemed not reconstructable, and nephrectomy was performed. One operative mortality was encountered, and 12% of patients had significant perioperative morbidity, with 96% of repairs maintaining patency at 48 months.

A significant body of literature (almost all case reports) has accumulated over the last few years reporting successful endovascular management of renal artery aneurysms as well as dissection of the renal artery. In the case of renal artery aneurysms, two methods of endovascular treatment are reported. The first involves embolization of the aneurysm (usually with coils) to occlude it without disrupting the renal blood flow (Halloul et al, 2000; Karkos et al, 2000; Mounayer et al, 2000; Tshomba et al, 2002; Lupattelli et al, 2003). The second method involves placing an arterial stent in the renal artery or the branch where the aneurysm originates, thereby maintaining flow through the stent and effectively excluding the aneurysm (Tan et al, 2001; Bruce and Kuan, 2002; Pershad and Heuser, 2004). Stenting the renal artery across an aneurysm has also been described as a successful and rapid method of dealing with ruptured renal artery aneurysm (Schneidereit et al, 2003). Dissection of the renal artery can be managed endovascularly as well by placing a renal artery stent through the area of dissection to keep the lumen patent and keep the dissected intima immobilized against the outer layers of the artery (Bilge et al, 2003).

Renal Arteriovenous Fistula

Renal arteriovenous fistulas are relatively uncommon lesions that are generally discovered during the course of angiographic evaluation for suspected renal or renovascular disease. There are three categories of renal arteriovenous fistulas: congenital, idiopathic, and acquired (Tynes et al, 1970; Novick, 1982).

Congenital fistulas have a cirsoid or angiomatous configuration with multiple communications between arteries and veins. They are usually supplied by a renal arterial branch of normal caliber. The angiographic appearance is one of multiple, small interconnecting arterial and venous channels with impaired distal renal parenchymal vascularity and early filling of the renal vein. They constitute 22% to 25% of all renal arteriovenous fistulas, occur equally in both sexes, and generally do not become manifest until adult life.

Idiopathic fistulas are single, are not cirsoid, and have no apparent cause. They constitute only 3% to 5% of all renal arteriovenous fistulas. These lesions are called *idiopathic* because their angiographic appearance is similar to that of acquired arteriovenous fistulas, but their origin is unclear.

Acquired fistulas are the most common type, accounting for 70% to 75% of all renal arteriovenous fistulas. On angiography they appear as solitary communications between an artery and a vein. By far the most common cause is iatrogenic trauma resulting from needle biopsy of the kidney (Fig. 36–17). Other causes include renal carcinoma, blunt or penetrating renal trauma, inflammation, and renal surgery such as nephrectomy, partial nephrectomy, or nephrolithotomy.

The clinical manifestations of a renal arteriovenous fistula depend on the size of the fistula. **Approximately 75% of patients have an abdominal bruit,** which is usually loud, high pitched, and continuous with systolic accentuation. Congestive heart failure, cardiomegaly, and diastolic hypertension are observed in 50% of patients. Hematuria is present in about one third of cases, tachycardia is occasionally found, and a palpable flank mass from spontaneous rupture is rarely encountered.

The management of a patient with a renal arteriovenous fistula depends on the cause of the fistula and the associated clinical manifestations. For patients with renal carcinoma, immediate nephrectomy is obviously indicated. **Approximately 70% of fistulas occurring after needle biopsy of the**

Figure 36–17. Left renal arteriogram shows renal arteriovenous fistula with early filling of the renal vein. This patient had previously undergone needle biopsy of the left kidney.

kidney close spontaneously within 18 months. A smaller number of fistulas diagnosed immediately after renal trauma have also resolved spontaneously. Therefore, in the absence of significant related symptoms, expectant management is appropriate initially in these cases.

Treatment of renal arteriovenous fistulas is indicated for patients who have hypertension, heart failure, severe hematuria, serial angiographic evidence of an expanding lesion, rupture, or progressive renal failure. When specific therapy of these lesions is indicated, renal-sparing procedures should be employed whenever possible.

Transcatheter angiographic occlusion is a nonsurgical therapeutic alternative that has been employed primarily in treating patients with postbiopsy fistulas, in which the arteriovenous connecting vessels are usually small. More recently, transcatheter occlusion of congenital or idiopathic fistulas with a stainless steel coil has also been performed.

Various operations have been employed in the surgical treatment of renal arteriovenous fistulas. **Most congenital or cirsoid fistulas have been managed with total or partial nephrectomy** because of the difficulty of completely excising the many small communicating vessels. In patients with idiopathic or acquired fistulas, a single communication between the artery and the vein is characteristically present, and surgical obliteration of the fistula with preservation of the involved kidney is more often possible.

Renal Artery Thrombosis or Embolism

Thromboembolic disorders of the renal artery can arise as fulminant clinical syndromes that threaten life or may be entirely asymptomatic and detected only at postmortem examination (Hoxie and Coggins, 1940; Schoenbaum et al, 1971). The various causes of acute renal artery thrombosis or embolism are listed in Table 36–14. The term *paradoxical embolism* refers to a clot originating in the venous circulation that gains entrance to the systemic arterial circulation through an intracardiac septal defect.

Table 36–14. Causes of Renal Arterial Thrombosis and Embolism

Saccular renal artery aneurysm
Cardiac tumor
Acute myocardial infarction
Ventricular aneurysm
"Paradoxical" embolism

Renal arterial thrombosis commonly involves the proximal or middle third of the main renal artery, whereas renal arterial embolization generally involves peripheral arterial branches. Acute arterial occlusion is more common on the left side because of the more acute angle between the left renal artery and the aorta. Post-traumatic renal arterial occlusion is also more common on the left side, presumably because of the acute angulation of the shorter left renal artery at its aortic junction, which predisposes to intimal disruption with deceleration of the mobile kidney.

The clinical symptomatology in these disorders is extremely varied. Bilateral acute renal arterial occlusion arises with rapidly progressing oliguric renal failure, whereas chronic occlusion of a single renal artery may be unnoticed because of the development of collateral circulation. The most common symptoms, when present, are dull aching abdominal or flank pain often associated with nausea, vomiting, and fever. Other findings include hypertension, albuminuria, microscopic hematuria, leukocytosis, and elevation of serum lactate dehydrogenase levels.

Patients with unilateral renal arterial embolic occlusion generally have serious underlying extrarenal disease and are best managed nonoperatively with systemic anticoagulation or by percutaneous transcatheter thromboembolectomy (Millan et al, 1978; Hamilton, 1996). Patients with unilateral traumatic renal arterial thrombosis also often have severe associated injuries, and the results of vascular reconstruction are generally unsatisfactory unless this is undertaken within several hours of the time of injury. Surgical treatment in these cases is generally ill advised when a normal contralateral kidney is present. Percutaneous intra-arterial infusion of a fibrinolytic agent such as streptokinase now offers a nonoperative approach to the management of acute renal arterial thrombosis (Hamilton, 1996).

Renovascular reconstruction is generally indicated when renal artery thrombosis or embolism occurs bilaterally or in a solitary kidney. Alternatively, if angiographic and isotopic studies in such cases demonstrate an extensive collateral vascular supply maintaining renal viability, an initial therapeutic trial with one of the previously mentioned nonoperative approaches may be worthwhile.

Neurofibromatosis

Neurofibromatosis affecting the renal arteries is a congenital hereditary disorder characterized by café-au-lait cutaneous pigmentation, cutaneous neurofibromas, tumors of the CNS, skeletal disorders, and occasional gigantism (Grad and Rance, 1972; Tilford and Kelsch, 1973). Hypertension in patients with neurofibromatosis is most often due to RAS; less commonly, this may be the result of an associated pheochromocytoma or aortic coarctation. Vascular abnormality occurs in the kidneys, heart, and gastrointestinal tract and consists of fibrosis and thickening of the intima, proliferation of neural tissue within the arterial wall, perivascular nodular proliferations, and occasional aneurysmal dilatation. In the kidney, arterial stenosis usually occurs at the origin or in the proximal third of the main renal artery, and the angiographic appearance may be indistinguishable from that of intimal

fibroplasia. Considering the young age of these patients, renal revascularization is generally the treatment of choice for associated RVH.

Middle Aortic Syndrome

The middle aortic syndrome is a rare disorder, occurring in children or young adults, characterized by nonspecific stenosing arteritis affecting the aorta and its major branches including the renal arteries (Fig. 36–18). This is thought to be a form of Takayasu's disease, and an autoimmune pathogenesis is suspected (Kaufman, 1973). This disease can extensively involve the subdiaphragmatic aorta or, in some cases, may spare the aorta and involve primarily the renal or splanchnic vessels. The natural history is not well understood because most cases are diagnosed when the disease has already resulted in significant renal arterial stenosis in young good-risk patients, necessitating early revascularization. Because the inflammatory process generally does not extend to involve the iliac arteries, renal autotransplantation is the surgical treatment of choice.

Extrinsic Obstruction

Extrinsic obstruction of the renal artery has been observed but is extremely rare (Silver and Clements, 1976). Neural tissue, musculocutaneous fibers, and diaphragmatic crura have been suggested as etiologic factors contributing to this process. Other possible causes of extrinsic perivascular fibrosis include inflammation, trauma, tumor, and prior radiation.

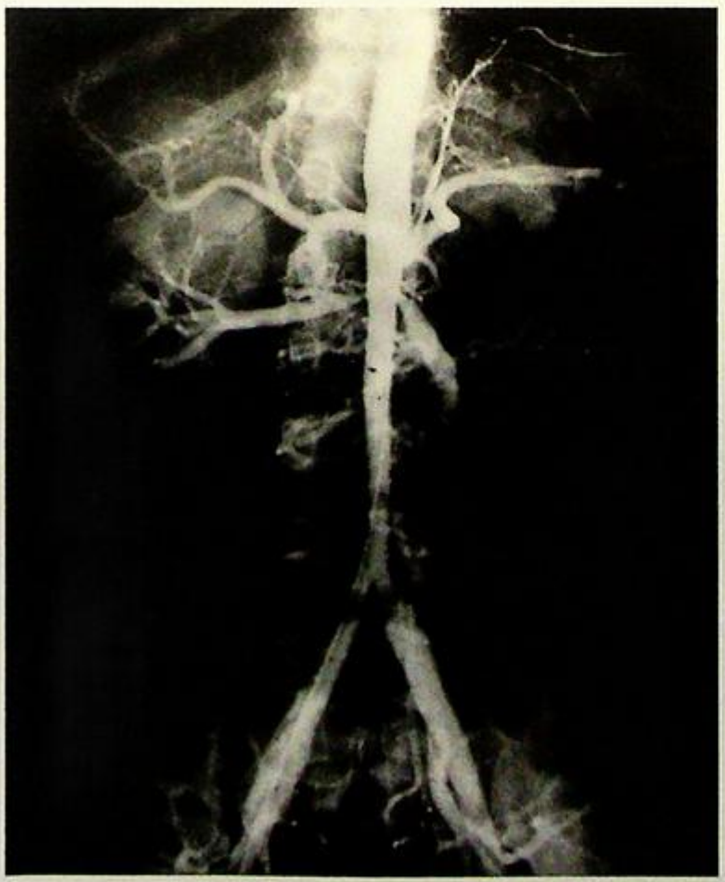

Figure 36–18. Aortography in a child with the middle aortic syndrome shows hypoplasia of the abdominal aorta and right renal artery stenosis.

Page's Kidney

In 1934, Page (1939) produced a renin-dependent model of hypertension by wrapping a dog kidney in cellophane. Hypertension could be reversed by removing the cellophane wrap or the kidney. **The clinical equivalent of this hypertensive model is the kidney compressed by a subcapsular or perirenal process causing renal ischemia, inducing unilateral hypersecretion of renin and contralateral suppression.** Causes of the perinephric process include blunt trauma, closed renal biopsy, anticoagulation, and hemorrhage from a tumor.

The diagnosis of Page's kidney depends on the presence of either a surrounding hematoma or an encasing fibrous pseudocapsule. Imaging with ultrasonography, CT, or MRI localizes the hematoma or fibrous capsule.

The treatment of Page's kidney aims to preserve renal function and cure hypertension. Medical antihypertensive therapy and observation, percutaneous evacuation of the perirenal hematoma, open drainage of the hematoma, and nephrectomy have all been used (Suffrin, 1975).

Some cases of acute Page's kidney with new-onset hypertension have resolved spontaneously. A hematoma may reabsorb, relieving the parenchymal compression without forming an adhesive fibrotic pseudocapsule. Treatment with medical antihypertensive therapy can control the blood pressure until the hematoma resolves. If the hematoma does not resolve, it may be drained percutaneously or surgically.

Renal Parenchymal Disease

Renin-mediated hypertension may be secondary to a variety of renal parenchymal diseases. The incidence of hypertension in patients with chronic pyelonephritis is approximately 5% to 10%. The mechanism of renin-mediated hypertension in such kidneys with segmental scars is ischemia of the relatively normal renal cortex in proximity to areas of interstitial fibrosis, within which are small vessels with intimal thickening. Other renal disorders that may cause hypertension include hydronephrosis, congenital hypoplasia or dysplasia, segmental hypoplasia (Ask-Upmark kidney), vesicoureteral reflux, renal cell carcinoma, benign cyst, Wilms' tumor, radiation nephritis, and juxtaglomerular cell tumor.

SECTION IX

UPPER URINARY TRACT OBSTRUCTION AND TRAUMA

37 Pathophysiology of Urinary Tract Obstruction

VERNON M. PAIS JR., MD • JACK W. STRANDHOY, PHD • DEAN G. ASSIMOS, MD

PREVALENCE OF THE PROBLEM
GLOBAL RENAL FUNCTIONAL CHANGES
PATHOLOGIC CHANGES OF OBSTRUCTION
GENERAL ISSUES IN MANAGEMENT OF PATIENTS
SELECTED EXTRINSIC CAUSES OF URETERAL OBSTRUCTION

Obstruction of the urinary tract can occur during fetal development, childhood, or adulthood. The point of obstruction can be as proximal as the calyces and as distal as the urethral meatus. The cause of obstruction may be congenital or acquired and benign or malignant. The impact of the obstruction is influenced by the extent or degree of obstruction (partial or compete, unilateral or bilateral), its chronicity (acute or chronic), the baseline condition of the kidneys, the potential for recovery, and the presence of other mitigating factors such as urinary infection. These may ultimately lead to permanent renal damage, which may result in limiting the excretion of metabolic wastes and altering water and electrolyte balance.

Certain terms utilized in this chapter as descriptors of this process need to be defined from the outset. *Hydronephrosis* is the dilation of the renal pelvis or calyces. It may be associated with obstruction but may be present in the absence of obstruction. *Obstructive uropathy* refers to the functional or anatomic obstruction of urinary flow at any level of the urinary tract. *Obstructive nephropathy* is present when the obstruction causes functional or anatomic renal damage.

PREVALENCE OF THE PROBLEM

The prevalence of urinary tract obstruction is best estimated from autopsy series. In a series of 59,064 autopsies performed on individuals ranging from neonates to geriatric subjects, hydronephrosis was reported in 3.1% (Bell,1950). There were no gender differences in this series until the age of 20 years. However, hydronephrosis was more prevalent in women in the 20- to 60-year interval. The latter was attributed to pregnancy and development of gynecologic malignancies. It was more prevalent in males after age 60 years because of prostatic diseases. Hydronephrosis has been reported to be present in 2% to 2.5% of children subjected to autopsy (Campbell, 1970; Tan et al, 1994). It is somewhat more prevalent in boys, and the majority of cases were in subjects younger than 1 year. The aforementioned prevalences are most likely an underestimate of obstructive events, as temporary bouts of obstruction such as those induced by prior pregnancy or stone episodes were not captured.

The pathophysiology of obstructive nephropathy is discussed in detail in the beginning of this chapter to provide a platform for understanding the clinical ramifications of this process, some of which are detailed in later sections that focus on unique causes of obstructive uropathy. The mechanisms of obstructive nephropathy are unveiled at genetic, molecular, cellular, glomerular, renal tubular, whole kidney, and systemic levels. The impact of obstruction on the fetal and developing kidney is not emphasized as this is covered in other sections of this book. A list of possible causes of obstructive nephropathy is provided in Table 37–1.

GLOBAL RENAL FUNCTIONAL CHANGES

Glomerular Filtration, Renal Blood Flow, Collecting System Pressure

There are many functional changes in the kidney associated with obstructive uropathy that affect renal hemodynamic variables and glomerular filtration. These are influenced by the extent and severity of obstruction, whether the obstruction is unilateral or bilateral, and whether the obstruction currently persists or has been relieved. A brief discussion of the determinants of glomerular filtration is in order to understand the interrelationships between changes in renal hemodynamics and alterations in the glomerular filtration rate (GFR) during and after obstruction. Factors influencing GFR are expressed in the following equation:

$$GFR = K_f (P_{GC} - P_T - \pi_{GC})$$

K_f is a glomerular ultrafiltration coefficient related to the surface area and permeability of the capillary membrane. P_{GC} is the glomerular capillary pressure, which is influenced by

renal plasma flow and the resistances of the afferent and efferent arterioles. The hydraulic pressure driving fluid into Bowman's space is resisted by the hydraulic pressure of fluid in the tubule (P_T) and also the increasing oncotic pressure (π) of the proteins remaining in higher concentration in the late glomerular capillary and efferent arteriolar blood. Although filtered fluid is not completely free of small proteins, for practical purposes, its oncotic pressure is negligible. The net pressure determining glomerular filtration is referred to as the ultrafiltration pressure (P_{UF}) and is derived from ($P_{GC} - P_T - \pi_{GC}$). P_{GC} is also influenced by renal plasma flow (RPF). RPF depends upon the renal perfusion pressure and intrarenal resistance to flow, the latter primarily mediated by the resistances in the afferent and efferent arterioles. The aforementioned relationships are depicted in the following equation:

$$RPF = \frac{(\text{aortic pressure} - \text{renal venous pressure})}{\text{renal vascular resistance}}$$

Thus, constriction of the afferent or efferent arteriole or both would reduce RPF. Constriction of the afferent arteriole results in a decrease of P_{GC} and GFR, whereas an increase in efferent arteriolar resistance increases P_{GC}. Whole kidney GFR depends upon factors regulating perfusion of each glomerulus and also upon the percentage of glomeruli actually filtering. For each glomerulus, the single-nephron glomerular filtration rate (SNGFR) is determined by the previously mentioned GFR equation. Obstruction can transiently or permanently alter GFR and some or all of the determinants of GFR.

The results of animal experiments are used here to profile the hemodynamic, renal, and systemic responses of renal obstruction. The limitations of animal models including the potential for a species-specific response must be taken into consideration when making analogies or comparisons with humans.

Hemodynamic Changes with Unilateral Ureteral Occlusion

There are differences between unilateral ureteral obstruction (UUO) and bilateral obstruction (BUO) that have been characterized in animal models. These include hemodynamic patterns and other factors that influence GFR. Renal blood flow (RBF) was assessed in the classical studies characterizing hemodynamic differences. In some, RBF was measured directly with various types of flow probes, and in others it was determined indirectly by measuring RPF using secretory markers and indexing this to hematocrit. A number of vasoactive substances are thought to play a role in the changes in RBF and GFR occurring with both models of obstruction. The timing of changes in intrarenal concentrations of vasoconstrictors and vasodilators during the course of obstruction and the release of obstruction is poorly understood. The varying hemodynamic patterns during the time course of obstruction may be due to a combination of vasoactive hormones synthesized and released at different rates, physical damage to glomerular and tubular units, and extrarenal compensatory mechanisms.

Animal experiments have demonstrated a triphasic pattern of RBF and ureteral pressure changes in UUO that differs from BUO or unilateral obstruction of a solitary kidney (Fig. 37–1). With UUO, RBF increases during the first 1 to 2 hours and is accompanied by a high P_T and collecting system pressure because of the obstruction. In a second phase lasting 3 to 4 hours, these pressure parameters remain elevated but RBF begins to decline. A third phase beginning about 5 hours after obstruction is characterized by a further decline in RBF, now paralleled by a decrease in P_T and collecting system pressure. These changes are explained by physical alterations in flow dynamics within the kidney and are modified by changes in the biochemical and hormonal milieu regulating renal resistance.

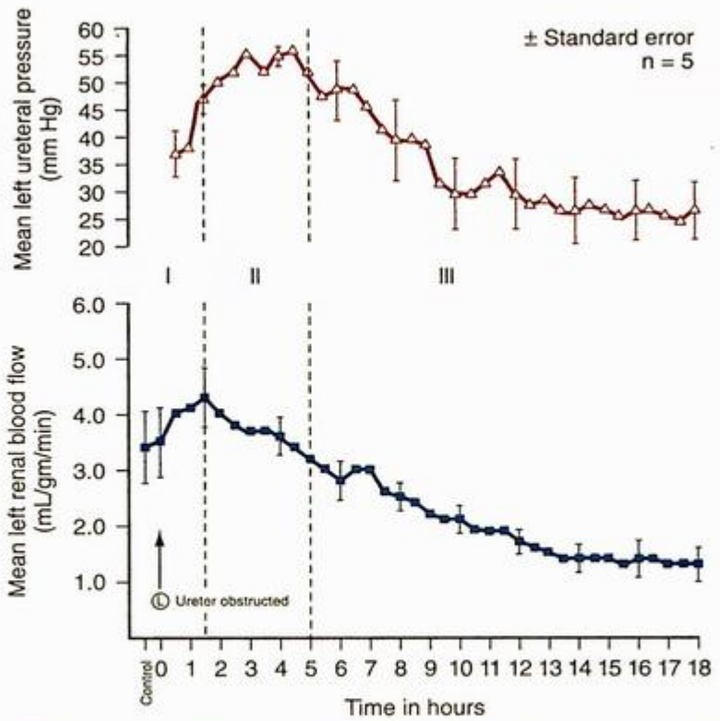

Figure 37–1. Triphasic relationship between ipsilateral renal blood flow and left ureteral pressure during 18 hours of left-sided occlusion. The three phases are designated by Roman numerals and separated by vertical dashed lines. In phase I, renal blood flow and ureteral pressure rise together. In phase II, the left renal blood flow begins to decline and ureteral pressure remains elevated and, in fact, continues to rise. In phase III, the left renal blood flow and ureteral pressure decline together. (From Moody TE, Vaughn ED Jr, Gillenwater JY: Relationship between renal blood flow and ureteral pressure during 18 hours of total unilateral urethral occlusion. Implications for changing sites of increased renal resistance. Invest Urol 1975;13:246-251.)

In the first phase of UUO, the increase in P_T would logically be expected to reduce GFR greatly. However, this is counterbalanced by an increase in RBF related to afferent arteriolar vasodilation (Vaughan et al, 1970), which limits the fall in GFR because P_{GC} rises. This hyperemic response has been attributed to stimulation of the tubuloglomerular feedback mechanism that relaxes the afferent arterioles as a consequence of decreased sodium delivery to the macula densa (Wright and Briggs, 1979), changes in interstitial pressure within the kidney (Vaughan et al, 1971; Francisco et al, 1980), or the release of vasodilators such as prostanoids like prostaglandin E_2 (PGE_2) (Allen et al, 1978). There are various lines of evidence supporting the role of prostaglandin involvement. Frøkiær and Sørensen (1995) demonstrated an increase in PGE_2 excretion in the urine from the contralateral kidney after UUO. In addition, studies have shown that the increase in PGE_2 and the vasodilation of the obstructed kidney could be blocked by indomethacin, a prostaglandin synthesis inhibitor (Allen et al, 1978; Blackshear and Wathen, 1978; Gaudio et al, 1980). Nitric oxide (NO) may also contribute to the early renal vasodilation in UUO. The kidney contains nitric oxide synthases that are both constitutive (endothelial and neuronal isoforms) and inducible (iNOS). In obstructed kidneys from rabbits and rodents, iNOS increases (Salvemini et al, 1994; Miyajima et al, 2001). Furthermore, Lanzone and colleagues (1995) showed that administration of the NOS inhibitor N^{ω}-monomethyl-L-arginine (L-NMMA) before UUO attenuated the early rise in RBF and that the renal vasodilation returned when L-NMMA was discontinued. **Thus, it is likely that both PGE_2 and NO contribute to the net renal vasodilation that occurs early following UUO.**

After this initial phase of several hours, GFR and RBF progressively decline in UUO (Jaenike, 1972; Harris and Yarger, 1974; Dal Canton et al, 1980). In contrast to the early rise in P_T in the initial phases of UUO, this parameter and RBF both decline 12 to 24 hours after obstruction. This is best explained by an increase in afferent arteriolar resistance (R_{aff}) that occurs. At this time, there are also shifts in regional blood flow in the kidney with large portions of the cortical vascular bed not perfused or underperfused (Harris and Yarger, 1974; Gaudio et al, 1980). A shift in RBF from the outer cortex to more juxtamedullary regions was reported by Yarger and Griffith (1974) in dogs with UUO. **Thus, reduced whole kidney GFR at this stage of obstruction is due not only to reduced perfusion of individual glomeruli related to afferent vasoconstriction and reduced P_{GC} but also to global reduction in filtration related to no perfusion or underperfusion of many glomeruli** (Arendshorst et al, 1974).

Vasoconstrictors appear to play a role in the reduction in RBF after UUO. There is evidence that the renin-angiotensin system is activated during UUO because during the first phase of UUO renal vein renin levels increase (Moody et al, 1975; Yarger et al, 1980) even though there is a net renal vasodilation at this time. **Infusion of the angiotensin-converting enzyme (ACE) inhibitor captopril attenuates the declines in RBF and GFR in UUO, suggesting that angiotensin II is an important mediator of the preglomerular vasoconstriction occurring during the second and third phases of UUO** (Ichikawa et al, 1985).

Other vasoconstrictors also appear to be involved in the reduction of RBF with UUO. Thromboxane A_2 (TXA_2) is also thought to be an influential postobstructive vasoconstrictor that contributes to the continued reduction in GFR and RBF. Administration of TXA_2 synthesis inhibitors to the obstructed kidney limits the reduction in RBF and GFR (Klotman et al, 1986; Loo et al, 1987; Purkerson and Klahr, 1989). TXA_2 may be generated in the kidney itself, perhaps in glomeruli (Yanigasawa et al, 1990), but synthesis from macrophages migrating to the kidney during obstruction is another potential source of this vasoconstrictor (Schreiner et al, 1988; Harris et al, 1989).

Endothelin is another endogenous vasoconstrictor thought to participate in these events, although perhaps later in the established phase of UUO and after release of the obstruction. Administration of endothelin antagonists limits the reduction of RBF and GFR in rats during and after release of UUO (Syed et al, 1998; Bhangdia et al, 1998; Colon et al, 2000). Furthermore, endothelin excretion is increased in the targeted kidney after release of UUO in swine but not in the contralateral renal unit (Kelleher et al, 1992).

The kidney's response to the release of UUO depends on the duration and extent of obstruction and is also species specific. Many models of UUO use complete obstruction of the ureter for 24 hours before release. After release of 24-hour UUO, the GFR is initially 50% of normal in dogs and less than 25% of normal in rats, accompanied by greatly reduced RBF.

There are also regional differences within the kidney. Harris and Yarger (1974) showed a marked decrease in perfusion of the superficial cortex accompanied by an increase in juxtamedullary glomerular perfusion after release of 24 hours of UUO in rats. Tubuloglomerular feedback may play a role these responses (Tanner, 1985). Some of the mediators of the hemodynamic changes in the kidney following release of the obstruction may be different from those involved in the earlier phases.

Hemodynamic Changes with Bilateral Ureteral Occlusion

The changes with BUO or obstruction of a solitary kidney are different. **In contrast to the early robust renal vasodilation with UUO, there is a modest increase in RBF with BUO lasting approximately 90 minutes followed by a prolonged and profound decrease in RBF that is greater than that found with UUO** (Gulmi et al, 1995). Reyes and Klahr (1992) found that an NO synthesis antagonist caused a further decline in RBF and GFR compared with control values, suggesting that NO helps maintain renal hemodynamics in early BUO. Other potential vasodilators, such as platelet-activating factor, have been postulated to contribute to renal hemodynamic changes with BUO. Reyes and Klahr (1991) showed in rats that when vasoconstrictors such as TXA_2 were blocked, endogenous or exogenous intrarenal PAF vasodilation contributed to the preservation of RBF and GFR. The earlier and more profound decrease in RBF with BUO may be contributed to by increased renal nerve stimulation that initiates vasoconstriction related to increased renorenal reflex activity (Francisco et al, 1980; Ma et al, 2002). Endothelin may also contribute to these responses in BUO. The administration of an endothelin antibody to rats with BUO was reported to attenuate the decreases in GFR and RPF (Reyes and Klahr, 1992). Angiotensin II and TXA_2 are also probably involved in the changes occurring with BUO. The administration of inhibitors of either of these vasoconstrictors to rats prior to BUO resulted in improved postobstructive GFR and RPF as compared with when they were administered at the time of release of obstruction (Purkerson and Klahr, 1989).

The intrarenal distribution of blood flow is quite different with BUO than with models of UUO. Jaenike (1972) used microspheres to show that 55% of the RBF perfused the cortical nephrons while the innermost zones received only 14% of the flow in rats after BUO. Similarly, Solez and associates (1976) showed a 92% decrease in inner medullary plasma flow with 18 hours of BUO in rats. **Thus, the shift seen with UUO of blood flow from outer to inner cortex is the opposite with BUO.**

Ureteral pressure is higher with BUO than with UUO. Although in both cases ureteral and tubular pressure is increased for the first 4 to 5 hours, the ureteral pressure remains elevated for at least 24 hours with BUO, whereas it begins to decline and approaches preocclusion pressures by 24 hours with UUO. The prolonged elevation in intratubular pressure contributes to the profound decrease in SNGFR and whole kidney GFR. Micropuncture studies (Yarger et al, 1972; Dal Canton et al, 1980) in which intratubular pressure is measured directly have demonstrated that it remains elevated in rats after 24 hours of BUO in comparison with pressure normalization in animals after 24 hours of UUO. Ureteral pressure remains high because BUO passes through a phase of preglomerular vasodilation and then a prolonged postglomerular vasoconstriction. This explains the persistent elevation in ureteral pressure in spite of a decrease in RBF and increase in renal resistance. In contrast, in UUO the initial preglomerular dilation and short-lived postglomerular vasoconstriction are followed by a more prolonged preglomerular vasoconstriction that tempers elevations in P_{GC} and hence in P_T. **This difference between the two pathophysiologic conditions has been hypothesized to be due to an accumulation of vasoactive substances in BUO that could contribute to preglomerular vasodilation and postglomerular vasoconstriction. Such substances would not accumulate in UUO as they would be excreted by the contralateral kidney. Atrial natriuretic peptide (ANP) appears to be one of these substances** (Purkerson et al, 1989). With excretory ability abrogated, BUO increases intravascular volume, as evidenced by an increase in pulmonary capillary wedge pressure and body weight, which serves as the stimulus for secretion of ANP. ANP increases afferent arteriolar dilation and efferent arteriolar vasoconstriction, thus increasing P_{GC}. It also decreases the sensitivity of tubuloglomerular feedback, inhibits release of renin, and increases K_f (Fried et al, 1987; Brenner et al, 1990; Cogan, 1990).

Glomerular filtration and RBF remain depressed after release of BUO. This is due to persistent vasoconstriction of the afferent arteriole (Jaenike, 1972; Moody et al, 1977). The decrease in RBF in the renal medulla remains more prominent than in the cortex (Solez et al, 1976). Tubuloglomerular feedback does not appear to contribute to this response as it does with UUO (Tanner, 1985). Urine flow and sodium excretion are increased after release of BUO. ANP appears to play a prominent role in this response based on its natriuretic properties and those previously reviewed. It may also have a protective effect. Ryndin and associates (2005) reported that the administration of ANP or phosphoramidon, an inhibitor of ANP degradation, to rats with BUO resulted in improved GFR and a more brisk diuresis and natriuresis after release of obstruction.

In summary, both UUO and BUO involve increases in renal vascular resistances and increases in ureteral pressures. However, the timing and regulation of these changes differ (Fig. 37–2). With UUO, early renal vasodilation primarily mediated by prostaglandins and NO is followed by prolonged vasoconstriction and normalization of intratubular-ureteral pressure as the contralateral kidney contributes to fluid balance. With BUO, little early vasodilation is seen and vasoconstriction is more profound. When the obstruction is released, the postobstructive diuresis is much greater with BUO because volume expansion, urea and other osmolytes, and secreted ANP contribute to a profound diuresis and natriuresis.

Partial Ureteral Occlusion

Although most models of urinary tract obstruction study complete obstruction over a fixed time interval such as 24 hours, many clinical conditions involve partial obstruction over varying times. Partial obstruction models often involve

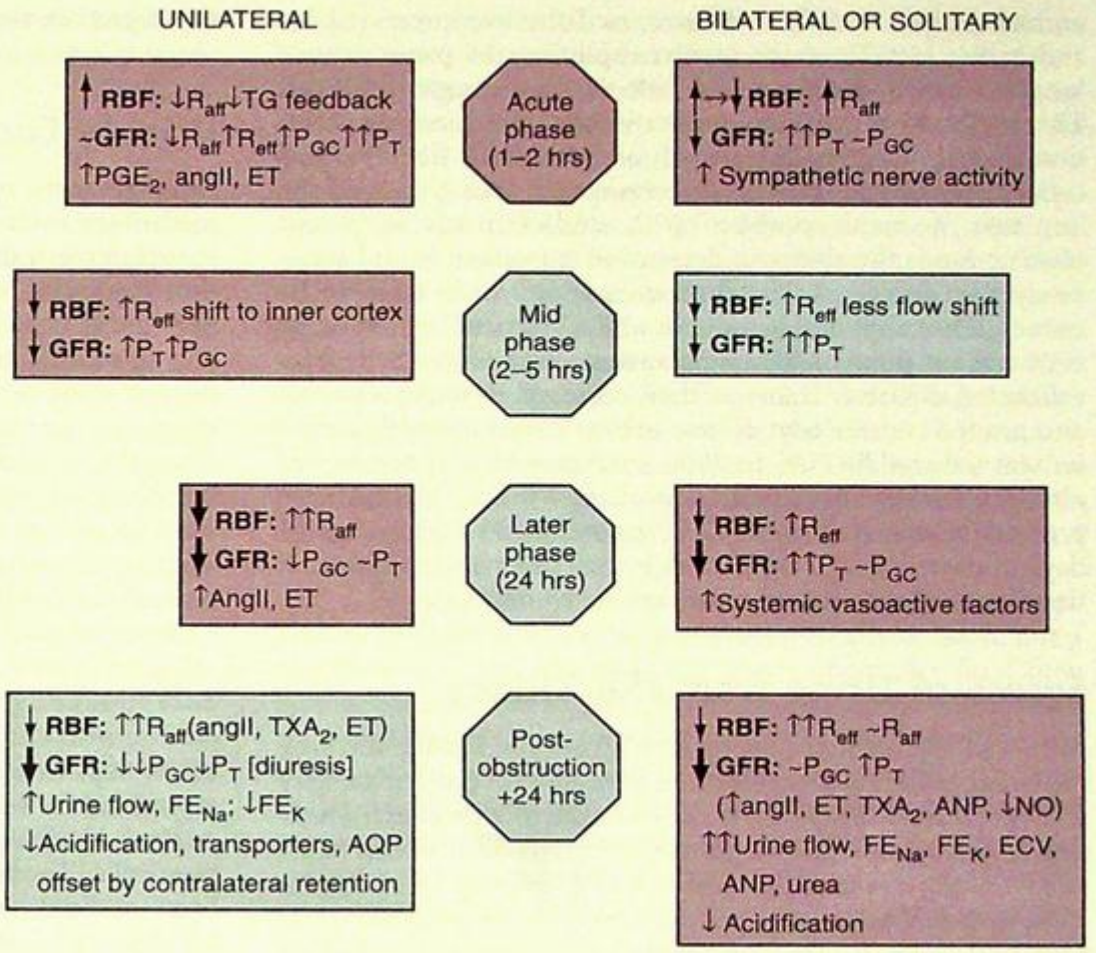

Figure 37–2. Summary of the functional changes during and following ureteral obstruction. Symbols and abbreviations indicate ↑↓, increases and decreases; ~, little change; angII, angiotensin II; ANP, atrial natriuretic peptide; AQP, aquaporin; ECV, extracellular volume; ET, endothelin; FE, fractional excretion; NO, nitric oxide; P_{GC}, glomerular capillary hydraulic pressure; P_T, proximal tubular hydraulic pressure; PGE_2, prostaglandin E_2; R_{aff}, afferent arteriolar resistance; R_{eff}, efferent arteriolar resistance; RBF, renal blood flow; TG feedback, tubuloglomerular feedback; TXA_2, thromboxane A_2.

perinatal obstruction because renal growth and differentiation may be affected as well as hemodynamics and excretion. In many cases, the changes in renal hemodynamics and in tubular function are similar to those induced by more acute, complete models of obstruction but develop more slowly. In other cases, such as perinatal models of obstruction either before or shortly after birth, an animal such as a rat is still in a period of nephrogenesis. **Consequently, formation of glomeruli and tubules may be compromised so that irreversible changes occur without total loss of kidney function.**

Recovery of renal function in adult animals with partial obstruction has been studied as a potential guideline for clinical treatment. Leahy and coworkers (1989) studied dogs in which partial UUO with stents was studied for up to 60 days. Reversibility of renal function was estimated by creatinine clearance. Renal function became normal in dogs partially obstructed for 14 days. Animals partially obstructed for 28 days recovered 31% of function, and those partially obstructed for 60 days recovered only 8% of function. Casts of the microvasculature showed arteriolar constriction, supporting the concept that postobstructive renal dysfunction is influenced by vascular responses.

Much less is known about the roles of vasoactive or inflammatory mediators in the partial ureteral obstruction model. As with acute occlusive models, administration of indomethacin or meclofenamate, both prostaglandin synthetase inhibitors, decreases GFR and increases arteriolar resistance (Ichikawa and Brenner, 1979) so that changes in eicosanoids are implicated in partial obstruction responses. Several investigators have shown that the renin-angiotensin-aldosterone axis is activated with partial obstruction, including studies in the fetus. Gobet and colleagues (1999) studied fetal sheep in utero and showed that partial obstruction of the bladder outlet increased renin messenger RNA (mRNA) after 2 weeks and increased the expression of renal AT_2 receptors as well as the mRNA for transforming growth factor β (TGF-β), a mediator of fibrosis.

One could hypothesize that changes in angiotensin II may be responsible for much of the hemodynamic, fibrotic, and apoptotic changes in neonatal animals with partial obstruction, as has been shown in more acute models. Beharrie and coworkers (2004) examined weanling male rats that had been subjected to a partial UUO. The partial obstruction led to proteinuria, hyperuricemia, and increased solute excretion primarily from the unaffected contralateral kidney. A parallel group of rats treated with the ACE inhibitor enalapril was protected from these changes. This suggests that angiotensin is involved with functional tubular changes as well. Eskild-Jensen and colleagues (2002) examined partial UUO for up to 24 weeks in young, postnatal pigs. The number of glomeruli was 28% less in the obstructed kidney, yet function was just transiently reduced by the occlusion. **Thus, partial neonatal obstruction can impair nephrogenesis independently of renal functional decline and these changes may depend upon species, stage of renal development, or degree of occlusion.** More work is needed to define the variables.

Various methods have been used to create partial obstruction. The models for preparing partial ureteral occlusions fall into three main categories. Intraluminal stents or catheters of varying sizes have been placed in the ureters of sheep (Abu-Zidan et al, 1999) and in dogs (Ryan and Fitzpatrick, 1987; Leahy et al, 1989) to restrict flow. In rats, or in growing

animals, many investigators have used the technique of Ulm and Miller (1962), which involves splitting the psoas muscle longitudinally to form a groove into which the ureter is placed. This method has a potential advantage of increased constriction in proportion to the growth of the animal. Beharrie and colleagues (2004) used such a technique in young male weanling rats. A major problem with studies involving partial obstruction is the ability to determine reproducibly and accurately the degree of obstruction induced with these techniques. Thornhill and associates (2005) devised a method in neonatal rat pups of ligating a ureter along with a wire of a calibrated diameter that was then removed to make a partial and graded constriction of one ureter. When ureteral diameter was reduced by 70% to 75%, renal growth and number of glomeruli were reduced and fibrosis and pelvic dilation were proportionately increased. GFR was reduced by 80% after 28 days of partial UUO. Such models may offer new opportunities to model the clinical condition reproducibly.

Egress of Urine from the Kidney

Although the normal flow of urine from the kidney through the urinary tract is compromised with obstruction, urine may still egress from the kidney. An example of this is extravasation at the calyceal fornix (pyelosinus) that occurs with acute obstruction, typically ureteral stones (Stenberg et al, 1988). Extravasation of urine into the venous (pyelovenous) and lymphatic system (pyelolymphatic) may also occur in this setting. In chronic obstruction, fluid is thought to exit into the renal venous system.

Effects of Obstruction on Tubular Function

Obstruction of one or both kidneys can have profound effects on sodium, potassium, and hydrogen excretion and mechanisms of urinary concentration and dilution. In the case of UUO, relatively normal function of the nonobstructed kidney partially offsets the reduced ability of the postobstructive kidney to reabsorb solutes and water. **Postobstructive diuresis, something that is commonly encountered after reversal of BUO, occurs uncommonly after release of UUO, probably as a consequence of the contralateral renal unit's functional capacities.** The eventual correction of abnormal renal excretory function depends upon the degree and duration of obstruction.

Changes in tubule function after correction of UUO related to ureteropelvic junction or ureteral obstruction were characterized in 10 patients by Gillenwater and colleagues (1975). The mean period of obstruction in these cases was 12 months and the range was from days to years. Functions of the normal and obstructed kidney were evaluated 1 week after relief of the obstruction. The GFR in the obstructed kidney was significantly less than that in the nonobstructed kidney (24 versus 60 mL/min), and the urine osmolality, osmolar clearance, and fractional free water clearance were all significantly less in the postobstructed kidney. The similar osmolar clearances (volume of urine required to excrete urinary solute isosmotically) relative to GFR of the previously obstructed and unobstructed kidneys indicate that there is a true concentrating defect in the obstructed kidneys 1 week after relief of obstruction.

Urinary Concentrating Ability

Normal urine concentrating ability requires a hypertonic medullary interstitial gradient because of active salt reabsorption from the thick ascending limb of Henle, urea back flux from the inner medullary collecting duct, and water permeability of the collecting duct mediated by vasopressin and aquaporin water channels. Obstructive nephropathy can disrupt some or all of these mechanisms and lead to deficits in urinary concentration. A brief review of the normal concentrating mechanisms is provided to facilitate understanding the effects of obstruction.

In normal physiology, AVP is secreted into the bloodstream from the posterior pituitary gland in response to increased serum osmolality or a reduction in effective circulating volume. Arginine vasopressin binds to the V2 vasopressin receptor located on the basolateral surfaces of the collecting duct cells. This promotes G protein signaling, resulting in generation of cyclic adenosine monophosphate (cAMP). Generation of cAMP in turn activates protein kinase A, which stimulates the fusion of cytoplasmic vesicles containing aquaporin 2 (AQP2) with the apical membranes of the collecting duct cells. The fusion causes the normally water tight membrane to become water permeable. This promotes transcellular absorption of water through the AQP2 channels, which is transported through aquaporin 3 (AQP3) and aquaporin 4 (AQP4) channels located in the basolateral cell membrane into the interstitium. This sequence of events is driven by the osmotic gradient of sodium (Knoers, 2005). Another aquaporin, aquaporin 1 (AQP1), is abundant in renal proximal tubules, the thin descending limb of Henle, and the descending vasa recta in the kidney. It promotes urinary concentration through the countercurrent multiplier by facilitating water transport from the descending limb of Henle into the interstitium (King et al, 2001).

The onset of concentration defects may develop soon after obstruction. Jaenike and Bray (1960) demonstrated a concentrating defect in the unilaterally obstructed kidney after only 6 minutes of ureteral obstruction. Development of vasopressin resistance has been hypothesized as a mechanism of this occurrence. However, various studies have demonstrated conflicting results concerning whether vasopressin resistance is present. Vascular changes may play a role. Even after only 18 hours of UUO, Solez and colleagues (1976) found a decrease in inner medullary plasma flow that increased when the occlusion was released. Necrosis of both the inner and outer medullae was present, indicating that ischemia may contribute to the development of a concentrating defect.

Evidence from Li and coworkers (2001) demonstrated that the polyuria following the release of BUO correlates with a decreased expression of the aquaporin water channels AQP1, AQP2, and AQP3 in rats. Release of obstruction resulted in polyuria that gradually decreased over a 30-day period, even though urinary concentrating capacity remained significantly impaired. Expression of AQP2 and AQP3 became normal by 30 days after release, but the expression of AQP1 remained decreased. **Thus, dysregulation of aquaporin water channels in the proximal tubule, thin descending loop, and collecting**

duct may contribute to the long-term polyuria and impaired concentrating capacity of obstructive nephropathy.

Sodium Transport

A decrease in sodium transport in the nephron appears to play an additional prominent role in the decreased ability of the postobstructed kidney to concentrate and dilute urine. When UUO is released after an occlusion period of 24 hours, total urine excretion is normal to modestly increased despite increased fractional excretion of sodium (FE_{Na}) in the previously obstructed kidney. This is attributed to the contralateral kidney compensating for the sodium losses of its mate. However, with BUO, sodium and water excretions may be quite robust after release of obstruction. The FE_{Na} may be increased to as much as 20 times normal in this setting (Zeidel and Pirtskhalaishvili, 2004). **Although ANP appears to play a role in sodium diuresis after release of BUO, it is unlikely to affect sodium transport defects associated with UUO.** The latter is most likely due to selective cell membrane changes in the nephron that reduce the number and effectiveness of sodium transporters. Such changes may also occur with BUO.

In spite of differential quantitative responses between UUO and BUO after release of the obstruction, the reabsorption defects in segmental nephron Na^+ transport are similar. Micropuncture studies of kidneys from animals have been undertaken to assess these responses. These studies demonstrate normal to modestly enhanced isotonic volume flux (J_v) in superficial proximal convoluted tubules after release of UUO or BUO. On the other hand, sodium delivery to the loop of Henle in juxtamedullary nephrons and to the first accessible portion of the inner medullary collecting duct is substantially increased after release of both UUO and BUO, indicative of reduced sodium transport. Sonnenberg and Wilson (1976) even found evidence for net addition of sodium throughout the medullary collecting duct, which further contributed to an increased FE_{Na}. However, this was more prominent with BUO in their rat model.

Studies in isolated perfused nephron segments have also provided knowledge about the impact of obstruction at the level of the nephron. They have shown normal isotonic reabsorption in the superficial proximal convoluted tubules from animals with either UUO or BUO, whereas J_v in proximal straight tubules from juxtamedullary nephrons was demonstrated to be impaired (Hanley and Davidson, 1982). Similarly, chloride reabsorption and transport-dependent oxygen consumption (QO_2) from the medullary thick ascending limb of Henle's loop (MTAL) were severely impaired (Hanley and Davidson, 1982; Hwang et al, 1993a).

Cell suspensions from nephron segments have been used to assess the effects of obstruction at a cellular level. Active transport of Na^+ across cell membranes requires apical entry through selective Na^+ transporters or channels and basolateral exit driven by sodium-potassium adenosine triphosphatase (Na^+,K^+-ATPase). Furthermore, adequate adenosine triphosphate (ATP) must be generated to drive these primary transport steps. Hwang and associates (1993c) showed that the amount and activity of the apical Na^+, K^+, $2Cl^-$ cotransporter and bumetanide binding sites were reduced in cells isolated from the MTAL derived from obstructed rabbit kidneys. Basolateral transport is also affected in that ouabain-sensitive oxygen consumption, an index of Na^+,K^+-ATPase activity, has been shown to be reduced in cell suspensions from obstructed kidneys (Hwang et al, 1993a). A marked decrease in amiloride-sensitive oxygen consumption and Na^+ entry in isolated cells from the inner medullary collecting ducts of obstructed rabbit kidneys reflects reduced activity of the apical Na channel (ENaC). In addition, ouabain-sensitive transport as measured by oxygen consumption and ATPase activity was shown to be reduced in cells from this portion of the nephron harvested from obstructed kidneys (Hwang et al, 1993c). Because cell suspension studies indicate that ATP generation is not the rate-limiting step underlying sodium transport dysfunction in this setting, the evidence points to downregulation of sodium transporters. This may be due to translational factors (reduction in mRNA for transporter synthesis) or post-translational processing of receptor proteins (Hwang et al, 1993c).

The signals responsible for downregulation of transporter activity with obstruction have not been clearly defined, but a number have been hypothesized. Stasis of tubular fluid flow may be one of the signals. When urine flow is obstructed, upstream Na^+ delivery to apical cell membranes slows so that the transmembrane gradient is reduced. This could then serve as the signal for the downregulation of transporter activity or expression resulting in reduced active Na^+ transport across the basolateral cell membrane (Zeidel, 1993). Several studies indicate that this is a feasible mechanism. For example, ouabain-sensitive Na^+,K^+-ATPase activity is reduced in MTAL and collecting duct cells when mineralocorticoid activity is controlled and chronic furosemide or amiloride is given to reduce Na^+ entry into tubule cells (Petty et al, 1981; Grossman and Hebert, 1988). Additional studies have explored this concept in established cell lines. When A6 cells, an established line of collecting duct cells, are grown on a permeable substrate, Na^+ influx across the apical membrane through the ENaC Na^+ channel occurs. When Na^+ entry was blocked, this induced a decreased expression of the β-subunit of the epithelial sodium channel in the apical membrane (Rokaw et al, 1996). Ischemia has also been proposed as a signal in this setting, where ischemia that accompanies the reduced perfusion of the kidney with obstruction can also be a mediator of reduced transporter expression. The reduction in major renal sodium transporters reported with ischemic models of renal failure supports this concept (Kwon et al, 2000). Other proposed downstream signals include changes in renal interstitial pressure and local generation of natriuretic substances. **Thus, substrate delivery may be a regulatory step in the expression of sodium and possibly other transporters.**

Intrarenal and extrarenal substances and hormones can also modulate sodium transport. The milieu of influential hormones may be substantially different between UUO and BUO. A number of investigators have shown that obstruction markedly increases the endogenous production of PGE_2 in the renal medulla. Furthermore, supraphysiologic concentrations of PGE_2 are well known to produce natriuresis (Strandhoy et al, 1974), and studies in isolated tubules and cell suspensions show that PGE_2 inhibits Na reabsorption in the MTAL and throughout the collecting duct (CD). One mechanism of this natriuretic response may be that PGE_2 reduces the amount of Na^+,K^+-ATPase at the basolateral membrane (Marver and Bernabe, 1992). PGE_2 can also inhibit the tubular effects of

vasopressin (Zook and Strandhoy, 1980), thereby contributing to the free water loss from the post-UUO kidney. The influence of other substances and hormones in the post-obstructed UUO kidney is counterbalanced or minimized by the contralateral renal unit.

Extracellular fluid volume may be greatly expanded with BUO. When the BUO is relieved, both intrarenal and extrarenal factors greatly enhance salt and water excretion so that a postobstructive diuresis is often seen. The normal physiologic consequences of extracellular fluid volume expansion ensue. These include a downregulation of sympathetic tone and the secretion of aldosterone and manifestation of the effects of ANP and probably other natriuretic factors. Levels of ANP are significantly elevated following BUO but not UUO (Purkerson and Klahr, 1989). The direct and indirect consequences of increased ANP levels include partial support of glomerular filtration, reduction of renin secretion and effects of angiotensin on transport, reduced aldosterone secretion, and direct inhibition of Na transport in the collecting duct (Brenner et al, 1990). Furthermore, BUO results in the accumulation of osmotic substances such as urea that can contribute to salt and water loss when the obstruction is relieved (Harris and Yarger, 1975, 1977). **Thus, the FE_{Na} following relief of BUO is typically greater than that after UUO because BUO causes retention of Na, water, urea nitrogen, and other osmolar substances and increased production of ANP, all of which stimulate a profound natriuresis.**

Potassium Transport

Obstruction has a complex impact on renal potassium handling, depending upon the type of obstruction. Harris and Yarger (1975) reported that there is a decrease in K^+ excretion, in proportion to the decrease in GFR, after release of a 24-hour period of UUO. This may be partially due to reduced delivery of Na to the distal nephron and a low volume flow rate that would minimize the transmembrane gradient for K^+ secretion. Other investigations indicate that there is also an intrinsic defect in K^+ secretion after relief of UUO (Thirakomen et al, 1976). In contrast, K^+ excretion increases in parallel with Na excretion with the relief of BUO. Micropuncture studies in rats showed that proximal reabsorption of K^+ remains unchanged whereas secretion in the collecting duct is increased following release of BUO. This may be due to the massive increases in Na^+ and water delivery to the collecting duct acting as stimuli to secretion and also to the presence of high levels of ANP that can stimulate K^+ secretion in the distal nephron (Sonnenberg and Wilson, 1976).

Hydrogen Ion Transport and Urinary Acidification

Obstruction causes a deficit in urinary acidification that has been demonstrated in human subjects as well as animal models. The cumulative evidence indicates that the major acidification defect is in the distal nephron. Release of obstruction does not result in increased bicarbonate excretion, indicating that bicarbonate reclamation in the proximal tubule remains intact. In contrast, urinary pH does not decrease after an acid load, which is indicative of a distal nephron acidification defect, most likely related to defective H^+ transport in the collecting duct. A number of causes for the lack of acidification have been proposed including defects in H^+-ATPase or H^+,K^+-ATPase, Cl^-/HCO_3^- exchange, a back leak of protons into the renal interstitium, or failure to generate a satisfactory transluminal electrical gradient. Obstruction has been demonstrated to decrease the expression of H^+-ATPase in the apical membrane of the intercalated cells of the collecting duct. However, the extent of this apical transporter decrease was too small to explain the significant acidification defects that develop. Therefore, other mechanisms are also likely to play a role in the development of this acidification defect (Purcell et al, 1991). Valles and Manucha (2000) showed that the decrease in H^+-ATPase with UUO depends upon an increase in iNOS, which, in turn, appears to be regulated by angiotensin II. Thus, recovery of H^+-ATPase activity in the inner medullary collecting duct of obstructed kidneys by losartan treatment may be related to a decrease in angiotensin-stimulated iNOS activity.

In the proximal tubule, glutamine uptake and oxidation and ammonia generation are diminished after release of obstruction. This has an impact on acid elimination in that a greater proportion of H^+ is buffered as titratable acid. Because phosphate excretion may be compromised and binding of protons to phosphate has a limited capacity, the net result may be a lower urinary pH related to unbuffered protons in spite of a net decrease in total H^+ secretion.

Effects of Obstruction on Anion and Other Cation Transport

The effects on phosphate reabsorption after the release of obstruction vary depending upon whether it was bilateral or unilateral. When BUO is released, accumulated phosphate is rapidly excreted in proportion to sodium (Beck, 1979). Conversely, a decrease in phosphate excretion and a net retention occur with release of UUO. Weinreb and colleagues (1982) showed that the decrease in the fractional excretion of phosphate following release of UUO in dogs produced no change in the transport of phosphate across brush border membrane vesicles. A reduced filtered load in the previously obstructed renal unit may stimulate increased phosphate reabsorption. Westenfelder and coauthors (1998) reported findings supporting the latter. They demonstrated that the increased reabsorption of phosphate after release of UUO in rats is due to a generalized increase in proximal tubular sodium reabsorption, a process linked to a reduction in GFR. They noted that this was linked to increased cotransport of phosphate and glucose with sodium.

Other cation excretion is also induced by obstruction. **Magnesium excretion is markedly increased after the release of either UUO or BUO.** The increase most likely results from compromised transport in the thick limb of Henle related to ischemia. This causes decreased influx of Na^+, K^+, and Cl^- by the cotransporter and reduced back flux of K^+ across the apical membrane. It attenuates the positive luminal transepithelial voltage that normally drives the paracellular flux of both magnesium and calcium from lumen to basolateral membrane. The result is reduced passive reabsorption of Mg^{2+} and Ca^{2+} from the loop of Henle. However, calcium excretion may be increased or decreased, which depends to a degree on the type

of obstruction and the species. Although Mg^{2+} and Ca^{2+} are handled similarly in the thick limb of Henle's loop, calcium handling in the early distal tubule differs. Beaumont and coworkers (1989) demonstrated that the thiazide-inhibitable sodium-chloride cotransporter is rapidly downregulated during ischemia such as may accompany ureteral occlusion. Blocking influx of Na^+ and Cl^- through this transporter hyperpolarizes the cells in the distal nephron, thereby increasing calcium reabsorption (Gesek and Friedman, 1992). Thus, disruption of transport in areas of the nephron where Ca^{2+} and Mg^{2+} are differentially transported may account for varying effects of obstruction on their net transport and excretion.

Organic anions and cations are transported by the renal tubules as substrates of metabolism and as a mechanism of drug elimination. In rats, BUO decreases the renal clearance of *p*-aminohippurate (PAH), a prototypical substrate for the organic anion transporter 1 (OAT-1). Although secretion of PAH was reduced, the reduction did not correlate with a decrease in OAT-1 abundance or with cortical blood flow. It is postulated that decreased Na^+,K^+-ATPase activity, which provides the primary active transport to which OAT-1 is coupled, explains the decrease in PAH transport. In addition to the implications for drug transport and excretion with obstruction, this indicates that PAH clearance without measurement of extraction is an inaccurate index of RPF in post-obstructed kidneys (Villar et al, 2004).

Effect of Obstruction on the Excretion of Peptides and Proteins

Some peptides and small proteins are normally filtered by the glomerulus and readily absorbed in the nephron. Some enzymes and proteins such as Tamm-Horsfall protein and aquaporins may normally be secreted into the tubular fluid. Obstruction can exaggerate or disrupt the excretion of these proteins and peptides. Some changes simply represent alterations in transport, whereas others are due to tubular damage and remodeling.

Monocyte chemoattractant protein 1 is a mediator of the inflammatory process accompanying obstruction in the kidney. Its excretion in the urine after UUO increases (Stephan et al, 2002) and has been considered an index of tubular damage. Conversely, epidermal growth factor (EGF) excretion, the renal cortical and outer medullary concentration of pre-pro-EGF, and excretion of Tamm-Horsfall protein (Storch et al, 1992) all decrease with obstruction. Urinary enzymes thought to be derived from the proximal tubule such as alkaline phosphatase, γ-glutamyltransferase, *N*-acetyl-β-D-glucosaminidase, and leucine aminopeptidase have been reported to be elevated in patients with obstructed kidneys (Carr et al, 1994). However, such increases in enzymuria have been reported to be either biphasic, occurring only in the early stages of obstruction, or absent in animal models of partial or total ureteral obstruction (Everaert et al, 1998).

In summary, major changes occur with the ability of the kidney to concentrate the urine because of downregulation of transporters and aquaporin water channels. These defects are enduring and correct slowly with time. Sodium excretion is greater after relief of bilateral obstruction because extracellular volume is expanded and ANP directly affects transport and glomerular filtration. Potassium and phosphate excretions follow changes in sodium; they are decreased with UUO because of altered transporters and postobstructive retention and increased transiently with BUO in parallel with the massive natriuresis. Obstruction causes a deficit in urinary acidification that has been demonstrated in humans and in animals. Magnesium excretion is increased in both models, but calcium handling is more complex. Changes in peptide excretion reflect mediators and markers of renal damage.

Metabolic Determinants of Ion Transport

An overview of the normal metabolic processes linked to ion transport provides a foundation for the understanding of changes that occur with obstruction. The myriad of transporters involved in maintaining cellular homeostasis and electrolyte balance is integrated longitudinally and vertically within the nephron. Families of ion-translocating ATPases mediate primary and secondary transport and are fueled by the availability and synthesis of ATP. In addition to providing energy for ion pumps, the adenine nucleotides can directly influence ATP-sensitive K^+ channels that link the activity of the sodium pump with the leak of potassium in some of the nephron segments such as the thick ascending limb of Henle and the collecting duct.

Although there is considerable variability between nephron segments and even between species in the normal physiologic substrate for ATP generation in nephron segments, a few generalizations can be made. Aerobic glycolysis in several cell types including renal tubules links ATP generation to increased activity of Na^+,K^+-ATPase, QO_2 and ATP, and primary active transport of ions. In normal physiology, the renal cortex has a high rate of aerobic metabolism indicative of fatty acid oxidation and a low content of glycogen. Proximal tubules have relatively little glycolytic capacity and depend upon aerobic mitochondrial metabolism for ATP synthesis from substrates such as ketone bodies, fatty acids, glutamine, and lactate (Uchida and Endou, 1988; Ruegg and Mandel, 1990). Metabolism even varies along the length of the proximal tubule. For example, the proximal convoluted tubule cannot utilize glucose to support oxidative metabolism but the proximal straight tubules can.

The medullary and cortical regions of the thick ascending limb of Henle possess abundant mitochondria and high QO_2. Substantial energy reserve allows increased transport associated with glomerulotubular balance. This nephron segment and those downstream have the capability of aerobic and anaerobic glycolysis, which results in lactate accumulation and increased glycogen content (Abodeely and Lee, 1971; Cohen, 1979; Bagnasco et al, 1985). Compared with the proximal tubule, the medullary thick ascending loop of Henle has a greater capacity for anaerobic glycolysis but still requires ATP production from mitochondrial oxidative phosphorylation to maintain active Na^+ transport.

In addition to its role as a fuel for metabolism and transport, ATP and its metabolites can serve as regulators of solute transport such as the ATP-sensitive K^+ channels previously mentioned and activation of purinergic P2 receptors within

the kidney that modulate solute transport (Schwiebert and Kishore, 2001).

Although substrate availability for energy production related to transport is not generally rate limiting under physiologic conditions (Guder and Schmidt, 1976), some parts of the kidney such as the thick ascending limb of Henle are located in areas where there is a tenuous balance between oxygen supply and demand. Consequently, these parts of the nephron are more susceptible to hypoxic injury and associated transport dysfunction. Therefore, in addition to downregulation of the transport proteins themselves with obstruction, the energy sources for transport function are at risk.

Renal obstruction provokes a number of changes in the metabolic cascade. There is a shift from oxidative metabolism to anaerobic respiration. This shift results in a reduction of renal ATP levels, an increase in amounts of adenosine diphosphate (ADP) and adenosine monophosphate (AMP), and an increase in the renal lactate-to-pyruvate ratio (Stecker et al, 1971; Middleton et al, 1977; Nito et al, 1978; Klahr et al, 1986).

Cellular and Molecular Changes Leading to Fibrosis

Urinary tract obstruction leads to progressive and eventually permanent changes in the structure of the kidney including the development of tubulointerstitial fibrosis, tubular atrophy and apoptosis, and interstitial inflammation. A number of cytokines and growth factors have been shown to play roles in these events, among which the most prominent include TGF-β, angiotensin II, nuclear factor κB (NFκB), and tumor necrosis factor α (TNF-α). Some are produced directly from the renal tubular and interstitial cells; others are generated from infiltrating macrophages.

Tubulointerstitial fibrosis develops as a consequence of extracellular matrix being synthesized and deposited at a greater rate than it is degraded. A family of enzymes known as matrix metalloproteinases (MMPs) that includes collagenase normally cleaves and degrades the collagenous and noncollagenous components of the extracellular matrix. **Obstruction increases the synthesis of tissue inhibitors of metalloproteinases (TIMPs) that reduce MMP activity, resulting in the accumulation of extracellular matrix.** Infiltrating macrophages stimulate TGF-β synthesis, and this growth factor increases TIMP production, thus reducing collagen turnover. Macrophages also produce other cytokines and growth factors such as interleukin 2, interleukin 6, fibroblast growth factor, and platelet-derived growth factor (PDGF) that appear to contribute to this inflammatory and fibrotic process. Active TGF-β binds directly to its type 2 receptor, which subsequently activates and phosphorylates the type 1 TGF-β receptor. Both of these receptors have been shown to be upregulated in rats with UUO, in both the obstructed and contralateral renal units. This may be a factor in the hypertrophic response sometimes seen in the nonobstructed kidney (Sutaria et al, 1998). The activated type 1 TGF-β receptor subsequently phosphorylates SMAD (mobile transcription factors with a name derived from related genes in C. elegans (Sma) and drosophila (MAD)) proteins. A heteromeric complex of SMAD proteins translocates to the nucleus, where it interacts with transcription factors to regulate gene transcription (Wamsley-Davis et al, 2004) and stimulates tubulointerstitial fibrosis (Fukasawa et al, 2004). Stimulation of TGF-β furthermore stimulates the JNK1 (C-Jun N-terminal protein kinase 1) pathway, which targets the activation of c-Jun and activates transcription factor 2, which are critical components in activating fibronectin production. Increased mRNA expression of TGF-β is seen as early as 10 hours after obstruction and increases for 4 days (Walton et al, 1992; Diamond et al, 1994). The increase occurs primarily in medullary tubules and the interstitium and is less prominent in cortical tubules or glomeruli. Furthermore, TGF-β interacts with other profibrotic growth factors such as EGF and angiotensin II (Kaneto et al, 1993; Ishidoya et al, 1995; Chevalier et al, 1998).

Angiotensin II upregulates the expression of TGF-β1 in UUO, whereas ACE inhibitors or angiotensin receptor blockers diminish TGF-β1 expression and reduce tubulointerstitial fibrosis. This effect and increases in TNF-α and NFκB promoted by activation of the renin-angiotensin axis underscore the importance of this system in the obstructive process. Angiotensin II exerts its biologic effect through both AT1 and AT2 receptors, although in adult mammals the AT1 receptors predominate and account for most of the known effects of the peptide. With UUO, a significant rise in both renal angiotensin II content and AT1 receptor expression is found (Misseri et al, 2004). Nephron angiotensin receptors are found in areas of the kidney where the peptide is known to have its greatest biologic effect: the proximal tubule, the thick ascending limb of Henle, and the glomerulus (Sechi et al, 1992; Meister et al, 1993). The importance of this pathway has been shown in a murine AT1a receptor knockout model in which the mice have significantly less collagen expression and deposition, interstitial volume, and extent of obstruction-induced renal fibrosis (Morrissey and Klahr, 1998a). Angiotensin II activates the transcription factor NFκB, which in turn increases the expression of several chemokines and cytokines involved with the fibrotic process. The NFκB also upregulates the expression of the angiotensinogen gene and thereby provides a positive feedback for further angiotensin II production (Morrissey and Klahr, 1998b). The intimate link between angiotensin and NFκB was demonstrated in a study in which enalapril, an ACE inhibitor, reduced the levels of NFκB and fibrosis in a model of renal obstruction (Morrissey and Klahr, 1997).

The release of TNF-α, a potent inflammatory cytokine, is also stimulated by angiotensin, especially in the first few hours of renal obstruction. It can upregulate its own expression as well as that of other inflammatory mediators such as interleukin 1, platelet-activating factor, nitric oxide, eicosanoids, and cell adhesion molecules. Although macrophages are a major source of TNF-α, renal tubular cells are also capable of producing it and become the predominant source of TNF-α after renal injury. Its role in renal inflammation and fibrosis is supported by studies in mice with knockout deletions of the two types of TNF receptors having less fibrosis.

Although the events leading to fibrosis are thought to be initiated by increased angiotensin II, other profibrotic factors appear to play a significant role because inhibition of angiotensin synthesis by ACE inhibitors or antagonism of the AT$_1$ receptors blunts but does not completely abolish the fibrotic process (Kaneto et al, [illegible]; Ishidoya et al, 1995; Pimental et al, 1995).

Cellular and Molecular Mechanisms Leading to Tubular Cell Death

Besides inflammation and fibrosis of the kidney, renal obstruction produces atrophy and cell death. The major mechanism by which tubular cells die is apoptosis, a process that is normally involved in postnatal development and tissue renewal in adults. The process can be triggered by both intrinsic and extrinsic factors and results in degradation and condensation of the nucleus. The cells are further degraded into apoptotic bodies, which are eventually phagocytized by healthy cells without inducing inflammation. When rat kidneys are obstructed, renal tubular cell apoptosis begins in about 4 days and peaks after 15 days, with interstitial cell apoptosis continuing for the duration of obstruction (Choi et al, 2000). Glomerular cells appear to be resistant to obstruction-induced apoptosis.

Cysteinyl aspartate–specific proteinases (caspases) are known to mediate apoptotic cell death in obstructed kidneys (Hengartner, 2000; Truong et al, 2001). This family of 12 enzymes can be categorized into three main groups: initiators, effectors, and cytokine processors. Two distinct pathways of caspase activity are involved. One pathway involves activation of membrane death receptors by extrinsic binding of TNF-α to its receptor. A second pathway involves intrinsic stress signals that result in mitochondrial release of proapoptotic proteins such as cytochrome *c*. The two pathways converge to activate effector caspases, which cleave nuclear and cytoplasmic components, resulting in condensation of nuclear material and cell death. Truong and colleagues (2001) showed that all of the caspases increased with renal obstruction and that their levels paralleled renal cell apoptosis. Caspases 3 and 8 best correlated with renal cell apoptosis and appear to be central to this process (Choi et al, 2000; Truong et al, 2001).

In contrast to the defined role of angiotensin II in obstruction-induced renal fibrosis, its involvement in renal cell apoptosis is less clear. In mice with a knockout deletion of the AT2 receptor, there is a decreased degree of obstruction-induced apoptosis. However, these receptors are normally downregulated in the adult kidney, and their role in normal function and pathophysiologic responses is uncertain in the mature kidney. Enalapril pretreatment has been shown by one group of investigators to reduce apoptosis in the early phases of renal obstruction (Truong et al, 1998), but others have reported conflicting results.

TNF-α can be a directly cytotoxic cytokine that can induce apoptosis in addition to its role in renal inflammation. When TNF-α binds to its receptor, TNFR1, an associated death domain (TRADD) binds to the TNFR1 and activates several signaling pathways. When coupled to a Fas-associated death domain, it triggers caspase 8 activation, which is pivotal to apoptosis. Alternatively, the TNFR1-TRADD complex can activate NFκB, which can have both pro- and antiapoptotic activity depending upon the cellular milieu. Increased amounts of TNF-α and its receptors have been demonstrated in rat models of obstruction (Tartaglia et al, 1991; Kaneto et al, 1996; Choi et al, 2000) along with other components of this cascade. These findings suggest an important role for TNF-α in apoptosis after obstruction.

In summary, obstruction of normal ureteral outflow results in biochemical, immunologic, hemodynamic, and functional changes. It stimulates a cascade in which elevated levels of angiotensin II, cytokines, and growth factors lead to cellular inflammation, increased net matrix formation, tubulointerstitial fibrosis, and tubular cell apoptosis. Many of the mediators are intrinsic to the renal tubular cells, whereas others are contributed by fibroblasts and by migrating macrophages (Fig. 37–3).

Experimental Treatment Approaches to Attenuate Renal Fibrosis and Functional Impairment

The aforementioned cascade of events points to many possible avenues to attenuate renal damage associated with obstruction. Experimental strategies to attenuate these noxious responses are reviewed.

Wamsley-Davis and colleagues (2004) administered the ACE inhibitor enalapril, AT1 antagonists losartan or candesartan, or vehicle for up to 52 days to male rats with UUO. Candesartan inhibited the rise in JNK1 activity, losartan attenuated it, and enalapril did not affect it. Candesartan also reduced SMAD2 protein activation while attenuating the chronic tubulointerstitial fibrotic injury in obstructed kidneys and preserved renal mass. The apparent differences between candesartan, losartan, and enalapril may be dose or delivery related in that the AT1 antagonists were continuously infused by minipumps, whereas enalapril was added to the drinking water and dose-response relationships were not examined. In another study in which oral enalapril was studied in rats with UUO, enalapril accelerated the reversal of interstitial expansion after the release of obstruction.

Manucha and colleagues (2004) showed that losartan prevented the development of renal fibrosis and kept interstitial volume and TGF-β mRNA expression near control levels. Furthermore, these investigators implicated the well-known interactions between angiotensin II and activation of NOS isoforms and cyclooxygenase 2 (COX-2) in the inflammatory process. Whereas UUO increased iNOS in the obstructed renal medulla and increased neuronal NOS (nNOS) and endothelial NOS (eNOS) in the cortex, losartan treatment downregulated iNOS and nNOS with unchanged levels of eNOS. In addition, obstruction increased COX-2 expression in the obstructed renal cortex. It, too, was decreased by losartan treatment. **These studies suggest an important role of angiotensin-mediated profibrotic and apoptotic events occurring with renal obstruction that can be reduced with currently available inhibitors of angiotensin synthesis or receptor blockade.**

The known association of aldosterone and cardiac fibrosis prompted investigators to assess whether the administration of an aldosterone antagonist could attenuate the renal fibrosis generated with obstruction. Trachtman and coworkers (2004) examined this in a rat model of UUO. Whereas 1 week of obstruction produced minimal parenchymal damage, 2 weeks of obstruction produced renal fibrosis, which was significantly reduced by administration of the aldosterone antagonist spironolactone without raising serum potassium or aldosterone concentrations.

Nitric oxide synthases are known to be double-edged swords in the processes of tissue perfusion and tissue inflammation. Obstruction increases inducible, neuronal, and

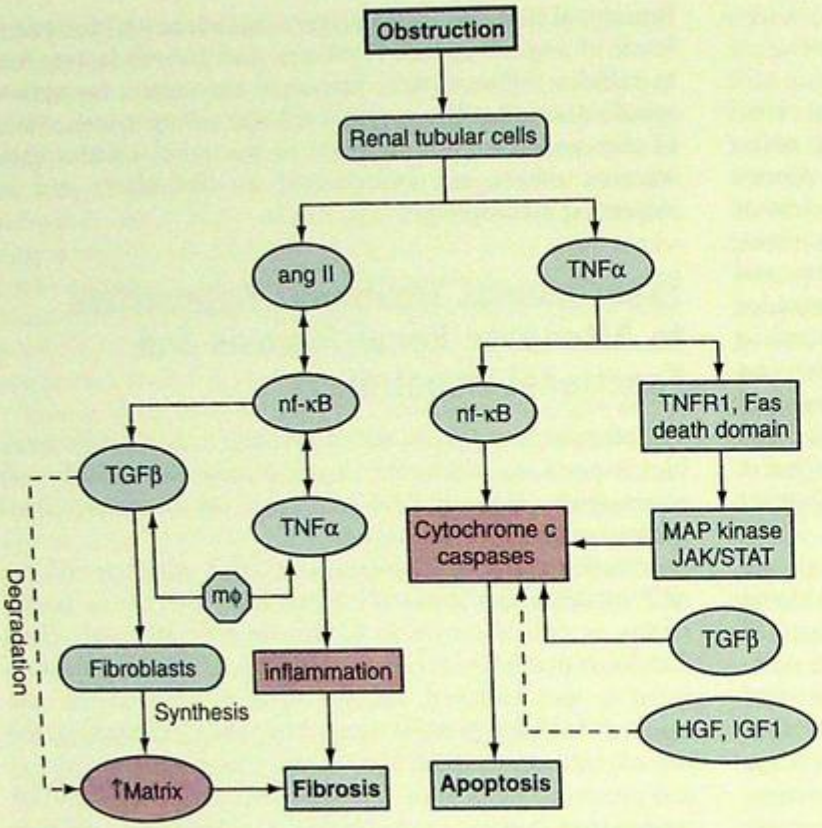

Figure 37–3. Summary of major pathways leading to tubulointerstitial fibrosis and tubular apoptosis as a consequence of ureteral obstruction. Membrane proteins and regulators are discussed in the text. ang II, angiotensin II; HGF, human growth factor; IGF, insulin-like growth factor; JAK/STAT, Janus kinase/signal transducers and activators of transcription; mϕ, macrophages; MAP, mitogen-activated protein; nf-κB, nuclear factor κB; TGF, transforming growth factor; TNF, tumor necrosis factor; TNFR1, tumor necrosis factor receptor 1.

endothelial NOS and high concentrations of NO can result in peroxynitrite production. Administration of L-arginine by infusion or even by oral administration prevents the upregulation of iNOS, blunts the increase in renal interstitial volume, and attenuates the infiltration of the renal parenchyma by macrophages in rats with obstructed kidneys (Ito et al, 2004b; Klahr and Morrissey, 2004).

Klahr and Morrissey (2003) showed that bone morphogenic protein 7, a structural relative of TGF-β, was effective in preventing the tubulointerstitial changes and accelerating the return of renal function in a rat model of obstruction. They demonstrated that this agent inhibited apoptosis. This group also reported that the administration of hepatocyte growth factor has similar beneficial effects and proposed that it works by suppressing expression of TGF-β and PDGF. Pirfenidone, a drug that purportedly inhibits collagen synthesis, downregulates production of multiple cytokines and blocks fibroblast proliferation. It may be another candidate to attenuate obstruction-induced renal injury and facilitate renal remodeling (Lasky, 2004).

Although the results of the preliminary studies are encouraging, these agents should not be prescribed to patients for this purpose at this time. Their safety and efficacy first need to be established through carefully designed and controlled clinical studies.

Compensatory Renal Growth

Compensatory renal growth of the unobstructed kidney was first described by Hinman (1943). This phenomenon has been subsequently demonstrated in a number of other animal models of UUO (Taki et al, 1983; Peters et al, 1993). There is evidence that it occurs in the human fetus. An increase in contralateral renal volume has been detected ultrasonographically when hydronephrosis or unilateral renal agenesis is present (Mandell et al, 1993).

The mechanisms and nature of this growth are influenced by several factors including age and degree and duration of obstruction. Both hyperplastic and hypertrophic compensatory growth have been demonstrated (Dicker and Shirley, 1973; Castle and McDougal, 1984; Peters et al, 1993). Compensatory growth was demonstrated to decrease progressively with increasing age at which the obstruction occurred in animal models (Taki et al, 1983). **Studies of humans subjected to nephrectomy, a functional surrogate for obstruction, have demonstrated that a reduction in renal compensatory growth occurs with increasing age** (Edgren et al, 1976). Animal experiments have also demonstrated that compensatory growth is directly proportional to the duration of obstruction (Chevalier et al, 1999). Compensatory growth is less prominent with partial than with total UUO (Chevalier and Kaiser, 1984; Eskild-Jensen et al, 2001). **While the kidney enlarges, an increase in the number of nephrons or glomeruli does not occur** (Peters et al, 1993). However, an increase in the length of the proximal tubule has been described (Moller, 1988).

Insulin-like growth factor I (IGF-I), a mitogenic and anabolic peptide, may play a role in compensatory renal growth after obstruction. There is both animal and clinical evidence for its role. In rats, mean renal IGF-I is significantly elevated in the normal kidney compared with the contralateral 7-day obstructed kidney (Serel et al, 2000). Inferences can also be made from nephrectomy performed in animals and humans. Renal IGF-I mRNA levels are increased in immature rats previously subjected to nephrectomy (Mulroney et al, 1991). Significant increases in serum IGF-I have been demonstrated

in humans after donor nephrectomy and peak 6 months after the procedure. Serum IGF-I was positively correlated with increases in renal volume demonstrated on serial postoperative imaging (Nam and Chang, 1999). It has also been demonstrated that the expression of IGF-I may be age dependent. Although renal IGF-I mRNA levels were found to be elevated after nephrectomy in immature rats, this did not occur in adult rats (Mulroney et al, 1991). Exogenous IGF-1 can attenuate renal injury from obstruction (Chevalier et al, 2000).

The presence of compensatory growth in infants has been considered by some as an indicator that contralateral hydronephrosis is functionally significant (Koff and Peller, 1995). However, this approach has been challenged by others (Brandel et al, 1996). In addition, it was demonstrated that functional deterioration occurred in a rat model of partial UUO before compensatory growth developed in the contralateral renal unit. This implies that there may be a risk for functional renal loss if one utilizes only compensatory growth as an indication of correction of obstruction (Wen et al, 1999).

Renal Recovery after Obstruction

The duration of obstruction has a significant influence on renal functional recovery. **When acute, complete ureteral obstruction is promptly relieved, full recovery of global GFR can occur.** In the rat model, after 3 days of UUO, GFR and RBF were reduced to less than 10% of their baseline values. Both returned to their baseline within 14 days of relief of obstruction (Ito et al, 2004a). Bander and colleagues (1985) also noted complete return of GFR by 14 days after 24 hours of acute UUO, although they noted that the recovery was heterogeneous at the nephron level. Studying SNGFR, they found that approximately 15% of superficial and juxtamedullary nephrons were permanently lost, but hyperfiltration of the remaining nephrons allowed maintenance of whole kidney GFR. **Longer periods of complete ureteral obstruction are associated with diminished return of GFR.** Kerr (1954) reported that in dogs with complete UUO for 7 days, GFR 1 hour after relief of obstruction was 25% of the preligation GFR. GFR was then followed over time to assess the degree and time course of renal recovery. Maximal recovery was 58% of baseline, and this occurred within 57 days. Similar studies were conducted by Vaughan and Gillenwater (1971), who demonstrated that there was full functional renal recovery at 2 weeks after a 7-day period of UUO in dogs. This result declined to 70% recovery of GFR after 14 days of UUO, 30% after 4 weeks of UUO, and no recovery after 6 weeks of UUO.

The fate of the human kidney after prolonged periods of obstruction is less well defined and may be unpredictable. Functional recovery has been reported after a 150-day period of UUO (Shapiro and Bennett, 1976). Permanent reductions in GFR may occur after UUO or BUO in humans. However, there may be a differential pattern of recovery after BUO in adults. Jones and associates (1988) described two phases of functional improvement: an initial phase during the first 2 weeks after relief of obstruction when tubular function improved and a later phase occurring over the next 10 weeks when GFR gradually improved. Patients with BUO or obstruction of a solitary kidney may also be at risk for unique sequelae such as chronic urinary acidification and concentrating defects (Berlyne, 1961).

Other factors influence functional return. Factors that have a positive influence on functional recovery include a smaller degree of obstruction, greater compliance of the collecting system, and presence of pyelolymphatic backflow (Shokeir et al, 2002). Conversely, older age and decreased renal cortical thickness are predictors of diminished recovery of renal function (Lutaif et al, 2003).

Nuclear renography may help predict functional recovery. An assessment of functioning cortex with such imaging is the best predictor. For example, **dimercaptosuccinic acid (DMSA), a cortical agent, has been shown to be superior to tubular selective agents such as diethylenetriaminepentaacetic acid (DTPA) or mercaptoacetyltriglycine (MAG3) for the prediction of renal recovery.** This was demonstrated in a prospective study in children undergoing pyeloplasty or ureteral reimplantation for ureterovesical junction obstruction (Thompson and Gough, 2001). It was postulated that DMSA better defines functional cortex and is less affected by the dilated collecting system and dilution by undrained urine. Similarly, when the tubular agent *ortho*-iodohippurate was utilized, whole kidney activity was less predictive than the cortical phase (Kalika et al, 1981).

Renal recovery after relief of obstruction is affected by the duration of obstruction, degree of obstruction, patient's age, and baseline renal function. Cortical phase nuclear renograms may offer accurate prediction of the capacity of the kidney to recover after reversal of the obstruction.

PATHOLOGIC CHANGES OF OBSTRUCTION

Distinct gross and microscopic pathologic changes may occur with obstruction of the upper urinary tract. These may be affected by the presence of infection, duration of obstruction, and intra- versus extrarenal localization of the renal pelvis.

Gross Pathologic Findings

The gross pathologic changes occurring in the kidney have been characterized in animal models and parallel those in humans. Hodson and colleagues (1969) performed unilateral ureteral ligation in a porcine model and described pathologic changes in both kidneys over several time points. Dilation of the pelvis and ureter and blunting of the papillary tips were present in the obstructed kidney at 42 hours after obstruction and the weight of this renal unit was heavier. Pelviureteric dilation and weight further increased and the parenchyma became edematous in the obstructed kidney at 7 days. The cortex remained slightly enlarged, and there was increased calyceal dilatation at 12 days in this renal unit; at 21 and 28 days, the external renal dimensions of both kidneys were similar. However, the cortex and medullary tissue in the obstructed kidney were diffusely thinned. Ladefoged and Djurhuus (1976) evaluated partial and complete obstruction in a porcine model. **They found that totally obstructed kidneys were enlarged, had a cystic appearance, and weighed less than the contralateral renal unit 6 weeks after obstruction. However, such gross differences in appearance were not present at this interval in the partially obstructed kidneys.**

Microscopic Pathologic Findings

Light microscopic changes reported in the aforementioned porcine model at 42 hours after obstruction included lymphatic dilation, interstitial edema, and tubular and glomerular preservation. Collecting duct and tubular dilatation was prominent by 7 days. In addition, further interstitial edema, widening of Bowman's space, tubular basement membrane thickening, cell flattening, and cytoplasmic hyalinization were demonstrated. Papillary tip necrosis, regional tubular destruction, and inflammatory cell response were noted at 12 days (Hodson et al, 1969). Interstitial fibrosis and thickening of the tubular basement membranes were reported at 16 days after obstruction in a mouse model (Sharma et al, 1993). The inner cortex demonstrated severe tubular loss, proliferation of fibroblasts, and collagen deposition 3 weeks after obstruction in the porcine kidney. Cortical thinning and development of glomerular crescents were present at the 3- to 4-week interval in this model (Hodson et al, 1969). **Widespread glomerular collapse and tubular atrophy, interstitial fibrosis, and proliferation of connective tissue in the collecting system were reported at 5 to 6 weeks after obstruction in the porcine model** (Ladefoged and Djurhuus, 1976). Similar findings are noted in the chronically obstructed human kidney (Figs. 37–4 to 37–6).

Electron Microscopic Pathologic Findings

Electron microscopic (EM) studies have confirmed the aforementioned light microscopic findings, including the presence of tubular atrophy, glomerular collapse, and renal pelvic smooth muscle atrophy at 5 to 6 weeks after obstruction (Fig. 37–7). Electron microscopic studies have also demonstrated other changes including the development of a cell-poor stroma composed of elastic and collagen fibers in the renal interstitium and obstructed portions of the collecting system (Ladefoged and Djurhuus, 1976). Collagen and elastin are normal components of the collecting system but are more prominent and have structural changes with obstruction (Gosling and Dixon, 1978; Murakumo et al, 1997).

GENERAL ISSUES IN MANAGEMENT OF PATIENTS

Diagnostic Imaging

As the clinical signs and symptoms of obstructive uropathy are so widely variable, prompt and accurate diagnosis is dependent upon appropriate imaging. The practicing urologist should be well versed in the diagnostic imaging modalities currently available as well as their relative advantages, limitations, and appropriate modifications. An overview of current imaging techniques, with an emphasis on recent modifications, is presented here.

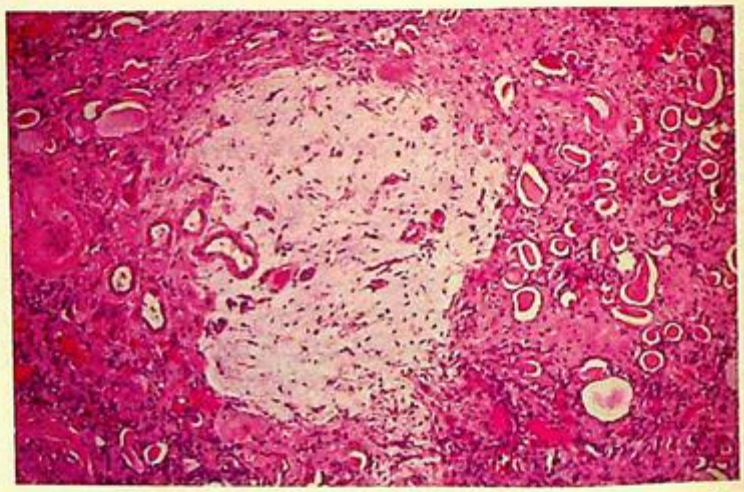

Figure 37–5. Sections of deep cortex and outer medulla from a patient with chronic obstructive uropathy. Obsolescent glomerulus (left edge) and pool of extravasated Tamm-Horsfall protein (center) are seen. Hematoxylin and eosin stain; original magnification, ×25. (Courtesy of Dr. Sami Iskandar.)

Ultrasonography

Renal ultrasonography is a mainstay in the evaluation of suspected urinary tract obstruction. Although it is primarily an anatomic study, Doppler modifications may add a functional component. **There is no associated ionizing radiation, and it is thus considered safe in pediatric and pregnant patients. Because there is no need for iodinated contrast material, ultrasonography can be utilized in those with azotemia or contrast allergy.** As it remains relatively inexpensive and widely available, ultrasonography is often a first-line investigation.

Renal parenchymal thickness can be measured readily, and cortical thinning may be indicative of chronic obstruction. The renal pelvis and calyces can be imaged, and dilatation is readily identifiable. **Caution in interpretation must be exercised, however, in that hydronephrosis is an anatomic as opposed to a functional diagnosis. Specifically, caliectasis and pelviectasis both may exist in an unobstructed system.** Functional inferences cannot be presumed from static images. For instance, the hydronephrosis of vesicoureteral reflux may not be obstructive. In addition, renal sinus cysts can be misinterpreted as hydronephrosis. Conversely, early in acute obstruction, hydronephrosis may not be prominent, and the presence of an intrarenal collecting system or dehydration may lead to false-negative interpretations. **A prospective study of ultrasonography in obstruction by Laing and colleagues (1985) revealed a 35% false-negative rate in acute obstruction, underscoring the need to correlate the clinical picture carefully with the radiologic findings.**

Doppler ultrasonography allows measurement of the renal resistive index (RI), which has been used to assess for obstruction. The RI is defined as peak systolic velocity (PSV) minus the end-diastolic velocity (EDV) divided by the PSV. Several groups have assessed its ability to diagnose obstruction, but its utility has yet to be fully established. Platt and coworkers (1991) have suggested 0.7 as the upper limit of normal, with values greater than 0.7 reflecting elevated resistance to blood flow and thus suggesting obstructive uropathy. They subsequently reported their experience using this modality in 23 patients with acute unilateral obstruction. Three patients had false-negative studies, two of whom had pyelosinus extravasation and one of whom had been obstructed for less than 5 hours. They concluded that Doppler determination of RI was a valuable adjunct to routine sonographic evaluation of urinary tract obstruction (Platt et al, 1993). Conversely, others have found the sensitivity inadequate for the detection of obstruction. Tublin and associates (1994) reported that of 32 patients with colic, 12 of 19 patients with obstruction had normal RI and 5 of 13 without obstruction had abnormal RIs.

One factor that may account for the dichotomy between such studies is the degree of obstruction. Chen and colleagues (1993) evaluated 27 patients with suspected obstruction by both Doppler ultrasonography and intravenous pyelography. Overall, utilizing an RI of 0.7 as the critical value, the sensitivity was only 52%. However, when correlated with degree of obstruction on intravenous pyelography, RI was shown to differentiate the kidneys with mild obstruction from those with severe obstruction. In those with mild obstruction, the mean RI was only 0.64, whereas in those with severe obstruction the mean RI was 0.74, and the sensitivity of an RI greater than 0.70 for significant obstruction was 93.3%. Fung and coauthors (1994) also assessed this modality for evaluating obstruction. They measured RI in nine patients undergoing Whitaker testing for grade 3 or 4 hydronephrosis and reported that RI directly correlated with renal pelvic pressure. They determined that when renal perfusion pressures were normal RI was less than 0.82. Major pitfalls in many of the studies assessing this modality have been the inconsistent definition of obstruction and degree of obstruction. **Although the presence of hydronephrosis associated with an abnormally elevated RI may be indicative of the severity of obstruction, it is important to recognize these limitations and use other clinical information and renal functional assessment for treatment planning.**

Excretory Urography

Long considered the "gold standard" for the evaluation of the upper urinary tract, excretory urography (EXU) has been gradually supplanted by other modalities for many of its prior indications. Nevertheless, it provides both anatomic and functional information, underscoring its utility. **Acute urinary**

obstruction may be inferred from the *functional* abnormality of a delayed nephrogram and pyelogram on the affected side or sides. Delayed images may then ultimately reveal the *anatomic* level of obstruction and perhaps causation. In addition, other signs may be present that may indicate chronicity of obstruction such as parenchymal thinning, extreme calyceal blunting, and ureteral tortuosity.

As the imaging is dependent upon glomerular filtration and renal concentration of the contrast medium, the utility of EXU is limited in those with renal insufficiency. Furthermore, the risk of contrast nephropathy increases with increasing serum creatinine. EXU, therefore, should not be performed in subjects with renal insufficiency, those who are at higher risk for developing contrast-induced nephropathy, or those with history of contrast allergy. Radiation exposure limits its utility in pregnancy, although abbreviated protocols have been established (Zagoria and Tung, 1997).

Retrograde Pyelography

Retrograde pyelography accurately defines ureteral and collecting system anatomy, including the location of an obstructive lesion and its extent. It should be considered in those who have renal insufficiency or have other risks for receiving intravenous iodinated contrast material. It may also be used in cases in which anatomy is not sufficiently defined with other imaging studies. In essence, a loopogram is another form of retrograde pyelography and may be useful in evaluating patients with cutaneous urinary diversion when obstruction is suspected.

Antegrade Pyelography

This technique may be helpful when other imaging studies do not adequately define collecting system or ureteral anatomy and when retrograde pyelography is not technically feasible.

Whitaker Test

First described by Whitaker in 1973, this study involves measurement of renal pelvic pressure during infusion of either saline or contrast material into the collecting system through a percutaneous needle or nephrostomy at a fixed rate of 10 mL/min. A catheter is placed in the bladder to monitor intravesical pressure, which is subtracted from the measured collecting system pressures to calculate the "true pressure" within the pelvis. **A true intrapelvic pressure of less than 15 cm H_2O is considered normal, greater than 22 cm H_2O indicative of obstruction, and between 15 and 22 cm H_2O indeterminate.** Although its reliability to detect obstruction and differentiate degree of obstruction has been established in animal models (Ryan et al, 1989), the clinical utility of this test has been advocated by some and questioned by others. For example, one group reported that it was a valid test to confirm ureteral obstruction after renal transplantation (Kashi et al, 1993). However, others have reported a sensitivity and specificity of only 79% and 50% in this setting (Sperling et al, 2000).

Other concerns regarding potential shortcomings of the Whitaker test have been noted. Mortensen and colleagues (1983) reported wide variation in pelvic pressures in a normal porcine model, questioning the definition of a "normal" study. It has also been noted that a small, noncompliant obstructed system may give rise to a more rapid increase in pressure than a large, dilated obstructed system (Wahlin et al, 2001). Modifications have been suggested to overcome this pitfall. Individualized infusion rates based on maximum physiologic urine output have been advocated by some (Fung et al, 1995). Wahlin and colleagues (2001) proposed measuring flow as a function of pressure over a range of physiologic pressures. Resistance was then calculated and used to categorize responses as nonobstructed, indeterminate, or obstructed. They found that the major benefit of this modification was that it allowed identification of obstruction in some patients categorized as indeterminate with the standard Whitaker test. These noted discordant results and the invasiveness of the study reflect the Whitaker test's limited applicability in contemporary clinical practice.

Nuclear Renography

Nuclear renography is a useful, noninvasive test for evaluating patients with suspected obstruction. **It provides a functional assessment without exposure to iodinated contrast material.** Radiopharmaceuticals for renography are selected on the basis of the function to be studied. The glomerular agent Tc 99m DTPA and the tubular agent Tc 99m MAG3 are most commonly used in the evaluation of obstruction. All radiopharmaceutical tracers are administered intravenously, and their uptake and subsequent clearance can then be evaluated and quantitated scintigraphically. From these data, relative renal function can be calculated. Obstruction can be assessed by measuring the clearance curves, either from a visual assessment of the pattern or from calculation of the half-time (time at which 50% of the radiopharmaceutical is eliminated from the collecting system). **By convention, a half-time less than 10 minutes is considered normal, greater than 20 minutes is considered obstructed, and between 10 and 20 minutes is equivocal.** Tracer clearance can be spuriously delayed because of renal insufficiency and the presence of vesicoureteral reflux, and some have suggested that renal immaturity in neonates may generate false-positive studies (Karam et al, 2003).

In order to detect obstruction, a high-flow state may be necessary. Patients therefore should be well hydrated to prevent misinterpretation related to low-flow states. Theoretically, bladder catheterization should be performed to maintain low intravesical pressure. However, in clinical practice this is utilized only in certain cases such as suspected lower urinary tract obstruction, vesicoureteral reflux, neurogenic or noncompliant bladder, or low-lying, pelvic kidneys from which the renal signal may be obscured by intravesical radiopharmaceutical (Karam et al, 2003). The diuretic renogram is a modification designed to maximize flow and potentially distinguish truly obstructed collecting systems from those that are dilated but unobstructed. Because a given patient's response to the diuretic may be affected by the patient's baseline renal function, adjustments may need to be made on the basis of creatinine clearance (Upsdell et al, 1988).

As classically described, the diuretic, typically furosemide (F), is administered 20 minutes after the tracer to induce a brisk diuresis (F +20 study). Others have suggested alteration of diuretic timing to coincide with tracer administration (F +0) or precede it by 15 minutes (F −15). English and colleagues (1987) recognized that some patients with a partial obstruction may eliminate the tracer in the 20 minutes before

the induction of diuresis using the standard, F +20 sequence. To address this, they advocated administration of diuretic 15 minutes before injection of the radiopharmaceutical (F −15) so that initial tracer clearance could be studied during the period of maximal diuresis. Thirty-five renal units with hydronephrosis having equivocal or normal standard (F +20) diuretic renograms were evaluated by English and colleagues using the F −15 sequence. Utilizing contralateral normal kidneys for comparison, they selected a clearance half-time less than 5 minutes as normal, greater than 10 minutes as obstructed, and between 5 and 10 minutes as equivocal. With these criteria, 13 of the kidneys were demonstrated to be obstructed and 18 were shown to be unobstructed. Only four kidneys remained in the equivocal range, underscoring the utility of this modified approach. This has also been confirmed in a crossover designed study demonstrating that **although an F +20 study is reliable when obstruction is demonstrated, both the F −15 and F +0 sequences can induce obstructed patterns in previously equivocal cases** (Turkolmez et al, 2004).

Computed Tomography and Magnetic Resonance Imaging

Cross-sectional imaging, provided by computed tomography (CT) and magnetic resonance imaging (MRI), generates greater anatomic definition of abdominal and retroperitoneal anatomy than EXU or ultrasonography. In the previous edition of this textbook, unenhanced helical CT was described as an alternative to EXU. Over the brief elapsed time, because of its speed, safety, and accuracy, this modality has now replaced EXU as an initial imaging study in those with suspected ureteral obstruction, especially in an acute setting such as stone-induced colic. In their landmark study, Smith and coauthors (1995) demonstrated the efficacy of unenhanced helical or spiral CT in the evaluation of possible ureteral obstruction, prospectively comparing it with EXU in 20 patients presenting with acute flank pain. Obstruction was identified by EXU and CT in 12 patients. In these 12 patients, the ureteral calculus was identified in 11 with CT and only 5 with EXU. In the last remaining patient with obstruction, multiple high-attenuating pelvic clips obscured definitive identification of a calculus, although a dilated ureter could be traced down to the level of these clips. **In the detection of ureteral calculi, CT has a sensitivity of 97%, specificity of 96%, and overall accuracy of 97%** (Smith et al, 1996b). **At this time, CT is the most accurate radiologic study for the diagnosis of ureteral calculi.**

CT directly demonstrates calculi classically considered radiolucent when evaluated by plain radiography, including uric acid, xanthine, dihydroxyadenine, and many drug-induced stones. Exceptions, however, are calculi composed of protease inhibitors, which are not visualized by CT (Gentle et al, 1997). Secondary CT signs of obstruction such as ureteral dilatation, nephromegaly, perinephric stranding, or fluid can facilitate the diagnosis of acute obstruction. These signs have been reported to have a positive predictive value of 99% and negative predictive value of 95% for identification of acute ureteral obstruction (Smith et al, 1996a). This is also an excellent study for evaluating patients suspected of having chronic obstruction who have renal insufficiency or other contrast risks.

Contrast-enhanced spiral CT has also been advocated for the evaluation of patients with chronic obstructive uropathy and normal serum creatinine. In addition to the aforementioned anatomic details afforded by noncontrast CT, functional evaluation including calculation of differential GFR is possible. Abo El-Ghar and colleagues (2004) compared contrast-enhanced CT with EXU and nuclear renography in 65 patients. **CT had significantly improved sensitivity for identification of the cause of obstruction compared with EXU.** Furthermore, they reported an excellent correlation between isotope and CT estimated GFR. Multiphasic helical CT has also been shown to be useful in surgical planning for ureteropelvic junction obstruction, with sensitivity for detection of crossing vessel of 97%, specificity of 92%, and overall accuracy of 96% (El-Nahas et al, 2004).

The role of magnetic resonance urography (MRU) is still being defined (Rothpearl et al, 1995). **Although this study accurately identifies hydroureteronephrosis, a limitation is its inability to demonstrate either calculi or the ureteral anatomy of unobstructed systems.** The latter can be overcome with the administration of diuretics, which facilitates imaging of the nonobstructed collecting system and ureters. Diuretic MRU thus has utility for assessing patients with obstruction. A prospective study compared it with EXU in patients with ureteral obstruction (Karabacakoglu et al, 2004). The accuracy of diuretic MRU for detection of obstruction was demonstrated to be 93% in those with obstructing stones and 100% in those with obstruction related to strictures or congenital anomalies, whereas the accuracy of EXU was 96% and 55%, respectively. The incorporation of intravenous administration of gadopentetate-DTPA has allowed a dynamic, functional assessment of the collecting system that correlates well with diuretic renal scintigraphy yet provides far greater anatomic detail than nuclear studies. Differential GFR can be assessed with postimaging processing, and contrast washout can be measured to calculate renal clearance, differentiating dilated systems from obstructed systems (Rohrschneider et al, 2002; Chu et al, 2004). Cost, availability, time for acquisition of images, and need for sedation in pediatric patients have all been cited as possible limitations of this technique, but the superior anatomic detail, functional assessment, elimination of risk of contrast-induced nephropathy, and lack of ionizing radiation make this an attractive option that is likely to continue to evolve. **The absence of ionizing radiation has allowed its utilization in the assessment of pregnant patients with flank pain and hydronephrosis, which is further explored in the discussion of hydronephrosis of pregnancy later in this chapter.**

Hypertension

Ureteral obstruction that is symptomatic, accompanied by fever, complicated by an undrained infection, or determined to be high grade, bilateral, or inducing renal failure warrants immediate drainage of the affected renal unit. The indications for the relief of urinary tract obstruction are outlined in Table 37–2.

Hypertension can be precipitated by ureteral obstruction and is a well-recognized sequela of BUO or obstruction of a solitary kidney. Vaughan and Gillenwater (1973) noted hypertension in 17 of 22 patients with BUO, which was corrected in

Table 37–2. Indications to Relieve Obstruction

Unilateral Obstruction	*Bilateral Obstruction*
Pain unrelieved by analgesics	Same as for UUO *or*
Signs and symptoms of sepsis	Elevated BUN and creatinine
Persistent nausea and vomiting	Signs and symptoms of uremia
High-grade obstruction	Hyperkalemia

BUN, blood urea nitrogen; UUO, unilateral ureteral obstruction.

15 subjects upon relief of BUO. This response has also been demonstrated in pregnant patients with BUO (Satin et al, 1993). Patients with BUO are typically volume overloaded. Gulmi and colleagues (1989) measured ANP and plasma renin activity (PRA) in nine patients with BUO before and after relief of obstruction and compared them with those of age-matched control subjects. ANP was significantly increased in the BUO group prior to relief and progressively returned to normal after drainage. Conversely, PRA was depressed prior to relief of BUO. These findings are suggestive of a volume-mediated mechanism for hypertension in BUO. Hypertension is significantly less common, however, with UUO (Vaughan and Sosa, 1995). In contrast to the BUO model, in UUO the contralateral, unobstructed kidney compensates and eliminates excess volume and solutes. Renin activation and resultant angiotensin II generation have been demonstrated in animal models of UUO and may be the mechanism by which new-onset hypertension occurs in this setting. Pain may be another contributing factor (el-Dahr et al, 1993). **In summation, there is a good chance of reversal of new-onset hypertension with relief of BUO but this is less likely with UUO.**

Renal Drainage

Minimally invasive endourologic and interventional radiologic techniques allow prompt drainage of the obstructed kidney. These measures may allow temporary drainage until a definitive procedure is performed or, in some circumstances, may be a permanent form of management. Urine specimens for urinalysis and culture should be obtained from the obstructed renal unit at the time of relief of obstruction when infection is suspected. Antibiotic therapy is started if these tests are indicative of infection or there are clinical signs and symptoms of infection.

The relative merits of indwelling ureteral stents and percutaneous nephrostomy tubes have been evaluated by several groups. Indwelling stents obviate the need for external collection devices but are associated with bothersome voiding symptoms. In spite of this, prospective studies have demonstrated that there is no statistically significant difference in health-related quality of life (Joshi et al, 2001; Mokhmalji et al, 2001). The choice of drainage ultimately depends on the clinical setting. If the patient has an uncorrectable coagulopathy or platelet abnormality, ureteral stenting is indicated. There does not appear to be a significant advantage of either approach in those requiring drainage for stone-related problems (Pearle et al, 1998; Mokhmalji et al, 2001).

Ureteral stenting may not be as effective for treating patients with extrinsic ureteral obstruction. Docimo and Dewolf (1989) reported a mean 43% failure rate in ureteral stents placed for extrinsic ureteral obstruction, the majority related to malignancy. This was subsequently confirmed in a prospective study evaluating success rates for retrograde ureteral stenting (Yossepowitch et al, 2001). Initial retrograde access failed in 27% of patients with extrinsic ureteral obstruction, compared with only 6% of those with intrinsic obstruction. At 3-month follow-up, 56.4% of stents placed for ureteral obstruction had failed. Of note, on multivariate analysis, stent diameter did not predict risk of stent failure. Chung and colleagues (2004) similarly identified an overall 42% rate of stent failure in patients with extrinsic obstruction of the ureter and additionally noted that 43% of those failures occurred within 6 days of the initial placement. **A diagnosis of cancer, metastatic disease requiring chemotherapy or radiation, and renal insufficiency were predictors of stent failure in this series.** Some have advocated the placement of two parallel ureteral stents to provide better drainage as an alternative to percutaneous nephrostomy (Liu and Hrebinko, 1998). **Closer monitoring for stent failure should thus be considered in patients with extrinsic ureteral obstruction** (Ku et al, 2004).

Compared with percutaneous nephrostomy placement, stent placement typically requires greater x-ray exposure (Mokhmalji et al, 2001). This may be of concern in pregnant patients, particularly early in gestation when the fetus is most sensitive to radiation effects (McAleer and Loughlin, 2004). Ultrasound-guided ureteral stent placement is a described option in this setting (Jarrard et al, 1993). Another issue in this cohort is acceleration of stent encrustation, which may be due to increased calcium excretion during pregnancy (Goldfarb et al, 1989). Nephrostomy tube drainage is an option for pregnant patients if this problem arises (Denstedt and Razvi, 1992). Percutaneous nephrostomy should be strongly considered if pyonephrosis is suspected. However, if it is not suspected and thick, purulent fluid is obtained from the kidney at ureteral stenting, placement of a large-diameter stent is recommended. If this does not provide satisfactory drainage, percutaneous nephrostomy should be performed.

Choice of Surgical Intervention

After the acute obstruction has been addressed, definitive management is based upon the cause of the obstruction, the functional recovery of the affected kidney and the condition of its counterpart, and the patient's age and medical status. Endoscopic, open, or laparoscopic ablative and reconstructive procedures may all be utilized. Indications and pertinent preoperative, intraoperative, and postoperative considerations are discussed elsewhere in this text. The threshold of differential renal function for which reconstruction may be preferable to nephrectomy, although still debated, has been proposed to be between 15% to 20% (Thompson and Gough, 2001). The decision to remove a kidney should be made only after the affected kidney has been adequately drained for a sufficient period of time, 6 to 8 weeks based on the results of animal experimentation (Kerr, 1954). Split renal function can be assessed by measuring creatinine or inulin clearance (both surrogates of glomerular filtration) directly from bilateral nephrostomy tubes or a nephrostomy tube and an indwelling urethral catheter when there is complete UUO and the other

renal unit is not obstructed. However, nuclear imaging techniques are more commonly utilized to assess renal function in this setting.

A less than 10% contribution to global renal function has been proposed as the threshold for nephrectomy. Another criterion has been the ability of the affected renal unit to provide sufficient function to prevent dialysis dependence if the contralateral kidney were removed. These criteria were not generated by prospective study but by clinical inference from functional reconstructive outcomes. For example, renal units with less than 10% renogram-derived differential function in children have been shown to derive no benefit from reconstruction (Dhillon, 1998). In addition, GFR of less than 10 mL/min/1.73 m^2 in the affected kidney successfully predicted renal function that did not stabilize or improve after surgical correction of obstruction in adults (Khalaf et al, 2004). The decision to proceed with nephrectomy in a patient with significant global renal insufficiency, however, should not be based solely on the aforementioned criteria as this could hasten dialysis dependence and dramatically affect quality of life. The patient may prefer life with a stent or percutaneous nephrostomy.

Pain Management

A time-honored, first-line therapy in the management of renal colic has been parenteral administration of narcotic analgesics. Nonsteroidal anti-inflammatory drugs (NSAIDs), however, have assumed an increasing role in the acute management algorithm. Both classes of medication may be administered parenterally or orally. Narcotics have a rapid onset of analgesia but may promote nausea and emesis, cause excessive sedation, and have a potential for abuse. NSAIDs are nonopioid analgesics that, unlike narcotics, target the inflammatory basis of pain. Prostaglandins, generated from arachidonic acid metabolism mediated by both *iso* forms of cyclooxygenase, potentiate pain receptors. Therefore, inhibition of prostaglandin synthesis prevents this potentiation of nociceptors (Mense, 1983).

Increases in collecting system pressure and ureteral wall tension are proposed mechanisms of renal colic (Holmlund, 1983). Primate models reveal that distention-mediated activation of renal pelvis mechanoreceptors results in spinothalamic (pain pathway) C fiber excitation. The mean threshold pressure to elicit this primate response was 32 mm Hg. This is similar to the 30 mmHg proposed threshold for evoking pain in humans (Ammons, 1992). Interventions that reduce collecting system pressure should theoretically reduce pain.

NSAIDs have been demonstrated to reduce collecting system pressure. Pretreatment with indomethacin significantly blunted the rise in pelvic pressure and RBF in pigs with UUO (Frokiaer et al, 1993). Indomethacin administered 30 minutes after UUO reduced an already elevated renal pelvic pressure by approximately 30% in rats (Sjodin et al, 1982). A study of four different NSAIDs in dogs with acute obstruction showed 25% to 58% reductions in renal pelvic pressure after administration of these drugs, which were most pronounced after the first dose (Gasparich and Mayo, 1986). A concomitant reduction in RBF induced by NSAIDs is thought to be one of the mechanisms for decreasing collecting system pressure. This has been demonstrated in a canine model of UUO in which the administration of ketorolac, an NSAID, induced prompt reduction in both RBF and intrapelvic pressure (Perlmutter et al, 1993). A second potential mechanism involves regulation of aquaporin water channels. COX-2 expression is upregulated in the obstructed ureter (Nakada et al, 2002). There is also a downregulation of AQP2 water channels associated with this COX-2 induction, and this promotes diuresis after obstruction is relieved. Rats treated with a COX-2 inhibitor during obstruction had only a 28% reduction of AQP2, attenuating the diuresis occurring after release of UUO (Cheng et al, 2004).

The utility of NSAIDs for managing renal colic was demonstrated in a meta-analytic study of 20 trials comparing NSAIDs with opioids in 1613 patients. A greater reduction in pain score, less need for "rescue" analgesia, and less emesis occurred in the NSAID cohort (Holdgate and Pollock, 2004).

The choice of pain management should be based on the patient's clinical profile. **NSAIDs should not be utilized in patients with renal insufficiency as this could be exacerbated by the induced reduction in RBF.** COX-1 inhibitors should not be administered to patients at risk for gastrointestinal bleeding or when optimal platelet function is needed. Although COX-2 inhibitors are attractive on a pathophysiologic basis, the market withdrawal of some COX-2 inhibitors related to increased risk of cardiac morbidity underscores the need for prospective trials to assess their long-term safety in managing patients with renal colic. Although opioid-derived agents have untoward side effects, they provide excellent analgesia and are still considered front-line drugs for colic management. They are certainly effective as initial analgesic therapy and can also be used to rescue those whose pain is not controlled adequately with NSAIDs or as an adjunct to NSAID therapy.

Postobstructive Diuresis

Mechanisms

Following the relief of urinary tract obstruction, postobstructive diuresis, a period of significant polyuria, may ensue. Urine outputs of 200 mL/hr or greater may be encountered. Although this occurs mainly after relief of BUO or obstruction of a solitary kidney, it can rarely occur when there is a normal, contralateral kidney (Schlossberg and Vaughan, 1984). The diuresis is typically a normal physiologic response to the volume expansion and solute accumulation occurring during obstruction. Sodium, urea, and free water are eliminated and the diuresis subsides after solute and fluid homeostasis is achieved. With the return of homeostasis, the period of diuresis ends (Loo and Vaughan, 1985).

However, a "pathologic" postobstructive diuresis may ensue, characterized by inappropriate renal handling of water or solutes, or both. It is due to a number of mechanisms previously reviewed in this chapter, including a derangement of the medullary solute gradient and a number of altered signaling and transport pathways. Downregulation of sodium transporters with subsequent impaired sodium reabsorption in the thick ascending limb of Henle prevents maintenance of the medullary interstitial solute gradient promoting a continued diuresis (Rokaw et al, 1996). The increased endogenous production and altered regulation of ANP induce a

saline diuresis (Kim et al, 2001b). In addition, other natriuretic peptides such as the *Dendroaspis* natriuretic peptide may play a role (Kim et al, 2002). Pathologic postobstructive diuresis is also marked by poor responsiveness of the collecting duct to ADH. This is thought to be due to a downregulation of aquaporin water channels in this segment of the nephron and perhaps in the proximal tubule, which has been demonstrated in experimental models of UUO and BUO (Nielsen and Agre, 1995; Frokiaer et al, 1996; Kim et al, 2001a; Li et al, 2003c).

Various reasons have been proposed for the rare occurrence of postobstructive diuresis with release of UUO and a normal contralateral kidney. GFR may be atypically preserved in the setting of distal tubular damage, such that the kidney filters a normal volume but there is limited free water reabsorption. Alternatively, a pronounced aquaporin channel defect may be present, causing diminished free water absorption in this setting (Schlossberg and Vaughan, 1984; Li et al, 2003c).

Clinical Management of Postobstructive Diuresis

The majority of patients do not demonstrate a clinically significant postobstructive diuresis following relief of urinary tract obstruction. Those who are susceptible to this phenomenon typically have signs of fluid overload including edema, congestive heart failure, or hypertension (Loo and Vaughan, 1985). The most common clinical setting is release of urinary retention. A catheter should be placed to drain the bladder rapidly in those with urinary retention. There is no role for gradual bladder decompression, as this has not been demonstrated to limit hematuria or the risk of postobstructive diuresis (Nyman et al, 1997).

Subjects in whom BUO or UUO in a solitary kidney is relieved should be monitored for a postobstructive diuresis. Serum electrolytes, magnesium, blood urea nitrogen (BUN), and creatinine should be checked. The intensity of monitoring depends on presence of risk factors for postobstructive diuresis and the subject's mental status, renal function, and electrolyte status. Those with normal renal function and electrolytes, no evidence of fluid overload, and who are mentally alert should have their vital signs and urine output monitored. They are allowed free access to oral fluids, and if they do not manifest signs of a postobstructive diuresis they can be discharged and return later for further urologic evaluation and care. If they show signs of a postobstructive diuresis but are alert, able to consume fluids, and have normal vital signs, observation is continued and the patients may consume fluids as desired. **This is a physiologic diuresis in the majority of cases that resolves when free water and excess solutes are eliminated.** Serum electrolytes, BUN, magnesium, and creatinine are checked daily until the diuresis resolves. If patients have signs of fluid overload, azotemia, or poor cognitive function or if hypotension or other indicators of hypovolemia develop, more intense monitoring should be instituted. Vital signs and urine output are checked more frequently. Electrolytes, BUN, magnesium, and creatinine are assessed every 12 hours and more frequently if necessary. Urinary osmolarity should be checked in this setting. Hypo-osmolar urine is indicative of a primary water diuresis as opposed to a solute diuresis. Of note, an initial solute diuresis may convert to a pathologic water diuresis, underscoring the need for obtaining a baseline urine osmolarity and continued monitoring of this parameter.

The clinically stable patient with good cognitive function should be given free access to oral fluids. Intravenous fluids should probably not be administered as this may prolong the period of diuresis. However, there may be a theoretical role for maintenance of volume expansion in this setting. Gulmi and associates (1995) demonstrated improved GFR in dogs undergoing volume expansion just prior to relief of BUO. This is linked to increased generation of ANP and the salutary effects of this peptide on RBF and GFR. A clinical trial is needed to determine whether this would facilitate recovery of GFR in humans.

Those with poor cognitive function should receive intravenous hydration but below the normal maintenance amounts. The majority of this group also have a self-limiting physiologic diuresis. On rare occasions a pathologic diuresis develops and the patients can become hypovolemic because of excess water loss; they can develop electrolyte abnormalities as a result of the former or salt and potassium losses, or both. These patients warrant the most intense monitoring and require careful electrolyte and fluid replacement, initially by an intravenous route. Assessing urinary output, vital signs, and both urinary and serum electrolytes facilitates prescribing the optimal amount and type of fluids to be administered. We have seen very few such cases at our medical center, and the diuresis resolved with time. Some patients have salt wasting associated with hyponatremia and hyperkalemia mimicking adrenal insufficiency. This has been reported to occur mainly in children (Melzi et al, 1995). It is thought to be due to tubular resistance to aldosterone, and supporting evidence for this is the significantly increased serum aldosterone levels reported in these cases. The underlying cause may be a reduction in aldosterone receptors (Kuhnle et al, 1993).

Experimental Modulation of Postobstructive Diuresis

Animal and cell culture experiments demonstrate the potential of pharmacologically attenuating postobstructive diuresis. Ureteral obstruction induces expression of COX-2 in collecting duct cells (Guan et al, 1997). Evidence suggests that the downregulation of AQP2 receptors is mediated by COX-2. Administration of COX-2 inhibitors prevented the downregulation of AQP2 and significantly diminished postobstructive diuresis in rats with BUO (Cheng et al, 2004). In addition, with ureteral obstruction, there is blunted cAMP generation in response to vasopressin (Kim et al, 2001a). Vasopressin-induced, cAMP-mediated pathways induce phosphorylation and subsequent membrane insertion of AQP2 (Nishimoto et al, 1999; Van Balkom et al, 2002). A cAMP-independent, cyclic guanosine monophosphate (cGMP) pathway has been demonstrated in both in vitro and in vivo models to allow membrane insertion of AQP2 (Bouley et al, 2000). Acute exposure to the phosphodiesterase type 5 inhibitor sildenafil citrate elevated intracellular cGMP and has been shown to facilitate collecting duct accumulation of AQP2 (Bouley et al, 2005). **Although such data are suggestive that postobstructive diuresis can be manipulated pharmacologically, it is unclear whether such manipulation would be ultimately beneficial or harmful.**

SELECTED EXTRINSIC CAUSES OF URETERAL OBSTRUCTION

A plethora of intraperitoneal and extraperitoneal disease processes may ultimately result in ureteral obstruction. Hydronephrosis, either symptomatic or incidental, may thus be the initial presentation of these conditions. Herein, selected extrinsic causes of ureteral obstruction are reviewed.

Retroperitoneal Fibrosis

Retroperitoneal fibrosis is an uncommon condition in which a predominantly inflammatory mass envelops and potentially obstructs retroperitoneal structures including either or both ureters. The initial report is now attributed to Albarran (1905), although idiopathic retroperitoneal fibrosis has had the eponym Ormond's disease after that author's description and definition of this clinical entity in 1948 (Albarran, 1905; Ormond, 1948). Of the two patients Ormond initially described, one had progressive renal deterioration and ultimately expired, whereas the other underwent exploration and ureterolysis without subsequent signs or symptoms of recurrent ureteral obstruction during the ensuing 12 years, underscoring the need to recognize and address this process (Ormond, 1960).

Grossly, retroperitoneal fibrosis appears as a fibrous, whitish plaque encasing the aorta, inferior vena cava, and their major branches, and the ureters, other retroperitoneal structures, and at times intraperitoneal structures including the gastrointestinal tract. Its longitudinal axis usually extends from the renal hilum to the pelvic brim, but it may extend into pelvis and mediastinum.

The development of retroperitoneal fibrosis is hypothesized to take place in two phases. The initial phase is thought to be inflammatory, histologically characterized by abundant plasma cells, lymphocytes, macrophages, and eosinophils. An autoimmune response has been proposed to incite this phase. Leakage of ceroid, a complex lipoprotein, originating from atheromatous plaques in the aorta has been hypothesized to induce an autoimmune antigenic response and generate a local inflammation leading to varying degrees of fibrosis (Baker, 2003). The second phase is characterized as a fibrotic maturation with the development of homogeneous fibrous tissue with limited cellularity.

The incidence of retroperitoneal fibrosis has been estimated to be 1 in 200,000 (Debruyne et al, 1982). There is a 3:1 male-to-female ratio, and the mean age at onset is 50 years (Wu et al, 2002). Numerous medications have been associated with the development of retroperitoneal fibrosis and are listed in Table 37–3, along with other etiologies of this process. A definitive etiology of retroperitoneal fibrosis is found in only 30% of cases (Koep et al, 1977). The term "idiopathic retroperitoneal fibrosis" should be used only when an inciting etiology is not defined. **An underlying malignancy should always be considered, as one is reported to be present in 8% to 10% of such cases** (Amis, 1991).

Patients usually have nonspecific symptoms, which may include back, abdominal, or flank pain, weight loss, anorexia, and malaise. Signs can be similarly nonspecific and include hypertension in 50%, fever, and lower extremity edema. Because of its insidious nature, many patients do not present until later in the course of the disease, manifesting with signs or symptoms attributable to ureteral or vascular obstruction (Amis, 1991). Reported laboratory abnormalities are nonspecific and include an elevated erythrocyte sedimentation rate in 80% to 90%, elevated serum creatinine, hypergammaglobulinemia, and normochromic, normocytic anemia (Monev, 2002).

Before the advent of cross-sectional imaging, radiologic diagnosis relied upon imaging not the disease process itself but its secondary effects on the ureters. The classic radiologic findings included medial deviation of extrinsically compressed ureters with hydronephrosis. Medial deviation is a nonspecific finding as it has been demonstrated in up to 18%

Table 37–3. Suspected Causes of Retroperitoneal Fibrosis

Drugs	*Hemorrhage*
Methysergide	Abdominal and pelvic surgery
Hydralazine	Ruptured viscera
Reserpine	Henoch-Schönlein purpura with hemorrhage
Haloperidol	*Periarteritis*
LSD	Aortic or iliac artery aneurysm
Methyldopa	Inflammatory response to advanced atherosclerosis
β Blockers	Collagen vascular disease
Ergotamine alkaloids	*Infection*
Phenacetin	Gonorrhea
Amphetamines	Tuberculosis
Chemicals	Chronic UTI
Avitene	Syphilis
Methyl methacrylate	*Radiation Injury*
Talcum powder	*Other*
Retroperitoneal Tumors	Sarcoidosis
Inflammatory Processes	Biliary tract disease
Ascending lymphangitis	Endometriosis
Chronic inflammatory bowel disease	

LSD, lysergic acid diethylamide; UTI, urinary tract infection.

concomitant ureterolysis if malignancy is not suspected on frozen section analysis. If the percutaneous biopsy demonstrates findings compatible with retroperitoneal fibrosis, possible inciting medications should be discontinued.

The potential morbidity of ureterolysis, accurate image-guided biopsy techniques, and more sensitive cross-sectional imaging studies for diagnosis and follow-up have made medical therapy the preferred approach in this setting. However, it should be noted that there have been no randomized prospective studies addressing the merits of initial medical therapy versus a surgical approach. Patients should be informed about the side effects of the proposed medical therapy and the risk of disease progression or undiagnosed malignancy. Medical therapy has been directed to address the presumed autoimmune and inflammatory components of retroperitoneal fibrosis.

The administration of corticosteroids has been used for primary therapy. Although many steroid regimens have been described, appropriate dosing schedules and duration of therapy have not been clearly established. The sequence suggested by Kardar and colleagues (2002) has been demonstrated to be effective after long-term follow-up. Their algorithm for adults consists of prednisolone administered at an oral dose of 60 mg on alternate days for 2 months, tapered to 5 mg daily over the next 2 months. The latter dose is continued for a total duration of 2 years. Of the 11 patients who completed this regimen at a median follow-up of 63 months, 9 maintained a good response, 1 required ureterolysis, and 1 recurred but responded to reinitiation of therapy.

Tamoxifen, a nonsteroidal antiestrogen, has also been used for primary treatment. It is thought to alter TGF-β, potentially limiting fibrosis. There have been scattered case reports documenting successful outcomes with tamoxifen therapy but no published series. The most commonly reported dose was 20 mg/day, and duration of therapy varied (Loffeld and Van Weel, 1993; Al Rabi et al, 2002). Successful combination therapy using a tapered steroid regimen and daily tamoxifen has also been described (Tziomalos et al, 2004).

Aggressive immunotherapy has also been used as primary therapy for those afflicted with retroperitoneal fibrosis. Marcolongo and colleagues (2004) reported 26 patients who were treated with a 6-month course of prednisone, combined with either 6 months of cyclophosphamide or 1 year of azathioprine. Severe adverse effects in the cyclophosphamide group included death in one, sepsis in one, and severe leukopenia in two patients. In the azathioprine group, activation of hepatitis, pancreatitis, and oral candidiasis developed. All surviving patients had disease resolution, although seven required a second course of treatment.

Ureterolysis is undertaken if medical therapy fails or if the patient is not a candidate for medical therapy. Traditionally, this has been done by an open surgical approach, but successful laparoscopic ureterolysis has been reported and may be a feasible option for selected patients. Bilateral ureterolysis is recommended, even in the setting of unilateral disease, as the disease typically progresses to involve the contralateral side. The ureteral dissection should begin in a region free of disease, and care must be taken to avoid devascularization of the ureter. A biopsy of the fibrotic area should be repeated to limit the risk of sampling error associated with percutaneous biopsy. Several strategies have been employed to prevent recurrent ureteral involvement in the fibrotic process. **The ureter may be displaced to a lateral position, brought to an intraperitoneal location by closing the peritoneum behind it, or wrapped within a sleeve of omentum. One method has not been definitively demonstrated to generate superior results** (Barbalias and Liatsikos, 1999). If it is determined intraoperatively that ureterolysis is not technically possible, alternatives include ileal ureter replacement, autotransplantation, chronic ureteral stenting, or nephrostomy tube drainage.

It has been suggested that ureteral stents can generally be removed 6 to 8 weeks after ureterolysis (Varkarakis and Jarrett, 2005). Some have advocated postoperative steroid therapy to expedite disease resolution or prevent recurrence, but there is limited experience with this approach (Varkarakis and Jarrett, 2005).

There is limited published information on the results of ureterolysis; 66% to 100% success rates were reported for small series. The best success rates were reported by Elashry and colleagues (1996); 100% for seven laparoscopic and 100% six open surgical procedures. Alexopoulos and associates (1987), however, noted only 66% long-term success with

ureterolysis combined with postoperative steroid administration in six patients with severe retroperitoneal fibrosis. Of note, one of their patients failed 16 years after surgery and became dialysis dependent. **Long-term follow-up in those subjected to medical or surgical therapy is warranted.** Serial cross-sectional imaging should be obtained to assess for disease recurrence, progression, or findings suggestive of malignancy. Renal function should also be monitored.

Pelvic Lipomatosis

Pelvic lipomatosis is a rare, benign condition marked by exuberant pelvic overgrowth of nonmalignant but infiltrative adipose tissue. Engels first described the condition in 1959, and it has been the subject of several reviews and many case reports in the interim. The largest review to date comprised 130 patients, of whom the mean age at presentation was 48 years. Racial and gender differences were noted, with 67% of the patients black and 33% white; there was an 18:1 male-to-female ratio (Heyns, 1991).

The etiology of this disorder is unknown. Obesity has been proposed to play a role, as radiographic improvement and worsening have been noted in response to weight loss and gain (Sacks et al, 1975). In addition, obesity has been noted in over one half of the patients afflicted (Heyns, 1991). However, if pelvic lipomatosis were simply a manifestation of obesity, its observed frequency should be far greater (Morretin and Wilson, 1971). The reported occurrence of pelvic lipomatosis in two brothers raises the possibility of an underlying genetic etiology (Tong et al, 2002). An abnormality in the chromatin-regulating high mobility group A (HMGA) proteins has been implicated as a possible causative factor in pelvic lipomatosis, as transgenic mice with truncated HMGA developed pelvic lipomatosis (Fedele et al, 2001).

Approximately one half of patients present with lower urinary tract symptoms and one quarter with bowel symptoms, typically constipation. Suprapubic, back, flank, or perineal discomfort can also be an initial clinical manifestation. The nonspecific nature of these symptoms may result in a significant delay in diagnosis (Heyns, 1991). **Physical findings may include a suprapubic mass, a high-riding prostate, and an indistinct pelvic mass.** Hypertension has been reported in as many as one third of patients (Klein et al 1988; Heyns, 1991).

There are various radiologic signs of pelvic lipomatosis. On plain film, increased pelvic lucency may be noted (Fig. 37–11). **On excretory urography, the bladder characteristically assumes a pear or gourd shape, extrinsically compressed and elongated, and the bladder base is frequently elevated** (Fig. 37–12). Hydroureteronephrosis may be seen (Heyns, 1991). CT is quite helpful in establishing the diagnosis as it readily demonstrates pelvic fat (Fig. 37–13). Extrinsic compression of the rectum may also be demonstrated (Susmano and Dolin, 1979). Liposarcoma should be suspected if there is tissue heterogeneity, areas of positive attenuation coefficients, enhancement with contrast, and poor margination (Andac et al, 2003). MRI can also be used to make the diagnosis as it permits characterization of fat deposits (Demas et al, 1988).

Evaluation should include cystoscopy, as some form of proliferative cystitis has been found in 75% of patients including cystitis glandularis in up to 40% (Heyns, 1991).

Figure 37–11. Plain film of pelvis in a patient with pelvic lipomatosis. Note increased pelvic lucency. (Courtesy of Dr. Ronald Zagoria.)

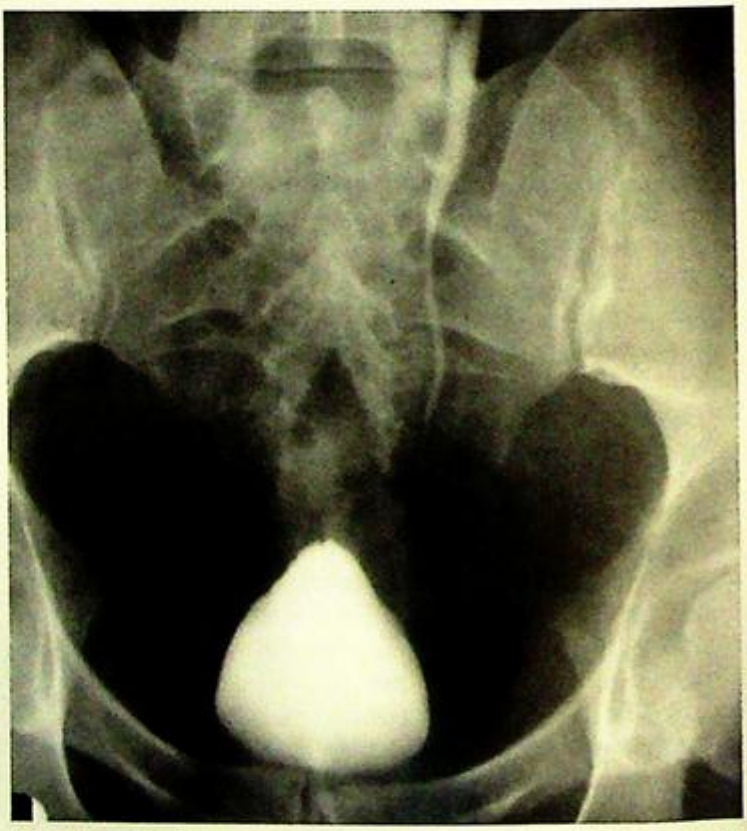

Figure 37–12. Excretory urography of a patient with pelvic lipomatosis. Note classic pear-shaped bladder with increased surrounding pelvic lucency. (Courtesy of Dr. Ronald Zagoria.)

Continued cystoscopic surveillance is recommended in those with cystitis glandularis as there have been reports of the development of adenocarcinoma of the bladder in this cohort (Sozen et al, 2004). **Elongation of the prostatic urethra, elevation of the bladder neck, and pelvic fixation may impair**

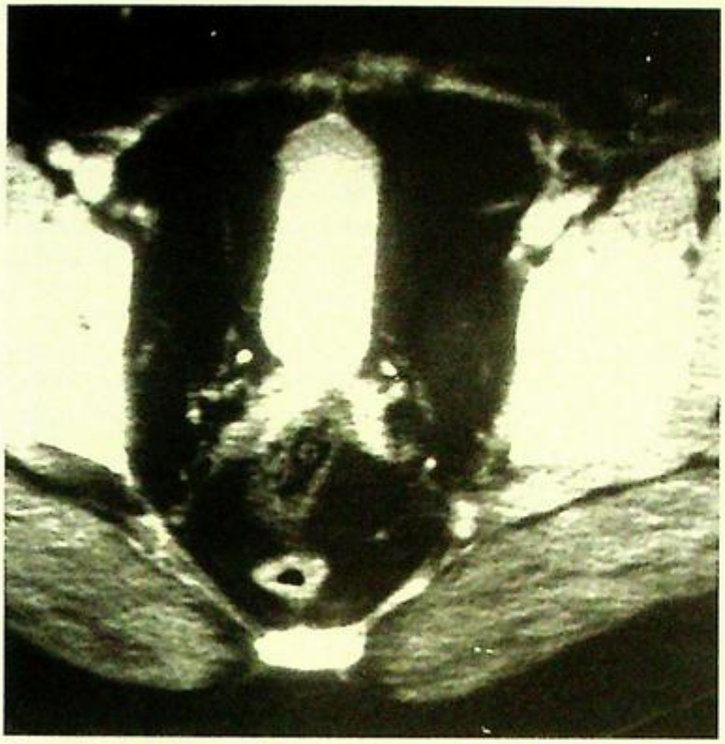

Figure 37–13. Computed tomography cystogram of a patient with pelvic lipomatosis. Note narrowed bladder and increased pelvic fat in perivesical and perirectal spaces. (Courtesy of Dr. Ronald Zagoria.)

cystoscopic access to the bladder. In Heyns' review (1991) of 72 patients in whom cystoscopy was attempted, evaluation of the bladder was difficult in 24% and impossible in 18%. Hence, flexible cystoscopy may be required if anatomic distortion precludes rigid cystoscopy.

Klein and associates (1988) suggested that there are two clinically separate groups of patients. The first is composed of young, stocky men with irritative lower urinary tract symptoms, vague pelvic complaints, hypertension, and proliferative cystitis. This group may be more susceptible to developing progressive ureteral obstruction. The second group includes older men with incidentally discovered pelvic lipomatosis who are reported to have a more indolent course. Others have not found age to affect disease progression (Heyns, 1991). **Nevertheless, there is agreement that in light of the potential for progressive ureteral obstruction, long-term follow-up is mandated.** Overall, 39% of patients in Klein's series ultimately required operative intervention for upper tract obstruction.

Surgical options in patients with obstructive uropathy secondary to pelvic lipomatosis include ureteral stenting, percutaneous nephrostomy, ureteral reimplantation, and urinary diversion. Pelvic exploration should be approached cautiously, as there is obliteration of normal anatomic planes and increased vascularity within the fatty mass.

Obstetric and Gynecologic

Pregnancy

Hydronephrosis develops commonly during pregnancy, the reported occurrence varying between 43% and 100% (Faundes et al, 1998). This wide variability is due to the utilization of different definitions of hydronephrosis. The right kidney becomes hydronephrotic two to three times more commonly than the left (Cietak and Newton 1985; Faundes et al, 1998). Hydronephrosis may initially manifest in the first trimester, and it increasingly develops through pregnancy (Au et al, 1985; Loughlin, 1997). This progression was also reported in a large prospective study by Faundes and colleagues (1998), who found that hydronephrosis was present in 15%, 20%, and 50% of women during the first, second, and third trimesters, respectively . The degree of hydronephrosis also increased over time. Hydronephrosis has been demonstrated to be more common during a first-time pregnancy (Erickson et al, 1979). The maximal calyceal diameters during pregnancy over time were measured by Faundes and associates (1998). These parameters are provided (Table 37–4), as they may be useful when evaluating patients with hydronephrosis during pregnancy. After delivery, hydronephrosis gradually resolves. **Approximately one third of patients may have persistent hydronephrosis during the first postpartum week, but it resolves in the majority within 6 weeks** (Cietak and Newton, 1985).

Two etiologies for hydronephrosis of pregnancy have been postulated, one hormonal and one mechanical. The 10% to 15% incidence of observed first-trimester ureteral dilatation, occurring before the uterus reaches the pelvic brim, supports a nonmechanical mechanism. Progesterone, a hormone in more abundance during pregnancy, has been hypothesized to promote ureteral dilatation and subsequent development of hydronephrosis (Faundes et al, 1988). The increased incidence and degree of hydronephrosis after the 20th week of gestation, a time when the uterus is large enough to compress the ureters extrinsically, supports a mechanical etiology. The significantly lower incidence of left-sided hydronephrosis also supports this hypothesis (Cietak and Newton, 1985). However, it is quite plausible that both mechanisms play a role.

Hydronephrosis of pregnancy is usually clinically silent. However, some with hydronephrosis of pregnancy may experience flank pain or develop pyelonephritis or renal failure. Renal ultrasonography should be undertaken in this setting. **The typical ultrasonographic findings of this entity are hydroureteronephrosis extending to the pelvic brim. When ureteral dilation extends below this, a different etiology of obstruction such as a ureteral stone should be considered.** If the latter is suspected, limited IVU is a diagnostic option. However, MRI is now another consideration. **Magnetic resonance urography has been advocated by some as a noninvasive, nonradiating method of assessing those with hydronephrosis of pregnancy. The presence of hydroureter below the pelvic brim is readily apparent on high-resolution T2 sequences, and filling defects representing stones or soft tissue may be seen** (Spencer et al, 2004). In addition, MRI has proved useful in identifying other causes of acute abdominal pain in pregnancy, including appendicitis, ovarian torsion, and adrenal hemorrhage (Birchard et al, 2005).

The majority of patients with symptomatic hydronephrosis of pregnancy can be managed with conservative measures such as intravenous hydration, analgesics, and antibiotic therapy when clinically indicated. However, placement of ureteral stents may be necessary when these measures are unsuccessful, especially with signs of sepsis or compromised renal function. **Rapid stent encrustation may be problematic**

Table 37–4. Observed and Adjusted Percentiles of Maximal Caliceal Diameter (mm) of Right and Left Kidneys According to Gestational Age

	Observed Percentiles				Adjusted Percentiles

as urinary calcium excretion increases during pregnancy (Goldfarb et al, 1989). This may necessitate more frequent stent changes. Percutaneous nephrostomy is an alternative if this occurs, and it is also a consideration if pyonephrosis is suspected.

Benign Pelvic Abnormalities

Tubo-ovarian Abscess. Pelvic inflammatory disease (PID) is a common problem, affecting 10% of women during their lifetime. **Tubo-ovarian abscess, occurring in approximately 15% of those afflicted with PID, may cause extrinsic ureteral obstruction** (Aral et al, 1991). This process may be demonstrated with ultrasonography, CT, or MRI. Ureteral obstruction may resolve with antibiotic therapy or transvaginal drainage of the abscess. However, an open surgical or laparoscopic intervention may be required to drain or excise the involved ovary and fallopian tube if the aforementioned measures are unsuccessful. Placement of an internalized ureteral stent or percutaneous nephrostomy should be considered if high-grade renal obstruction or urosepsis is suspected. Stent or nephrostomy tube removal is undertaken after the inflammatory process has resolved. Follow-up renal imaging is recommended as some patients have persistent obstruction.

Endometriosis. Endometriosis is defined as the presence of functional endometrial tissue in an ectopic site. Although endometriosis is usually confined to the ovaries, uterosacral ligaments, and cul-de-sac, it has been documented in almost every organ system in the body (Jubanyik and Comite, 1997). It may affect 10% to 20% of women of reproductive age, with a peak incidence in the mid-20s (Eskenazi and Warner, 1997). There is no relationship of endometriosis to race or socioeconomic status.

Endometriosis of the urinary tract is predominantly found in the bladder, accounting for 70% to 80% of the cases. The ureter may be involved in 15% to 20% of the urinary tract cases (Williams, 1975). Involvement may be either intrinsic or extrinsic. Intrinsic endometriosis is characterized by endometrial glands and stroma within the lamina propria, tunica muscularis, or ureteral lumen; extrinsic endometriosis is localized within periureteral tissue. Eighty percent of ureteral endometriosis is extrinsic and primarily involves the distal ureter (Klein and Cattolica, 1979). The left side is more often affected, and bilateral disease has been reported in up to 23% of cases (Antonelli et al, 2004).

Classic symptoms and signs of urinary tract endometriosis include cyclical flank pain, dysuria, urgency, urinary tract infection, and hematuria (Jubanyik and Comite, 1997). Patients with intrinsic endometriosis experience these symptoms more than those with extrinsic disease. **Notably, a significant portion of patients with ureteral endometriosis do not have genitourinary symptoms.** For example, in one series ureteral obstruction was silent in approximately 40% of those with severe ureteral endometriosis (Antonelli et al, 2004). Furthermore, silent loss of renal function has been reported in 25% to 43% of patients with ureteral endometriosis, which may result in total loss of function of the affected kidney (Watanabe et al, 2004). Historically, up to one third of kidneys affected by ureteral endometriosis were lost (Klein and Cattolica, 1979).

Because a large percentage of patients with ureteral endometriosis can have asymptomatic obstruction of the kidney with a loss of renal function, it has been recommended to image the upper urinary tract in all patients with pelvic endometriosis. Initial imaging may be done with ultrasonography as a noninvasive test to look for hydroureteronephrosis. An EXU may be a better test when the index of suspicion for ureteral involvement is high. Pyelographic findings of intrinsic disease include ureteral filling defects, whereas smooth strictured ureteral segments are seen with [illegible] disease (Stebbing and Notley, 1995). Retrograde [illegible]graphy, CT, and MRI may help to ascertain the

exact location and volume of the disease and may provide valuable information for planning treatment.

Treatment has several goals: (1) preservation of renal function, (2) management of the ongoing disease process, (3) maintenance of the patient's fertility, and (4) relief of the patient's symptoms with the least invasive methods available.

If renal function is normal and there is minimal to mild hydronephrosis with no functional obstruction as determined by radionuclide renal scanning, hormone therapy may be prescribed. Ovarian hormonal ablation with gonadotropin-releasing hormone agonists has been utilized with success in some series. Rivlin and associates (1990) described three patients treated with leuprolide acetate for 6 to 9 months. One patient had BUO, and two had UUO. The obstruction resolved in the patient with BUO and in one of the patients with UUO. The failure occurred in the patient with intrinsic ureteral disease.

Hormonal therapy is not as effective for patients with extensive endometriosis as reflected by high treatment failure and recurrence rates (Lam et al, 1992).

Surgical intervention is the treatment of choice for most patients with significant hydroureteronephrosis and periureteral disease. If the patient does not desire future pregnancy, treatment is total abdominal hysterectomy and bilateral salpingo-oophorectomy. If pregnancy is desired, lesser extirpative procedures can be performed, such as unilateral oophorectomy. Ureterolysis may correct ureteral obstruction in those with extrinsic disease. If laparoscopic ureterolysis is undertaken, a transperitoneal approach is preferable in that it allows a superior assessment of endometrial implants on the peritoneum overlying the ureter (Watanabe et al, 2004). When intrinsic disease is present or in cases in which ureterolysis fails or is unlikely to work, distal ureterectomy with reimplantation is reported to have excellent long-term results with regard to renal preservation (Antonelli et al, 2004).

Ovarian Remnants. The ovarian remnant syndrome results from residual, viable ovarian tissue after bilateral salpingo-oophorectomy. Although uncommon, it is a recognized complication of a technically difficult oophorectomy, most typically in those with endometriosis, PID, or prior abdominal and pelvic surgery (Lafferty et al, 1996). Ovarian remnants may be quite large, up to 10 cm, and may be present in the normal ovarian bed but may be located in other areas as a consequence of dissemination and implantation occurring during surgery (Lafferty et al, 1996). **Mass effect or a localized fibrosis may cause extrinsic ureteral obstruction.** This process may be demonstrated with ultrasonography, CT or MRI (Klutke et al, 1993).

Treatment is usually surgical excision of the mass and ureterolysis. Preoperative ureteral stenting may be considered if there is high-grade obstruction or as an aid to intraoperative identification of the ureter, although the latter has not been reported to be necessary by some investigators (Lafferty et al, 1996). Medical management of ureteral obstruction is an option for poor surgical candidates. Successful resolution of the mass and hydronephrosis have been reported with leuprolide acetate therapy. However, chronic medical therapy may be required to prevent recurrence (Koch et al, 1994).

Mass Lesions of the Uterus and Ovaries. Other benign lesions of the uterus and ovary may become large enough to cause extrinsic ureteral obstruction. These include uterine fibroids, ovarian cysts, and ovarian fibromas. **Uterine fibroids, the most common tumor of the upper female genital tract, are also the most common, benign gynecologic neoplasm causing ureteral obstruction** (Greenberg and Kazamel, 1995). The most common site of extrinsic ureteral obstruction is at the pelvic brim. Surgical resection or ablation of the leiomyomas should be considered in this setting.

Vascular Causes of Ureteral Obstruction

The ureters course adjacent to vascular structures and as a consequence may be affected by various vascular disease processes and anomalies that may result in their obstruction. An overview of several of these entities is subsequently provided.

Arterial Causes of Obstruction

Abdominal Aortic Aneurysm. Clinical signs and symptoms of ureteral obstruction may be the initial manifestation of an abdominal aortic aneurysm (AAA) (Labardini and Ratliff, 1967). The obstruction may be due to a mass effect or localized inflammation (Pennell et al, 1985).

Currently, CT scanning is most frequently utilized to evaluate patients with an AAA that may demonstrate associated hydronephrosis (Fig. 37–14A and B). Ureteral findings associated with AAA vary. The ureters may be pushed laterally on both sides, or one side may deviate laterally while the opposite side is drawn medially within the perianeurysmal inflammation, or both may be medially deviated. Some have noted that lateral deviation of the ureter with AAA is usually not associated with obstruction (Labardini and Ratliff, 1967). **The medial deviation of the ureter associated with the desmoplastic reaction of inflammatory aneurysms (IAAA), however, carries a more significant risk of ureteral obstruction.** Although IAAA represents only between 4% and 15% of AAAs, the associated retroperitoneal desmoplastic reaction significantly increases the risk of ureteral obstruction, which has been reported in 21% of this cohort (Pennell et al, 1985; Arroyo et al, 2003).

At one time ureterolysis was routinely performed during repair of IAAA associated with ureteral obstruction. However, this practice has generally been abandoned as obstruction commonly resolves without ureterolysis. Placement of internalized ureteral stents is commonly undertaken prior to aneurysm repair. Ureteral obstruction has been reported to resolve in 80% of patients managed with this approach (Arroyo et al, 2003). Some have advocated endovascular repair of the IAAA in this setting (Nevelsteen et al, 1999). Internalized ureteral stents are inserted prior to endovascular graft placement and are removed when it is thought that the associated fibrosis has resolved. A 50% resolution of ureteral obstruction has been reported with this approach (Rehring et al, 2001; Deleersnijder et al, 2002). Patients with IAAA treated with open surgery or an endovascular approach warrant close monitoring for development of recurrent or de novo ureteral obstruction, as delayed ureteral obstruction has been reported to occur (Simons et al, 2002; Jetty and Barber, 2004; Lambie et al, 2004).

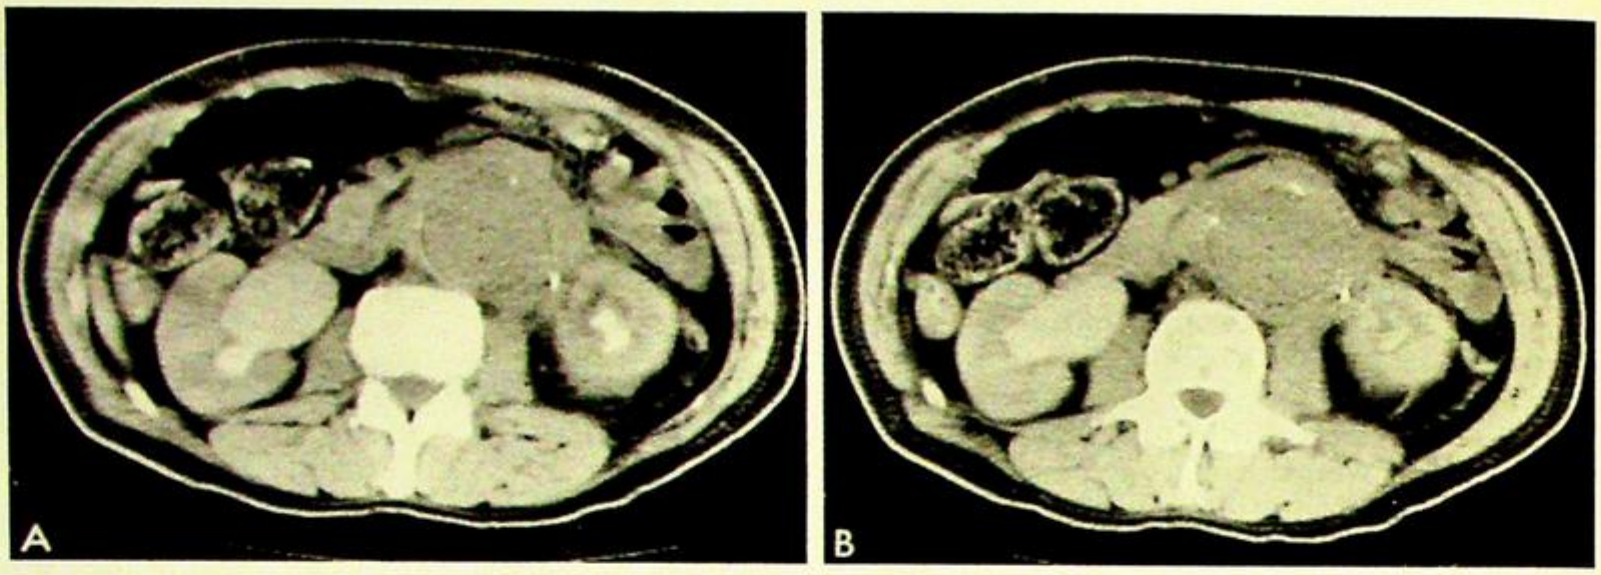

Figure 37–14. **A** and **B**, Computed tomography scans demonstrate extensive retroperitoneal fibrosis associated with aneurysm of the abdominal aorta.

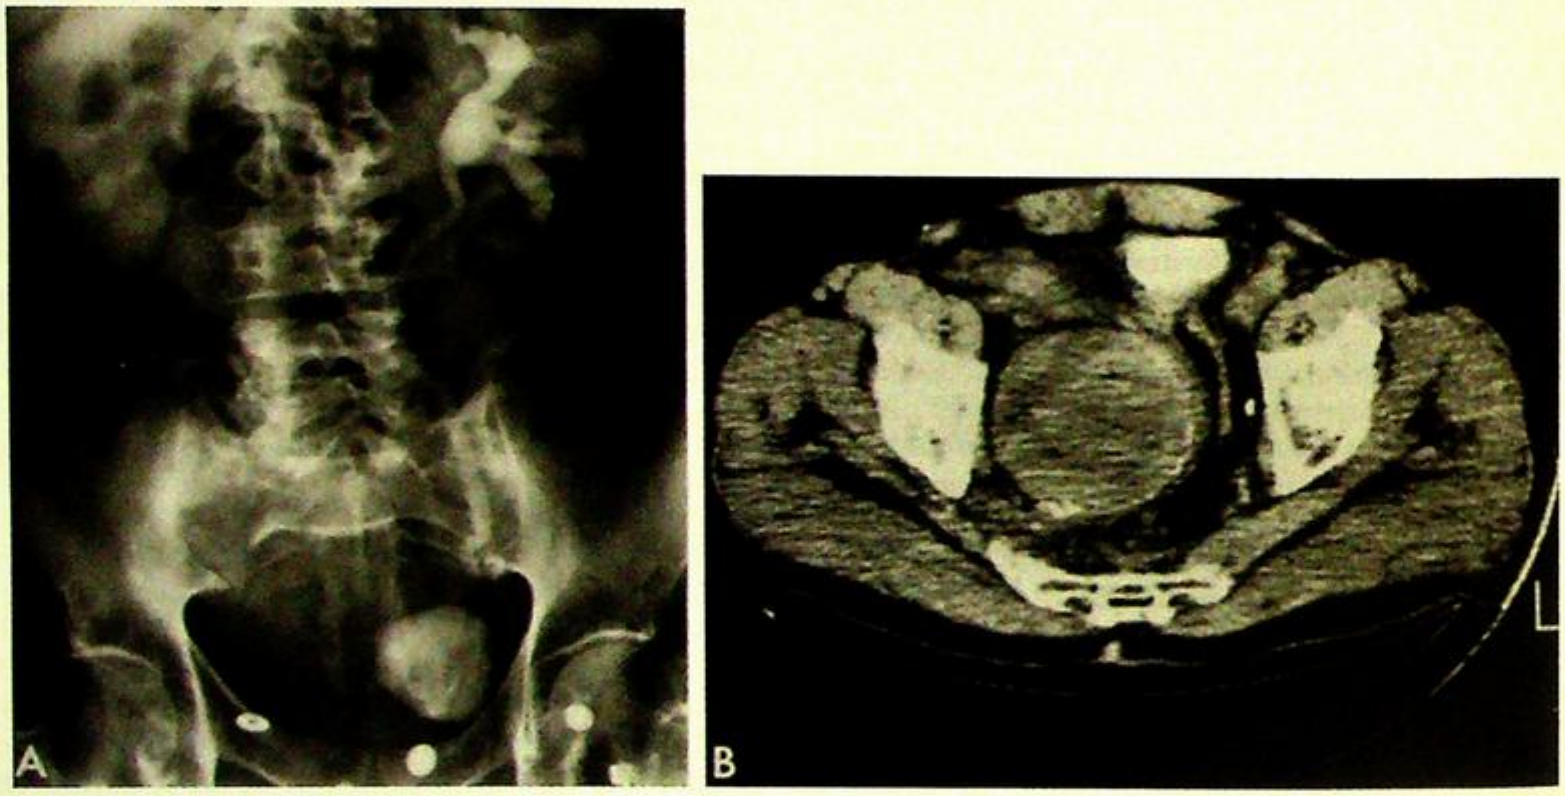

Figure 37–15. Right ureteral obstruction secondary to an aneurysm of the right hypogastric artery. **A**, Intravenous urogram demonstrates delayed visualization of the right kidney and marked deviation of the urinary bladder. **B**, Computed tomography scan demonstrates a large aneurysm. Note calcification of the wall.

Iliac Artery Aneurysms. Iliac artery aneurysms can cause ureteral obstruction. This has been reported in 35% of those with common iliac artery aneurysms and 19% of those involving the internal iliac artery. **An iliac artery aneurysm should be suspected if a pulsatile mass is palpated on rectal examination** (Marino et al, 1987). The diagnosis can be made with various imaging studies including ultrasonography, MRI, and CT (Fig. 37–15A and B). Ureteral obstruction may be due to extrinsic compression or localized inflammation (Mineta et al, 2004).

Treatment options for common iliac artery aneurysms in the setting of ureteral obstruction include ureterolysis, aneurysm resection and graft placement, or endovascular graft placement. Options for obstructing internal iliac artery aneurysms include open surgical ligation and ureterolysis or initial endovascular occlusion and subsequent retrograde placement of an iliac artery endovascular graft. Internalized ureteral stents are typically placed before these procedures and are removed 6 to 8 weeks later. These patients need to be observed closely to determine whether ureteral obstruction resolves or recurs. If it recurs, management options include chronic internalized ureteral stenting, ureterolysis, or ureteral reconstruction (Marino et al, 1987).

An additional cause of ureteral obstruction is the retroiliac ureter (Corbus et al, 1960). Treatment of the ureteral obstruction involves transection of the ureter and transposition to the normal, anterior position. Other genitourinary abnormalities are associated with this condition, including renal hypoplasia, vesicoureteral reflux, ureteral ectopia, ectopic vas deferens, hypospadias, bifid scrotum, hypoplastic or duplex uterus, and hydrometrocolpos (Nguyen et al, 1989; Kay and Meirow,

1993). **Therefore, a search for other genitourinary abnormalities should be undertaken in patients with retroiliac ureter.**

Ureteral Obstruction after Vascular Graft Placement. Hydronephrosis may occur in up to 10% to 20% of patients after aortic bypass graft surgery (Goldenberg et al, 1988; Schein and Saadia, 1991). There are several possible causes for this problem. Mechanical obstruction of the ureter may be due to graft placement anterior to the ureter, which is readily identified on axial imaging (Bouterie and Harbach, 1979). However, this is the cause in the minority of cases. Other possible etiologies include ureteral entrapment in perigraft fibrosis, ureteral devascularization, unidentified ureteral ligation, and ureteral compression from a postoperative pseudoaneurysm (Sant et al, 1983). Symptoms and signs of ureteral obstruction in this setting arise typically in the first postoperative year and include flank pain, anorexia, hypertension, anuria, and renal failure or insufficiency. A minority may remain asymptomatic or manifest delayed symptoms.

The management approach to this problem varies. **If hydronephrosis is demonstrated early in the postoperative period and renal function is not compromised, close observation is initially indicated as hydronephrosis resolves spontaneously in the majority of cases** (Goldenberg et al, 1988). Temporary internalized ureteral stent placement or percutaneous nephrostomy drainage may be required for those with renal impairment or severe symptoms while awaiting spontaneous resolution. If ureteral obstruction does not resolve spontaneously and the graft is placed anteriorly, transposition of the ureter and vascular graft should be a consideration. In order to reduce the risk of graft infection, however, it has been suggested that the vascular graft, rather than the ureter, should be transected and repositioned (Bouterie and Harbach, 1979). A trial of steroid or tamoxifen therapy, similar to that employed for retroperitoneal fibrosis, may be considered if persistent ureteral obstruction is ascribed to perigraft fibrosis. Although success has been reported with such regimens, careful follow-up is mandatory as delayed treatment failure has been reported (Huben and Schellhammer, 1981; Baskerville and Browse, 1987; Jetty and Barber, 2004). Ureterolysis and ileal ureter substitution if the former is not feasible are considerations if medical therapy is not successful. Chronic ureteral stenting may be required in those who are not candidates for the aforementioned procedures (Sant et al, 1983; Matlaga et al, 2003).

Venous Causes of Obstruction

Puerperal Ovarian Vein Thrombophlebitis. Ureteral obstruction has been ascribed to a mechanical effect from a dilated ovarian vein, a condition called "ovarian vein syndrome." The clinical relevance of this entity has since been questioned and discounted (Dure-Smith, 1979). **However, ovarian vein pathology has been documented to be the cause of ureteral obstruction in the postpartum period. Puerperal ovarian vein thrombophlebitis, a rare but well-documented postpartum condition, has been reported to cause ureteral obstruction** (Dure-Smith, 1979; Brown et al, 1999). Although more common on the right, it may occur in either or both ovarian veins. The associated signs and symptoms are often nonspecific but include abdominal or flank pain and fever, usually beginning 2 to 3 days after birth. On physical examination, abdominal tenderness and guarding may be elicited. A tender indurated adnexal mass may be discerned in 50% of patients (Toland et al, 1993). CT or MRI can detect this condition and the associated ureteral obstruction (Twicker et al, 1997).

The majority of patients respond to conservative measures, including antibiotic therapy (Brown et al, 1999). Internalized ureteral stent placement may also be required for management of ureteral obstruction and symptoms (Toland et al, 1993). Laparoscopic or open surgical ureterolysis and ovarian vein resection are undertaken if ureteral obstruction persists (Almeida et al, 2003).

Testicular Vein Thrombophlebitis. Thrombophlebitis of the left testicular vein causing extrinsic obstruction of the left ureter has been reported (Kretkowski and Shah, 1977). Although the patient presented with the clinical picture of ureteropelvic junction obstruction, surgical exploration revealed a dilated and thrombosed left testicular vein impinging upon the proximal ureter. Ureterolysis and excision of the thrombosed vein eradicated the obstruction. A similar event could also occur on the right side (Meyer et al, 1992).

Circumcaval Ureter. Obstruction of the ureter has been described in association with an anomalous course posterior, medial, anterior, and finally lateral to the inferior vena cava (IVC) (Bateson and Atkinson, 1969). This course may lead to extrinsic obstruction of the ureter. Although commonly referred to as circumcaval or retrocaval ureter, a more appropriate term may be preureteral vena cava as it is due to a congenital abnormality in development of the vena cava. The term retrocaval is now primarily used to describe ureters that simply knuckle behind the IVC and reemerge laterally.

Formation of the infrahepatic vena cava is based upon the development and regression of three pairs of embryonic veins: the posterior cardinal, the supracardinal, and the subcardinal. It is postulated that the normally developed IVC results from persistence of the right subcardinal vein suprarenally and the right supracardinal infrarenally. The posterior cardinal veins persist as the common iliac veins (Bass et al, 2000). The anastomosis between the right subcardinal and supracardinal vein crosses anterior to the fetal ureter. In normal development, this connection regresses and the supracardinal vein persists as the infrarenal IVC. The prevailing theory of the development of this anomaly is that the subcardinal vein persists as the infrarenal IVC, thus crossing anterior to the midportion of the ureter and resulting in its circumcaval course (Schulman, 1997). Others have suggested that the persistence of the posterior cardinal vein as the infrarenal cava is responsible for this anomaly. However, failure of the supracardinal vein to develop into the infrarenal IVC is common to both theories (Bass et al, 2000) (Fig. 37–16A to C).

The reported incidence of circumcaval ureter is approximately 1 in 1100. There is a 2.8-fold male predominance (Lutin et al, 1988). Symptomatic patients typically present in the third or fourth decade of life (Zhang et al, 1990). **This vascular anomaly is not always associated with ureteral obstruction** (Crosse et al, 1975). The majority involve the right ureter, although left-sided circumcaval ureter has been reported in association with a duplicated IVC and in association with situs inversus (Watanabe et al, 1991; Rubinstein

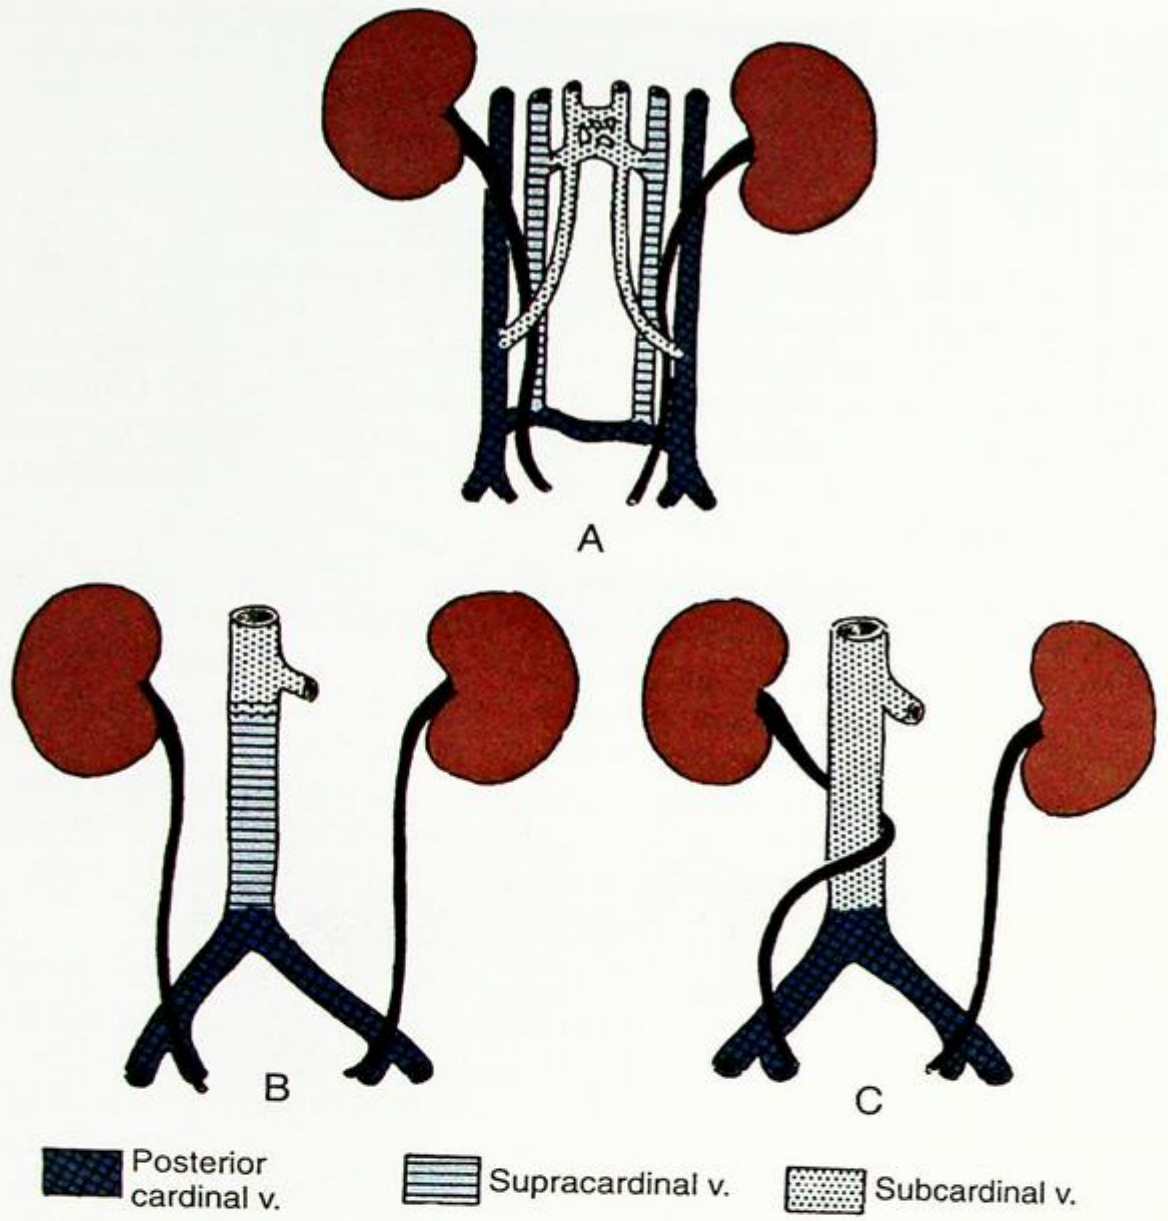

Figure 37–16. Relationship between the development of the infrarenal portion of the inferior vena cava and the retrocaval ureter. **A,** Primitive condition with the ureter winding among three cardinal veins. **B,** Usual method of formation of the vena cava from the right subcardinal vein (dorsal to ureter). **C,** Main portion of the vena cava formed from the subcardinal vein. (From Hollinshead WH: Anatomy for Surgeons, vol 2, 2nd ed. New York, Harper & Row, 1971.)

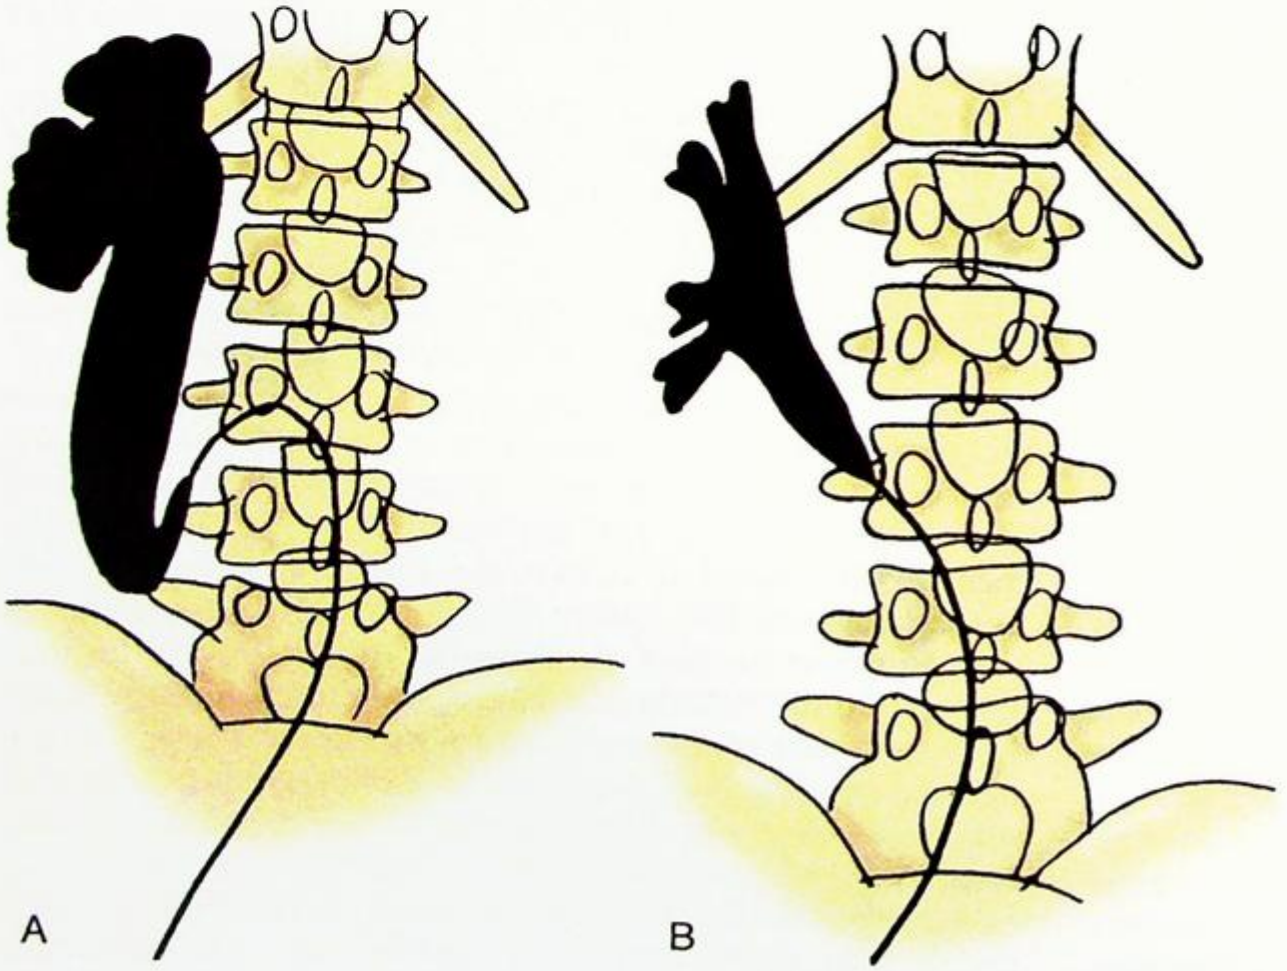

Figure 37–17. **A,** Diagram illustrating the radiologic features of the type 1 circumcaval ureter. **B,** Diagram illustrating the radiologic features of the type 2 circumcaval ureter. (**A** and **B,** from Bateson EM, Atkinson D: Circumcaval ureter: A new classification. Clin Radiol 1969;20: 173-177.)

et al, 1999). Other genitourinary anomalies may be present. Circumcaval right ureter with a retrocaval horseshoe isthmus has been reported (Knutson and Hawas, 2004).

Bateson and Atkinson (1969) classified a ureter with an S-shaped, fish hook, or shepherd's crook appearance as type I (Fig. 37–17A). The ureter typically runs medial to the

course in this setting. A less angulated "sickle-shaped" ureteral deformity is classified as type II (Fig. 37–17B). The point of maximal obstruction in type I is lateral to the lateral margin of the IVC and is associated with a greater degree of hydronephrosis than type II, in which the point of obstruction is at the lateral border of the IVC (Bateson and Atkinson, 1969). Another classification scheme is based on the level of obstruction; type I crosses at the level of the third lumbar vertebra and type II crosses at the level of the ureteropelvic junction. The latter may be confused with ureteropelvic junction obstruction (Kenawi and Williams, 1976). The obstruction has been attributed to extrinsic compression of the ureter by the IVC, its lumbar or gonadal branches, or the psoas muscle. However, an intrinsic ureteral abnormality may be contributory as histologic studies of involved ureteral segments have demonstrated fibrotic changes (Kumar and Bhandar, 1985).

Abdominal and flank pain, recurrent urinary tract infection, and hypertension are some of the initial symptoms and signs. A number of cases are now discovered on imaging studies performed to evaluate patients with nonurologic problems (Belis and Milam, 1980; Sener, 1993). The diagnosis should be suspected when the aforementioned pyelographic findings are present (Fig. 37–18A to C). The diagnosis can be confirmed with CT and MRI (Fig. 37–19A and B). Diuretic renography is used to confirm the presence and determine the functional impact of obstruction.

Treatment is undertaken only in the presence of obstruction. The ureter is divided proximally and at the distal point from which it emerges lateral to the IVC. A spatulated ureteroureterostomy is performed. This has been performed by open, laparoscopic, and retroperitoneoscopic approaches and is best dictated by the surgeon's experience (Polascik and Chen, 1998; Gupta et al, 2001).

KEY POINTS

- Ureteral obstruction leads to renal inflammation, increased extracellular matrix formation, tubulointerstitial fibrosis, and apoptosis of renal tubule cells.
- Unilateral and bilateral ureteral obstructions differ in the patterns of hemodynamic and ureteral pressure changes. Massive postobstructive diuresis occurs primarily with BUO.
- Ureteral obstruction causes persistent decreases in concentrating ability, urinary acidification, and electrolyte transport.
- Key mediators of obstructive uropathy that are potentially amenable to current pharmacotherapy include angiotensin II, TGF-β, TNF-α, nitric oxide, thromboxane, and endothelin.
- Recovery of renal function after the correction of obstruction is adversely affected by increasing duration and degree of obstruction, increasing age of the patient, and decreasing collecting system compliance.
- Nuclear renography provides reliable functional information, and cross-sectional imaging provides reproducible and reliable anatomic delineation.
- Drainage of the obstructed system is the first step in management in cases of threatened functional impairment or infection. Definitive management of the underlying pathology may then be considered as dictated by the disease process.
- Hydronephrosis of pregnancy is a common finding with overall predictable patterns.

38 Management of Upper Urinary Tract Obstruction

THOMAS H.S. HSU, MD • STEVAN B. STREEM, MD* • STEPHEN Y. NAKADA, MD

URETEROPELVIC JUNCTION OBSTRUCTION
RETROCAVAL URETER
URETERAL STRICTURE DISEASE
URETEROENTERIC ANASTOMOTIC STRICTURE
RETROPERITONEAL FIBROSIS

Technologic advances have significantly improved both the diagnostic and therapeutic alternatives available in the contemporary management of upper urinary tract obstruction. The obstructive processes can be congenital to iatrogenic, and the cause of obstruction may not be immediately evident. Furthermore, making the diagnosis of obstruction can also be a challenge.

The treatments of upper tract obstruction range from ureteral stent placement to complex open surgery involving ileal interposition or autotransplantation. Myriad skills are required for total surgical management of upper urinary tract obstruction. Not surprisingly, laparoscopy is now featured prominently in the management of upper urinary tract obstruction. As a result of the wide array of available treatments, the practicing urologist must have an understanding of the indications and risks of all the options.

This chapter provides a contemporary, state-of-the-art presentation of the major management strategies for patients with upper urinary tract obstruction. The chapter is organized by the anatomic location of obstruction. The etiology, diagnosis, indications for intervention, risks, and therapeutic options (including endoscopic, laparoscopic, and open approaches) are thoroughly reviewed.

URETEROPELVIC JUNCTION OBSTRUCTION

The diagnosis of "ureteropelvic junction (UPJ) obstruction" results in a functionally significant impairment of urinary transport from the renal pelvis to the ureter. Although most cases are probably congenital, the problem may not become clinically apparent until much later in life (Jacobs et al, 1979). Acquired conditions such as stone disease, postoperative or inflammatory stricture, or urothelial neoplasm may also present clinically as symptoms and signs of obstruction at the UPJ level. Similarly, extrinsic obstruction can occur at this level as well. The focus in this section is primarily on the diagnosis and treatment of "congenital" UPJ obstruction, although these techniques may be applied to the management of certain acquired conditions, in particular urinary stones.

Pathogenesis

Congenital UPJ obstruction most often results from intrinsic disease. A frequently found defect is the presence of an aperistaltic segment of the ureter, perhaps similar to that found in primary obstructive megaureter. In these cases, histopathologic studies reveal that the spiral musculature normally present has been replaced by abnormal longitudinal muscle bundles or fibrous tissue (Allen, 1970; Foote et al, 1970; Hanna et al, 1976; Gosling and Dixon, 1978). This results in failure to develop a normal peristaltic wave for propagation of urine from the renal pelvis to the ureter. Recognition that this type of segmental defect is often responsible for UPJ obstruction is of utmost importance clinically because such ureters may appear grossly normal at the time of surgery, and, in fact, may often be calibrated to 14 Fr or greater. Further investigations in the etiology of UPJ obstruction have shown decreased interstitial cells of Cajal at the UPJ in children (Solari et al, 2003). In addition, the cytokine produced in the urothelium has also been proposed to exacerbate UPJ obstruction (Chiou et al, 2005). Other experimental studies have implicated transforming growth factor-β, epidermal growth factor expression, nitric oxide, and neuropeptide Y in UPJ stenosis (Knerr et al, 2001; Yang et al, 2003). A less frequent intrinsic cause of congenital UPJ obstruction is true ureteral stricture. Such congenital ureteral strictures are most frequently found at the UPJ, although they may be located at sites anywhere along the lumbar ureter. Abnormalities of ureteral musculature have been implicated as electron microscopy has demonstrated excessive collagen deposition at the site of the stricture (Hanna et al, 1976).

Intrinsic obstruction at the UPJ may also result from kinks or valves produced by infoldings of the ureteral mucosa and musculature (Maizels and Stephens, 1980). In these cases, the

*Deceased.

obstruction may actually be at the level of the proximal ureter. This phenomenon appears to result from retention or exaggeration of congenital folds normally found in the ureter of developing fetuses. In some of these cases, the defects are bridged by ureteral adventitia. Grossly, this can manifest as external bands or adhesions that appear to be causing the obstruction. In fact, Johnston and coworkers, in 1977, reported that lysis of external adhesions can at times reestablish flow without pyeloplasty. In the majority of cases, however, these bands or adhesions are likely to be a secondary phenomenon associated with intrinsic obstruction, so that operative pyeloplasty would generally be most effective. The presence of these kinks, valves, bands, or adhesions may also produce angulation of the ureter at the lower margin of the renal pelvis in such a manner that, as the pelvis dilates anteriorly and inferiorly, the ureteral insertion is carried further proximally. In these cases, the most dependent portion of the pelvis is inadequately drained and the apparent "high insertion" of the ureteral ostium is actually a secondary phenomenon (Kelalis, 1976). In at least some cases, however, the high insertion itself is likely the primary obstructing lesion, because this phenomenon is found more frequently in the presence of renal ectopia or fusion anomalies (Zincke et al, 1974; Das and Amar, 1984). As such, a high insertion can have implications in the subsequent surgical management, particularly endourologic approaches.

Significant controversy persists regarding the potential role of "aberrant" vessels in the etiology of UPJ obstruction. Significant crossing vessels have been noted in as many as 40% of cases of UPJ obstruction but as little as 20% of cases of normal kidneys (Quillin et al, 1996; Zeltser et al, 2004). Although these lower pole vessels have often been referred to as aberrant, these segmental vessels, which may be branches from the main renal artery or arise directly from the aorta, are usually normal variants (Stephens, 1982). In some patients, these lower pole vessels cross the ureter posteriorly and truly have an aberrant course. Regardless, it is unlikely that the associated vessel alone is causing the primary obstruction (Hanna, 1978). In fact, the true etiology is an intrinsic lesion at the UPJ or proximal ureter that causes dilatation and ballooning of the renal pelvis over the polar or aberrant vessel. Recent studies using three-dimensional multidetector row computed tomography (CT) demonstrated that the precise location of crossing vessels did not correspond to the obstructive transition point in patients with UPJ obstruction (Lawler et al, 2005). In contrast, one group found improvement in patients undergoing only ligation of crossing vessels (Keeley et al, 1996). **Regardless, the presence of crossing vessels most certainly has a detrimental effect on the success rates of minimally invasive treatments of UPJ obstruction, in particular endopyelotomy** (Van Cangh et al, 1994, Nakada et al, 1998). UPJ obstruction with concomitant anatomic anomalies such as horseshoe kidney and pelvic kidney also present further surgical challenges. Preoperative spiral CT angiographic studies are very useful in these patients to identify crossing vessels and to aid in surgical planning (Pozniak and Nakada, 1997).

UPJ obstruction may also result from acquired lesions. In children, vesicoureteral reflux can lead to upper tract dilatation with subsequent elongation, tortuosity, and kinking of UPJ obstruction may definitely coexist with vesicoureteral reflux, although it may be difficult to determine whether the anomalies are merely coincident or whether the upper tract ureteral obstruction has resulted from the reflux (Lebowitz and Johan, 1982). Diuretic renography is most helpful for differentiating between UPJ obstruction and reflux.

Other acquired causes of obstruction at the UPJ include benign tumors such as fibroepithelial polyps (Berger et al, 1982; Macksood et al, 1985), urothelial malignancy, stone disease, and postinflammatory or postoperative scarring or ischemia. For these acquired diseases, the techniques discussed in this section may be useful adjuncts for management of the obstruction as long as the primary problem is also addressed where appropriate. For instance, fibroepithelial polyps can be managed using retrograde ureteroscopy and holmium laser excision (Lam et al, 2003a).

Patient Presentation and Diagnostic Studies

UPJ obstruction, although most often a congenital problem, can present clinically at any time of life. Historically, the most common presentation in neonates and infants was the finding of a palpable flank mass. However, **the current widespread use of maternal, prenatal ultrasonography has led to a dramatic increase in the number of asymptomatic newborns being diagnosed with hydronephrosis, many of whom are subsequently found to have UPJ obstruction** (Bernstein et al, 1988; Wolpert et al, 1989). A fraction of cases may also be found during evaluation of azotemia, which may result from bilateral obstruction in a functionally or anatomically solitary kidney. UPJ obstruction may also be incidentally found during studies performed to evaluate unrelated anomalies such as congenital heart disease (Roth and Gonzales, 1983). In older children or adults, intermittent abdominal or flank pain, at times associated with nausea or vomiting, is a frequent presenting symptom. Hematuria, either spontaneous or associated with otherwise relatively minor trauma, may also be an initial symptom. Laboratory findings of microhematuria, pyuria, or frank urinary tract infection might also bring an otherwise asymptomatic patient to the urologist. Rarely, hypertension may be a presenting finding (Riehle and Vaughan, 1981). **Radiographic studies should be performed with a goal of determining both the anatomic site and the functional significance of an apparent obstruction.** Excretory urography remains a reasonable first-line option for radiographic diagnosis. Classically, findings on the affected side include delay in function associated with a dilated pelvicalyceal symptom (Fig. 38–1). If the ureter is visualized, it should be of normal caliber. In some patients, symptoms may be intermittent and intravenous pyelography between painful episodes may be normal. In such cases, the study should be repeated during an acute episode when the patient is symptomatic (Nesbit, 1956). In some, provocative testing with diuretic urogram may allow accurate diagnosis. The patient should be well hydrated and the study then performed by injecting furosemide, 0.3 to 0.5 mg/kg, intravenously at the time of intravenous urography (Malek, 1983) (Fig. 38–2).

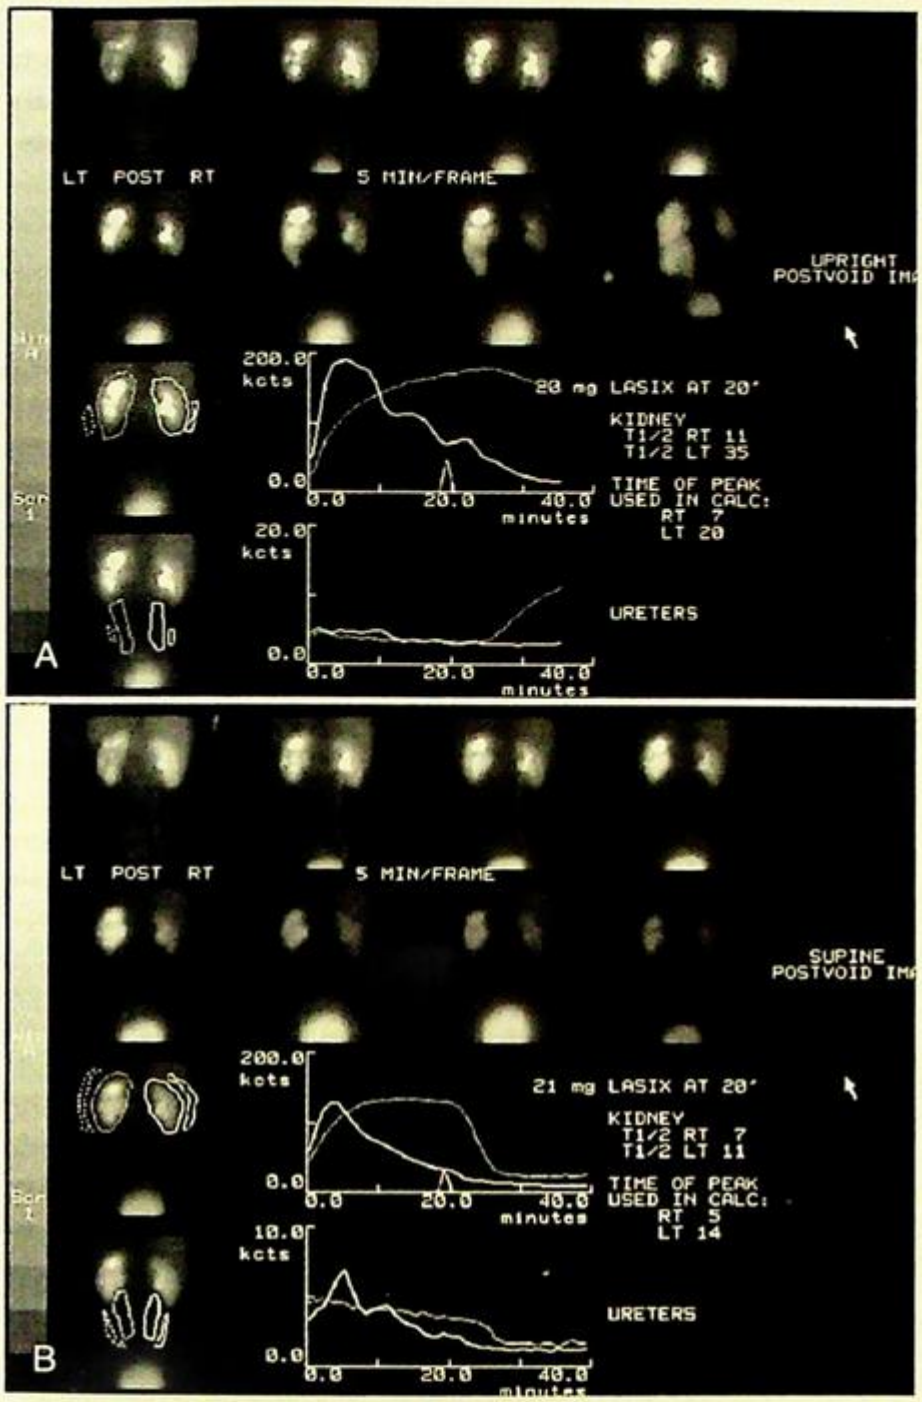

Figure 38–4. **A,** MAG-3 diuretic renography revealing functional UPJ obstruction of the left kidney, with a half-life greater than 35 minutes. **B,** Follow-up MAG-3 diuretic renography reveals normal drainage of the left kidney after successful laparoscopic pyeloplasty.

pyelography thus retains a role for confirmation of the diagnosis and for demonstration of the exact site and nature of obstruction before repair. In most cases this study is performed at the time of the planned operative intervention to avoid the risk of introducing infection in the face of obstruction. However, retrograde pyelography is indicated emergently whenever the UPJ obstruction requires acute decompression, such as in the setting of infection or compromised renal function. **In cases in which cystoscopic retrograde manipulation has been unsuccessful or may be hazardous, particularly in neonates or infants, placement of a percutaneous nephrostomy is an excellent alternative. This allows the performance of antegrade studies that will help define the nature and exact anatomic site of obstruction.** It also allows decompression of the system in cases of associated infection or compromised renal function and allows assessment of recoverability of renal function after decompression. **When there remains some doubt as to the clinical significance of a dilated collecting system, placement of a percutaneous nephrostomy tube allows access for dynamic pressure perfusion studies.** First described by Whitaker in 1973, the renal pelvis is continuously perfused at 10 mL/min with normal saline solution or dilute radiographic contrast solution under fluoroscopic control. Renal pelvic pressure is monitored during the infusion, and the pressure gradient across the UPJ is determined. During the infusion, the bladder is continuously drained with an indwelling catheter to prevent transmission of intravesical pressures. Renal pelvic pressure ranging up to 12 to 15 cm H_2O during this infusion suggests a nonobstructed system. In contrast, pressures in excess of 15 to 22 cm H_2O are highly suggestive of a functional obstruction. Pressures between these extremes may be nondiagnostic (O'Reilly, 1986).

Although pressure perfusion studies can often provide valuable information regarding the functional significance of an apparent obstruction, these studies can at times be inaccurate. This inaccuracy may be a result of variations in renal pelvic anatomy and compliance (Koff et al, 1986) or positional variations (Ellis et al, 1995). As such, there remains an important role for the urologist as a diagnostician to collate the clinical presentation and results of all diagnostic studies performed to recommend appropriate clinical intervention.

Indications and Options for Intervention

Contemporary indications for intervention for UPJ obstruction include the presence of symptoms associated with the obstruction, impairment of overall renal function or progressive impairment of ipsilateral function, development of stones or infection, or, rarely, causal hypertension. The primary goal of intervention is relief of symptoms and preservation or improvement of renal function. Traditionally, such intervention should be a reconstructive procedure aimed at restoring nonobstructed urinary flow. This is especially true for neonates, infants, or children in whom early repair is desirable, because these patients will have the best chance for improvement in renal function after relief of obstruction (Bejjani and Belman, 1982; Roth and Gonzales, 1983; Wolpert et al, 1989). However, timing of the repair in neonates remains controversial (DiSandro and Kogan, 1998; Koff, 1998, 2000; Hanna, 2000; Shokeir and Nijman, 2000), mostly because of difficulty in defining those kidneys truly at risk for functional obstruction. In a prospective study of 104 neonates with primary unilateral hydronephrosis suspected of being caused by UPJ obstruction, after a mean follow-up of 21 months only 7 (7%) required pyeloplasty for functional obstruction, defined as a progression of hydronephrosis or a 10% reduction in differential glomerular filtration rate on serial ultrasonography and diuretic renography (Koff and Campbell, 1994). All treated patients had a return of renal function to predetermination levels, supporting selective nonoperative management of neonatal hydronephrosis.

UPJ obstruction may not become apparent until middle age or later (Jacobs et al, 1979). Occasionally, if the patient is asymptomatic and the physiologic significance of the obstruction seems indeterminate, careful observation with serial follow-up studies may be appropriate, typically using diuretic renography. However, the majority of affected patients may

ultimately benefit from reconstructive intervention (Jacobs et al, 1979; Clark and Malek, 1987; O'Reilly, 1989). **When intervention is indicated, the procedure of choice has historically been open operative repair of the UPJ, usually dismembered pyeloplasty. However, less invasive endourologic approaches have gained a proven role as an initial procedure of choice in many centers** (Brannen et al, 1988; Motola et al, 1993a; Kletscher et al, 1995; Cohen et al, 1996; Nadler et al, 1996; Thomas et al, 1996; Tawfiek et al, 1998; Lechevallier et al, 1999; Gerber and Kim, 2000; Nakada, 2000; Conlin, 2002). **Most recently, laparoscopic pyeloplasty has gained acceptance in centers with laparoscopic expertise.** Yet despite the availability of various minimally invasive procedures for UPJ obstruction, one survey showed many academic urologists still perform a significant number of open pyeloplasties (Marcovich et al, 2003).

Although success rates with most endourologic techniques have not proven to be comparable with those of open or laparoscopic pyeloplasty, it has been suggested that the success rates may be significantly improved with careful patient selection. In an important prospective study, Van Cangh and associates (1994) achieved an overall success rate for endopyelotomy of 73%. However, these investigators found the presence of crossing vessels to be a major determinant of outcome (42% success rate in the setting of a crossing vessel vs. 86% success without a crossing vessel). Furthermore, when endopyelotomy was applied to patients with "a high degree of obstruction," the success rate was only 60% compared with an 81% success rate for those patients with "low-grade" obstruction. When patients with both a crossing vessel and a high degree of obstruction were excluded from analysis, the success rate improved to 95%, which is comparable with that of open pyeloplasty. However, other studies have suggested a less important role for these factors in regard to their impact on a successful outcome (Gupta et al, 1997; Danuser et al, 1998; Nakada et al, 1998).

Although the indications for intervention for UPJ obstruction are similar regardless of technique, it is critical to discuss the risks and benefits of all available options with patients. As such, each patient should be advised individually based on all the anatomic and functional information available preoperatively. In this setting, many patients will opt for a minimally invasive approach, even with the understanding that success rates may be lower or secondary intervention may become necessary. As a result of studies linking crossing vessels to hindered endourologic successes, there is increased interest in intraoperative management of the UPJ and crossing vessel by either an open or laparoscopic approach (Conlin, 2002). **Therefore, for "secondary" UPJ obstruction, it is reasonable to recommend an open or laparoscopic approach to any patient who has failed primary endourologic management and an endourologic approach to those who have failed open or laparoscopic repair.** The results of endourologic management in this setting were generally excellent (Jabbour et al, 1998).

Rarely, nephrectomy may be the procedure of choice. Indications for nephrectomy as primary therapy include diminished function or nonfunction of the involved renal moiety and a normal contralateral kidney based on radiographic and nuclear studies. These patients may be symptomatic with urinary tract infections or pain. In such cases, ultrasonography or CT is generally performed and will reveal only a thin shell of parenchyma remaining. **Renography can provide quantitative measures of renal function, and generally kidneys with less than 15% differential function are nonsalvageable in adults.** If the potential for salvageability of function is still unclear, an internal stent or percutaneous nephrostomy may be placed for temporary relief of obstruction and then renal function studies subsequently repeated. Nephrectomy may also be considered for patients in whom the obstruction has led to extensive stone disease with chronic infection and significant loss of function in the presence of a normal contralateral kidney. Removal of the kidney may also be chosen over reconstruction for patients in whom repeated attempts at repair have already failed and in whom further intervention would therefore be extremely complicated. This option should be considered only when the contralateral kidney is essentially normal.

Options for Intervention

Endourologic Management

Open operative intervention for UPJ obstruction has historically provided a widely patent, dependently positioned, well-funneled UPJ. In addition, the option to reduce the size of the renal pelvis is readily available with this approach. Although the procedure has stood the test of time with a published success rate of 95%, several less invasive alternatives to standard operative reconstruction are available (Clark and Malek, 1987). **The advantages of endourologic approaches include a significantly reduced hospital stay and postoperative recovery. However, the success rate does not approach that of standard open or laparoscopic pyeloplasty. Furthermore, whereas open or laparoscopic operative intervention can be applied to almost any anatomic variation of UPJ obstruction, consideration of any of the less invasive alternatives requires that the surgeon take into account the degree of hydronephrosis, ipsilateral renal function, concomitant calculi, and, possibly, the presence of crossing vessels.** Of note, Albani and colleagues (2004) reported contemporary long-term results with various endopyelotomy approaches to have a success rate of 67%, with the majority of failures in the first 32 months.

Endourologic management of UPJ obstruction was introduced by Ramsay and colleagues in 1984 as a "percutaneous pyelolysis" and then popularized in the United States by Badlani and coworkers (1986), who coined the term *endopyelotomy.* **Although various nuances in the technique have been described** (Korth et al, 1988; Van Cangh et al, 1989; Ono et al, 1992), **the basic concept is constant and involves a full-thickness incision through the obstructing proximal ureter, from the ureteral lumen out to the peripelvic and periureteral fat.** A stent is placed across the incision and left to heal, based on the original work of Davis in 1943, who performed an "intubated ureterotomy" to repair UPJ obstruction. Subsequently, alternative techniques utilizing a retrograde approach to the UPJ were developed. The retrograde techniques available today include a "hot-wire" cutting balloon, which incises the UPJ under fluoroscopic control, and the ureteroscopic approach, typically utilizing the holmium laser to incise the UPJ under direct visual control. Finally, hybrid

approaches, such as the percutaneous endopyeloplasty, have also been reported (Desai et al, 2004).

Percutaneous Antegrade Endopyelotomy

Indications and Contraindications. The indications to intervene for any patient with UPJ obstruction include the presence of symptoms, progressive or overall impairment of renal function, development of upper tract stones or infection, or, rarely, causal hypertension. Historically, a percutaneous approach for definitive management of UPJ obstruction was offered only to those patients undergoing percutaneous removal of associated stones or to those who had previously failed open pyeloplasty. However, encouraging results ultimately led many centers to offer percutaneous endopyelotomy as primary therapy for almost any patient with UPJ obstruction. **Even today, with several alternative minimally invasive options available including laparoscopy, a percutaneous approach is most appropriate for those patients with concomitant pyelocalyceal stones, which can then be managed simultaneously. Contraindications to a percutaneous endopyelotomy are similar to the contraindications to any endourologic approach and include a long segment (>2 cm) of obstruction, active infection, or untreated coagulopathy.** Whereas the impact of crossing vessels is controversial, the mere presence of crossing vessels is not a contraindication to an endopyelotomy (Motola et al, 1993a; Nakada et al, 1998; Lam et al, 2003b). However, significant entanglement of the UPJ by crossing vessels can occasionally be identified and this may render any endourologic approach unsuccessful. When such entanglement is suggested by intravenous or retrograde pyelography (Fig. 38–5), it can be reliably verified using three-dimensional helical CT (Kumon et al, 1997).

Patient Preparation. Patients undergoing a percutaneous endopyelotomy undergo preoperative evaluation and preparation as if they were undergoing any percutaneous, laparoscopic, or open renal intervention. The evaluation includes an assessment for any comorbidity that may increase the risk of anesthesia. Sterile urine should be ensured at the time of definitive intervention. If upper tract infection cannot be cleared because of obstruction, temporization should be accomplished using internal stenting or percutaneous nephrostomy drainage alone. The patient should be counseled as to the risks and benefits of the procedure, and in particular the fact that the success rate of any endourologic approach, including percutaneous endopyelotomy, may be less than that of operative intervention. Patients should also be counseled of the risk of bleeding requiring transfusion, urinary leak, drainage-related complications, and hydropneumothorax, particularly if upper pole access is utilized.

Technique. **An endopyelotomy cannot be performed safely by any route until access across the UPJ is established.** This can be accomplished in a retrograde fashion cystoscopi-

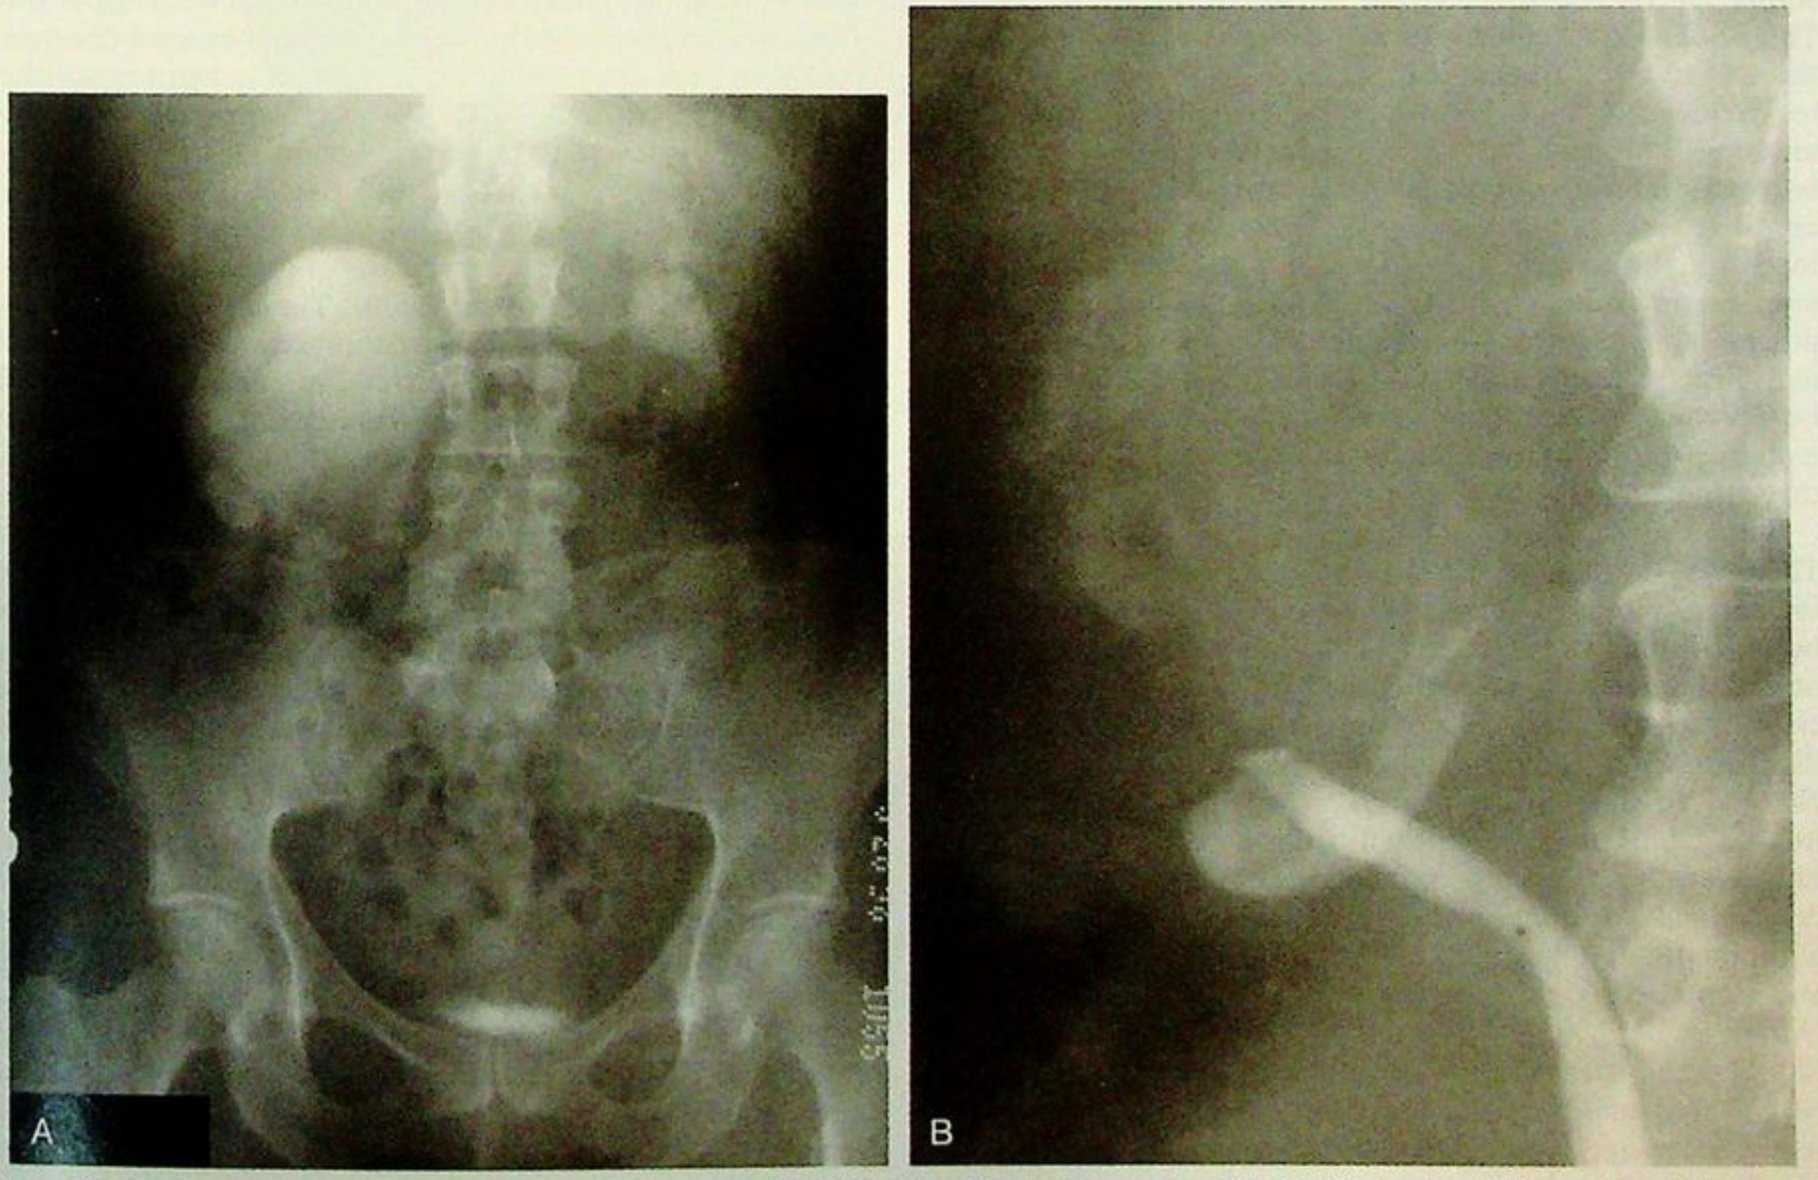

Figure 38–5. **A,** Intravenous pyelogram (IVP) reveals apparent right UPJ obstruction in this woman with right flank pain. **B,** Retrograde study suggests entanglement at the UPJ by crossing vessels. This was subsequently proved with three-dimensional CT angiography.

cally or in an antegrade manner percutaneously. For retrograde access, the UPJ can almost always be traversed utilizing a hydrophilic wire passed through an open-end catheter. Once the hydrophilic wire is successfully positioned in the pyelocalyceal system, the open-end catheter is advanced over it into the renal pelvis. The wire can then be withdrawn so that contrast material can be injected through the open-end catheter to guide subsequent percutaneous access.

With the patient in the prone position, the site for percutaneous access is chosen to allow straightforward access to the UPJ. Generally, a midposterior or superolateral calyx is chosen, although, occasionally, an inferolateral calyx may be utilized. Typically, the UPJ can be intubated in an antegrade fashion when the tract is initially established with fluoroscopic control. Alternatively, once the tract is dilated and nephroscopy is performed, a wire can again be passed in a retrograde fashion through the open-end catheter and grasped from above, so that through-and-through access is reestablished. In either case, as soon as access is obtained with one wire, an introducing catheter is utilized to pass a second wire as a "safety wire," so that a working and a safety wire are now both in place. At this point, percutaneous access is complete and the endopyelotomy may be performed.

In the original descriptions of the technique both from the Institute of Urology in London (Ramsay et al, 1984) and from Long Island Jewish Hospital in New York (Badlani et al, 1986), the endopyelotomy was performed using a cold knife technique under direct vision. With one or two wires in place across the UPJ, a direct vision "endopyelotome" is utilized. This hook-shaped cold knife may be used to completely incise the UPJ in a full-thickness manner, from the ureteral lumen to periureteral and peripelvic fat (Fig. 38–6). **Rigorous anatomic studies have shown the incision should generally be made laterally, because this is the location devoid of crossing vessels** (Sampaio, 1993). However, in cases of high insertion, the incision should instead "marsupialize" the proximal ureter into the renal pelvis, such that an anterior or posterior incision may be required (Fig. 38–7). When such incisions are done under direct vision, any crossing vessel can be directly visualized and avoided. In addition to the endopyelotome, the holmium laser or the cutting balloon catheter may also be utilized to perform an antegrade endopyelotomy.

Once the incision is complete, stenting is accomplished. There is no consensus as to the optimal stent size or duration for endopyelotomy, and a 14/7 Fr endopyelotomy stent may be passed in an antegrade fashion with the larger diameter end of the stent positioned across the UPJ. In some cases, especially when the patient has not been pre-stented, passage of this large-caliber stent may be difficult. In those instances, a No. 10/7 Fr endopyelotomy stent or even a standard No. 8 Fr internal stent may be utilized without compromising the ultimate outcome. Once proper positioning of the stent is determined fluoroscopically, any remaining safety wires are withdrawn. One group showed no difference between larger and standard stents in a porcine study of endopyelotomies (Moon et al, 1995). Alternatively, Danuser and colleagues (2001) demonstrated improved success rates using a modified No. 27 Fr stent after percutaneous endopyelotomy at nearly 2 years follow-up.

Whereas a "tubeless" percutaneous endopyelotomy is advocated by some authors (Bellman et al, 1997), our preference is to leave a nephrostomy tube indwelling for 24 to 48 hours, at which time a nephrostogram is performed to ensure proper positioning of a patent stent. The nephrostomy tube may then be removed, with or without a brief trial of clamping.

There is an alternative modification of percutaneous endopyelotomy utilizing a "stent first/hot knife" technique (Savage and Streem, 2000). We have found it advantageous at this point to pass a stent before performing the actual endopyelotomy incision. Having the stent in place at the outset of the procedure obviates concern about avulsing the UPJ during placement of a stent after the UPJ has already been incised. Additionally, we have found that placement of the stent before making the incision serves to better define the UPJ itself, thus allowing a more precise incision. The UPJ and proximal ureter can then often be seen to bulge into the renal pelvis, such that the subsequent endopyelotomy is equivalent to a ureteral meatotomy at the ureterovesical junction.

Once the stent is in place, the hot knife, the cold knife, or the holmium laser is used to marsupialize the proximal ureter into the renal pelvis. In the setting of a high insertion, the incision can often be extended to the dependent portion of the renal pelvis under direct vision, bridging the gap between the lateral wall of the ureter and the medial wall of the pelvis, across the periureteral and peripelvic fat. Once the incision is complete, the stent is already in place and nephrostomy drainage is instituted for 24 to 48 hours.

Simultaneous Percutaneous Nephrolithotomy/Endopyelotomy. **Percutaneous management is particularly favorable when the UPJ obstruction is associated with upper tract stone disease, because the stones can be managed concomitantly.** In such cases, percutaneous access is again established with a wire across the UPJ. The stone should be removed before the endopyelotomy, so that stone fragments do not migrate into the peripyeloureteral tissue, as can happen if the endopyelotomy is performed first. Otherwise, localized obstruction may result from fibrosis or granuloma formation (Giddens et al, 2000; Streem, 2000). The urologist must take care to ensure that the UPJ obstruction is not a result of edema from the concomitant stone disease, in particular with stone disease in the renal pelvis. In this circumstance, initial management of the stone percutaneously and subsequent radiographic assessment of the UPJ once the stone has been removed is most prudent. In addition, if a nephrostomy tube is retained, a Whitaker test is straightforward and definitive to assess for persistent obstruction. Conversely, UPJ obstruction and solitary lower pole calculi do not represent a dilemma regarding UPJ edema and combined percutaneous management remains most efficient. Alternatively, laparoscopic pyeloplasty and concomitant stone removal is also effective for these patients.

Postoperative Care. Avoidance of strenuous activity for 8 to 10 days after the procedure is recommended. The optimal time course for post-endopyelotomy stent placement has yet to be determined, although 2 to 4 weeks' duration has proven successful (Mandhani et al, 2003). Although the need for prophylactic antibiotics while the stent is indwelling is not literature based, our practice is to utilize a daily suppressive dose. Once the stent is removed, the patient returns 1 month later for clinical follow-up and radiographic evaluation. This generally includes a history, physical examination, urinalysis, and diuretic renography. If the patient remains asymptomatic and

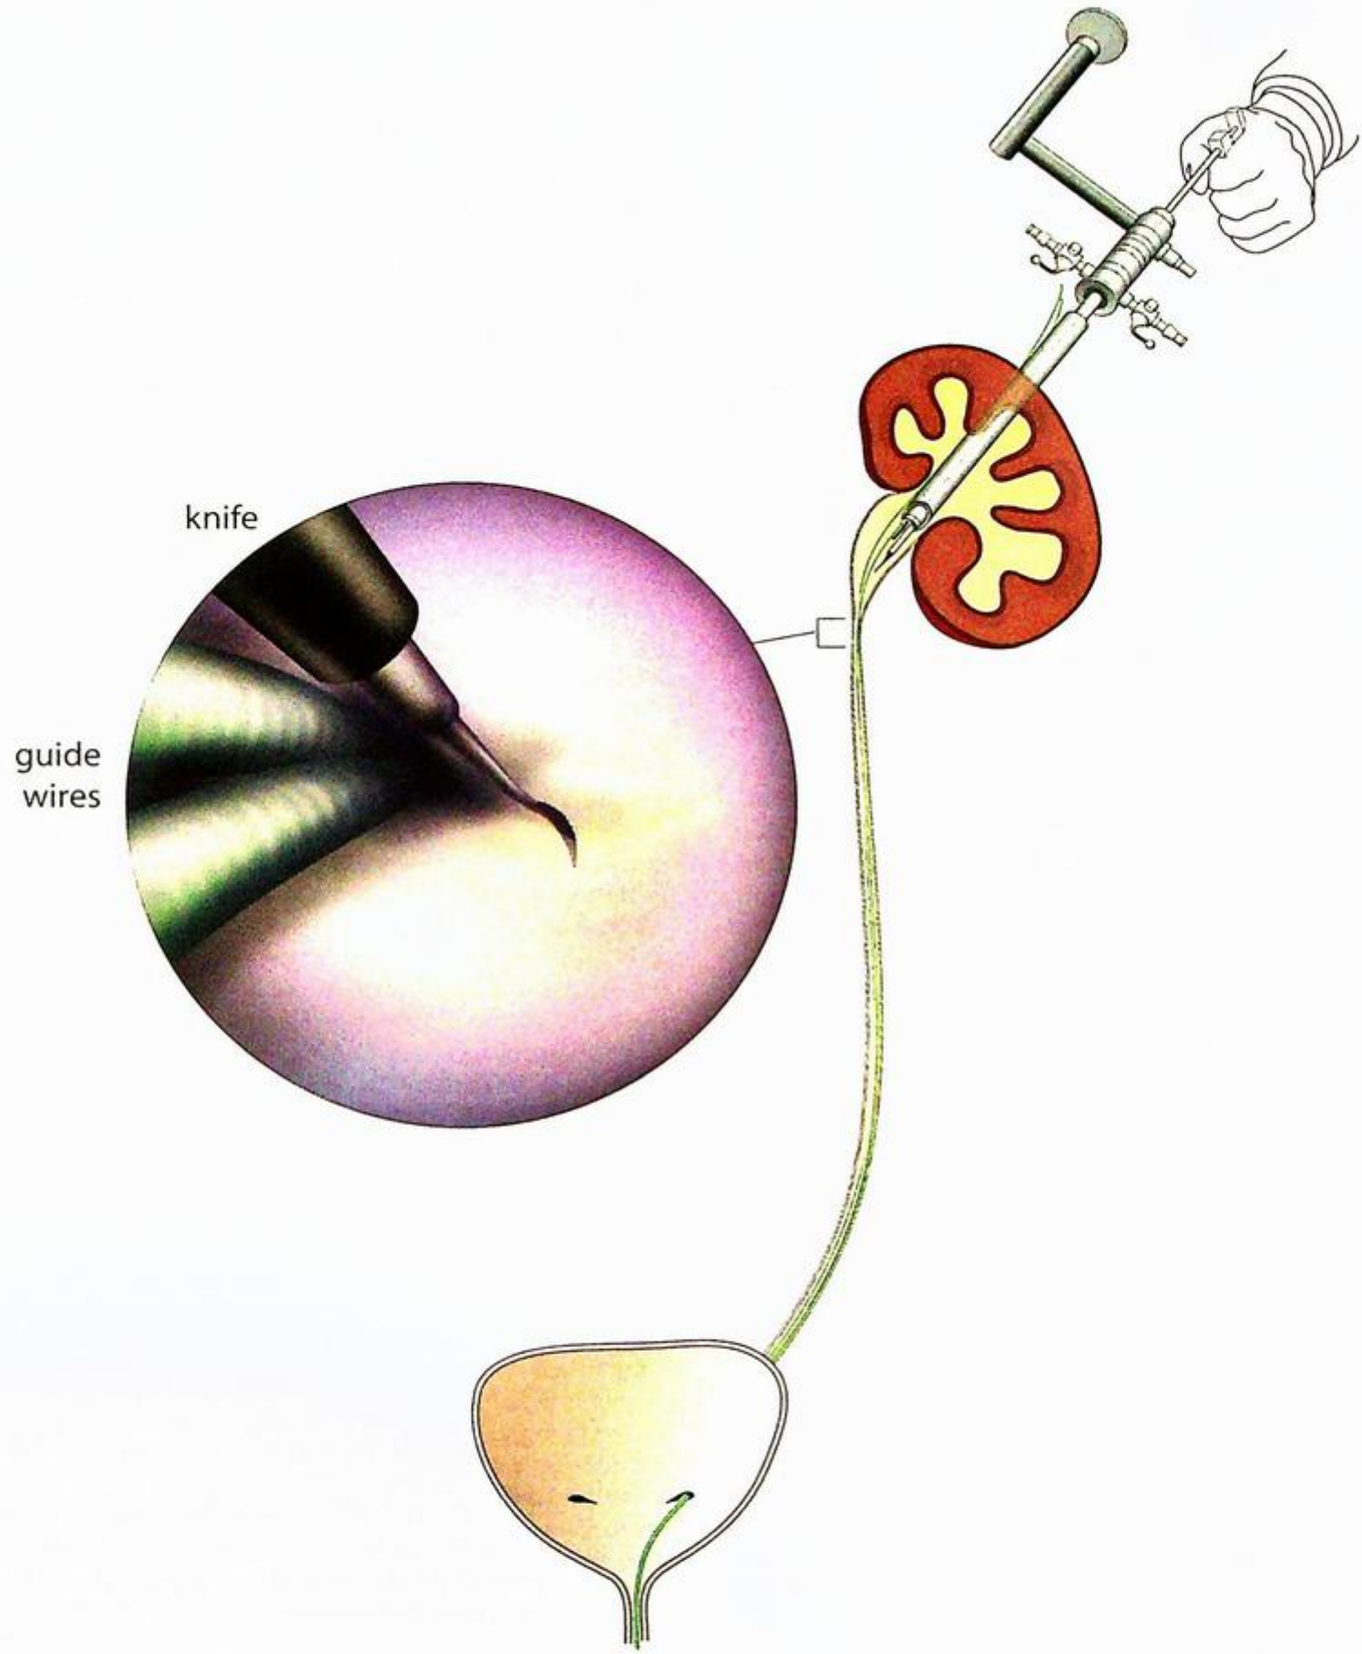

Figure 38–6. Percutaneous nephroscopic view of "cold knife" endopyelotomy *(inset)*. The line of incision is delineated by two guide wires, which have been passed across the UPJ in an antegrade fashion through a superior calyx using a rigid nephroscope through a No. 30 Fr sheath. The lateral incision is performed under direct visual control.

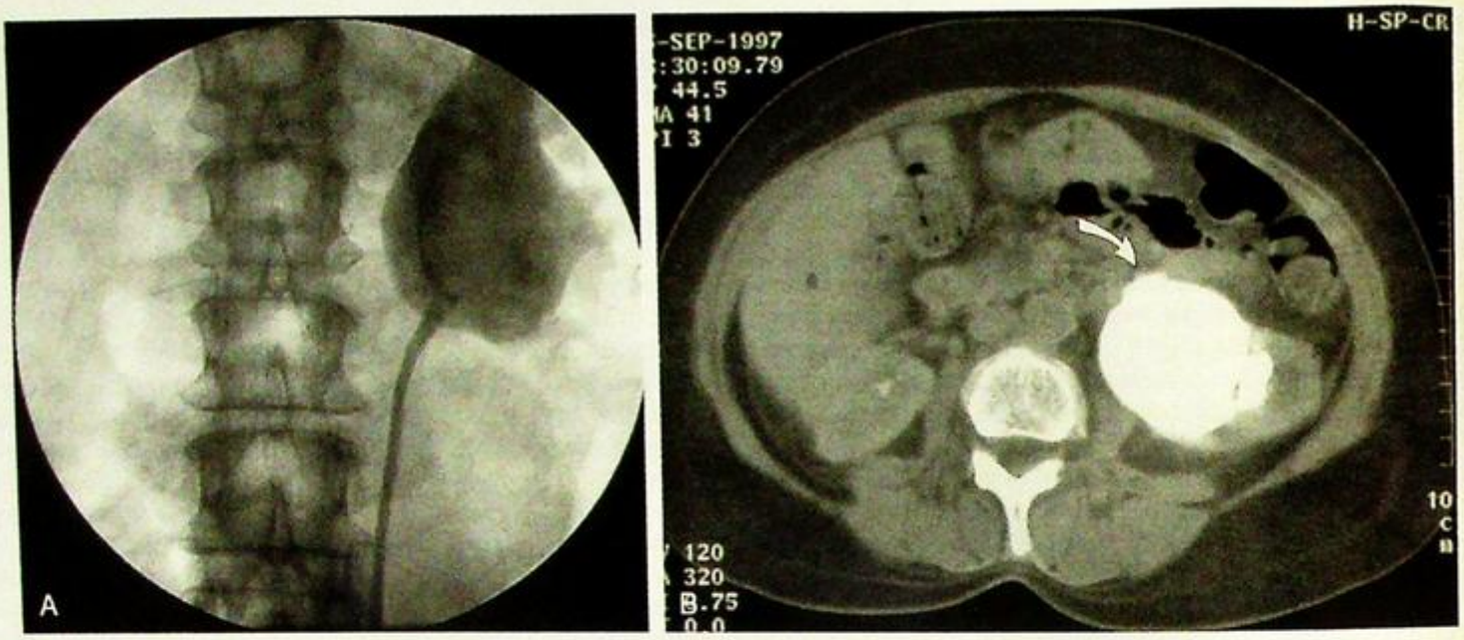

Figure 38–7. **A,** Retrograde study in this patient with left UPJ obstruction reveals a "high insertion" of the left ureter. **B,** CT scan in the same patient reveals the ureter inserting on the anatomically anterior aspect of the renal pelvis. A marsupializing incision must be made in a true posterior direction from the ureter into the renal pelvis.

the diuretic renography reveals normal drainage (normal half-life), reevaluation is performed at 6 months and then at 12-month intervals for up to 3 years. Most studies have shown that the majority of endopyelotomy failures occur within the first 24 months, but failures can appear up to 32 months postoperatively (Nadler et al, 1996; Albani et al, 2004).

Results. The immediate and long-term results of percutaneous endopyelotomy are well established. Although percutaneous endopyelotomy compares favorably with open operative pyeloplasty in terms of postoperative pain, length of hospital stay, and return to prehospitalization activities (Karlin et al, 1988; Brooks et al, 1995), retrograde endopyelotomy and laparoscopy also offer favorable convalescence.

Gerber and Lyon, in 1994, reviewed the outcome of percutaneous endopyelotomy in 672 patients reported from 12 centers and found a success rate ranging from 57% to 100% (mean, 73.5%) at follow-up ranging from 2 to 96 months. Currently, success rates approaching 85% to 90% are being reported at experienced centers, with little difference in outcome noted in those patients undergoing the procedure for primary versus secondary UPJ obstruction (Motola et al, 1993a; Kletscher et al, 1995; Shalhav et al, 1998). Of note, Knudsen and colleagues (2004) reported long-term results in 80 patients using the cold knife and holmium laser for antegrade endopyelotomy, with 55-month follow-up. This series had a success rate of 67%, slightly lower than otherwise reported.

When percutaneous endopyelotomy does fail, several options exist, including a retrograde endopyelotomy, repeat percutaneous endopyelotomy, or laparoscopic or open operative intervention. **There is a role for spiral CT angiography in failed endopyelotomy to rule out a crossing vessel. If a significant vessel is found, repeat endopyelotomy is generally not recommended** (Nakada, 2000). **As such, operative intervention is generally offered to any patient who has failed an endourologic approach. In this setting, the results of laparoscopic or open intervention will not be compromised** (Motola et al, 1993b; Gupta et al, 1997; Conlin, 2002).

Complications. **The complications associated with percutaneous endopyelotomy are analogous to those associated with percutaneous nephrolithotomy** (Badlani et al, 1988; Weiss et al, 1988; Cassis et al, 1991; Malden et al, 1992; Bellman, 1996), **and hemorrhage is a risk of any percutaneous procedure, including endopyelotomy.** However, because in patients with UPJ obstruction the renal parenchyma is generally thinner than that associated with a normal kidney, and because the collecting system is dilated, this risk may be different than that in the general population of stone patients undergoing percutaneous manipulation. Treatment of hemorrhage in this setting is generally conservative to start, and this includes bed rest, hydration, and transfusion as necessary. The nephrostomy tube should not be irrigated acutely. Rather, it is preferable to allow the pyelocalyceal system to tamponade the bleeding. When continued bleeding does not respond to these conservative measures, the next step is selective angiographic embolization. **Generally, the urologist should have a low threshold to proceeding to angiography to minimize the need for transfusion and potential exploration. Successful angiographic embolization often obviates the need for operative "exploration" that can lead to nephrectomy.**

Infection is a risk of any urinary tract manipulation, including percutaneous endopyelotomy, and all attempts should be made to sterilize the urinary tract before the procedure. Whereas the role of prophylactic antibiotics at the outset of the procedure in the setting of a sterile urine is unproven, most urologists give a second-generation cephalosporin "on call" to the procedure. Consideration should be given to the use of prophylactic antibiotics while the endopyelotomy stent is indwelling for the month after the procedure, especially in women who are more prone to [illegible]ruria.

Persistent obstruction is rare in the early postoperative period because of the internal stent. Occasionally, the stent can be obstructed from blood clots, and continued nephrostomy drainage for a few days typically allows the problem to resolve spontaneously.

"Cautery Wire Balloon" Endopyelotomy. Use of a cautery wire balloon for management of UPJ obstruction was first reported in a clinical series by Chandhoke and associates in 1993. The original device included as its essential elements a No. 7 Fr catheter on which was mounted an 8-mm balloon with a 150-μm-wide, 2.8-cm-long electrosurgical cutting wire. Use of this device gained rapid acceptance by many clinicians because standard cystoscopic techniques and real-time fluoroscopy are all that is needed for its use. Furthermore, the technique is readily mastered with a relatively short "learning curve" because advanced ureteroscopic skills are not necessary.

Indications and Contraindications. **As for any treatment of UPJ obstruction, the indications to intervene include associated symptoms, progressive or overall impairment of renal function, development of upper tract infection, or, rarely, causal hypertension. As for any endourologic approach, contraindications to this technique include a stricture greater than 2 cm. A more specific contraindication to this particular procedure is the associated presence of upper tract stones, because this approach does not allow their simultaneous management.** An area of ongoing controversy is the potential presence of crossing vessels. Because the procedure is guided fluoroscopically, such vessels may increase the risk of hemorrhage after activation of the cautery wire balloon. As such, some authors recommend preoperative imaging for such vessels with relatively noninvasive techniques such as CT or three-dimensional CT angiography (Fig. 38–8) (Streem and Geisinger, 1995; Quillin et al, 1996; Herts et al, 1999). Others, however, suggest that the risk of such bleeding is negligible as long as the incision is made in a true lateral or anatomically posterolateral position, because vessels crossing in that region are rare (Nakada et al, 1998; Nakada, 2000; Sampaio and Favorito, 1993).

Technique. The procedure begins with a retrograde pyelogram under fluoroscopic control, with C-arm imaging generally recommended to easily allow oblique views. During the retrograde study, the anatomy at the UPJ is completely defined (Fig. 38–9). At this point, a stiff, nonconducting guide wire is passed in a retrograde fashion across the UPJ and coiled within the pyelocalyceal system. The cautery wire balloon catheter is then passed with the cutting wire positioned laterally. The renal pelvis should be drained via the cautery wire balloon catheter and filled with dilute contrast material since the contrast medium or the retained urine may act as an electrolyte solution and inhibit activation of the cutting balloon. At this point, the 3-mL low-profile balloon is partially inflated. In general, a waist will be visualized to ensure proper positioning across the UPJ. C-arm fluoroscopy should also be used at this point to make sure the cutting wire is positioned appropriately.

The hot-wire electrocautery incision is then performed. The low-profile balloon is filled with another 1 to 2 cm of dilute contrast medium as 75 W of pure cutting current is applied to the cautery balloon wire for 2 to 3 seconds. During this time, the waist should be seen to resolve. If it does not, the procedure can be repeated once; multiple activations should be avoided. During deflation, extravasation of contrast material may often be identified at the incision site. If not, contrast agent can be reinjected to ensure extravasation is seen. If no extravasation is identified, ureteroscopy can be performed to ensure that an adequate incision has been made. Use of a ureteral access sheath allows rapid ureteroscopic access to the UPJ.

Figure 38–8. Spiral CT angiography with three-dimensional reconstruction clearly identifies an accessory lower pole crossing vessels at the level of the UPJ in a patient with UPJ obstruction. This case was managed successfully with laparoscopic pyeloplasty.

The cautery wire balloon catheter is now withdrawn completely, with a wire still in place across the UPJ. Completion of the procedure now requires ureteral stent placement. A Foley catheter is left in place initially to assess for bleeding and to minimize reflux through the stent.

Postoperative Care. At most centers, the patient is observed in an outpatient surgical area for 12 to 24 hours and the Foley catheter removed the morning after the procedure if the urine has grossly cleared. As previously noted, optimal stent duration remains unproven, although 4 weeks is common. Follow-up then generally involves an office evaluation 1 month later that includes diuretic renography. If the patient remains asymptomatic and if the half-life from the diuretic renography proves no obstruction, reevaluation is performed at 6- or 12-month intervals as necessary for 3 years.

Results. In their initial study, Chandhoke and associates (1993b) reported a 67% rate of complete resolution of symptoms and 85% improvement in radiographic appearance after hot wire balloon endopyelotomy. In a subsequent multicenter study, Preminger and colleagues (1997) reported an initial "patency" rate of 77% at a mean follow-up of 7.8 months. More recently, longer-term follow-up has become available. In 1999, Lechevallier and his associates in France defined success as both subjective and objective improvement and achieved this result in 75% of their patients followed for a median of

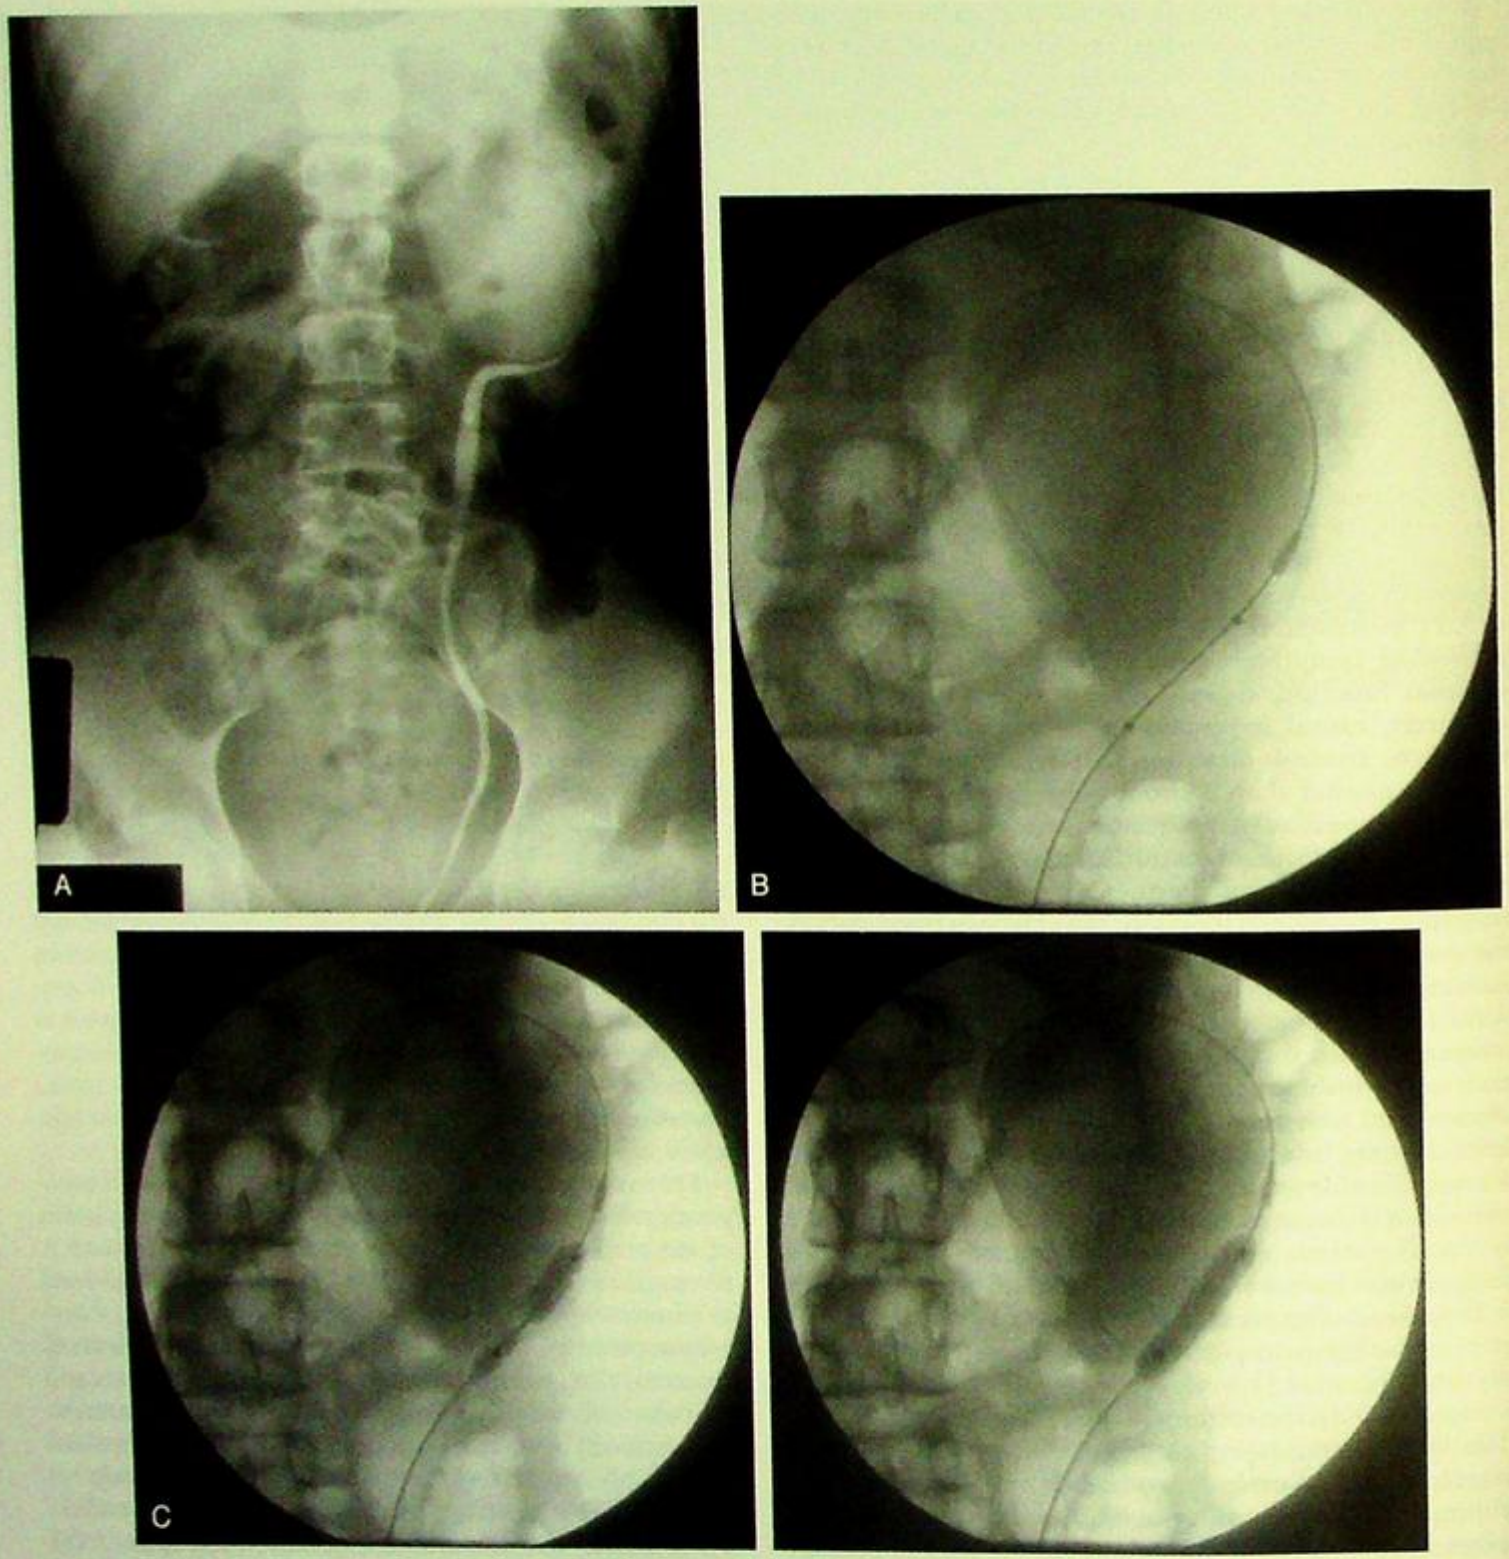

Figure 38–9. **A,** Retrograde study confirms lateral insertion of the ureter on the UPJ. **B,** Guide wire is in place across the UPJ. Note that the ureteral insertion is still lateral. **C,** *Left:* Fluoroscopic view of a balloon partially inflated before application of electrocurrent through the cutting wire. Note the "waist" at the UPJ. *Right:* After application of current and complete balloon inflation, the waist disappears.

2 years. Nadler and associates (1996) were able to reevaluate 28 patients 2 or more years after cautery wire balloon endopyelotomy. With a mean follow-up of 32.5 months, subjective improvement was noted in 61% of patients and 81% had a patent UPJ based on diuretic renography or Whitaker testing. In their study, all failures occurred within 1 year of treatment, and this early time to failure has been noted in other endopyelotomy studies. More recent studies have demonstrated lower success rates than these initial series (32% to 63%) and perhaps that high-grade hydronephrosis has a negative impact on success (Sampaio and Favorito, 1993; Albani et al, 2004; Sofras et al, 2004).

Complications. **The major complications associated with cautery wire balloon incision are hemorrhagic. Whereas injury to crossing vessels has been reported using the cutting balloon catheter, strict adherence to lateral incision**

principles minimizes this risk (Streem and Geisinger, 1995; Wagner et al, 1996). In addition, although some believe crossing vessels hinder success rates primarily, others believe hemorrhage is a real concern (Aslan and Preminger, 1998). Appropriate management includes arteriography to delineate the site of arterial injury and subsequent embolization. In a review of their complications with this procedure, Schwartz and Stoller (1999) reported lower pole accessory arterial injuries in three patients and ovarian vein laceration in another, who ultimately required nephrectomy. These authors also summarized other reported complications of the procedure, which have included ureteral avulsion, stent-related problems, and detachment of the cutting wire. Failure of balloon inflation has also been reported (McGuire and English, 1997).

Ureteroscopic Endopyelotomy. A ureteroscopic approach to endopyelotomy was first suggested in 1985 when Bagley and colleagues reported a combined percutaneous and flexible ureteroscopic procedure approach for management of an "obliterated" UPJ. Subsequently, Inglis and Tolley (1986) reported a ureteroscopic "pyelolysis" for UPJ obstruction. Shortly thereafter, Clayman and coworkers (1990) reported an initial experience in a small number of patients performing ureteroscopic endopyelotomy with a No. 3 or 5 Fr cutting electrode passed under direct vision using large, rigid or flexible ureteroscopes. In that series, however, a No. 8 Fr nephrostomy tube was placed at the outset of the procedure and left indwelling for at least 48 hours. As such, that series still represented a "combined" endourologic approach to endopyelotomy. Stents were routinely left in place for 6 to 8 weeks, after which diagnostic studies were performed. With a mean follow-up approaching 1 year, a success rate of 81% was achieved in 16 patients. However, two patients developed distal ureteral strictures probably resulting from the larger-diameter rigid instrumentation.

Thomas and associates (1996) subsequently reported their experience with ureteroscopic endopyelotomy. Again, only relatively larger-diameter ureteroscopic instrumentation was available such that preoperative stent placement was routine and some male patients required perineal urethrostomy. The endopyelotomy incision itself was performed with either cold knife or electrocautery attachments to the ureteroscope. The authors achieved a success rate of approximately 90%, although nephrectomy was ultimately performed in two patients, in one of whom it was done urgently for bleeding.

Advances in instrumentation and technique now allow a ureteroscopic approach to be performed reliably at a single setting (Conlin and Bagley, 1998), and this is now considered the standard. **The main advantage of a ureteroscopic approach is that it allows direct visualization of the UPJ and assurance of a properly situated, full-thickness endopyelotomy.** Another advantage of the ureteroscopic approach is a decrease in cost compared with the use of the cautery wire balloon, assuming ureteroscopic equipment and electroincision or holmium laser is already available. Gettman and associates (2003) found that the retrograde ureteroscopic endopyelotomy was more cost effective than hot wire cutting balloon endopyelotomy, antegrade endopyelotomy, and pyeloplasty for treating UPJ obstruction when taking into account treatment failures.

Indications and Contraindications. **The indications and contraindications to a ureteroscopic endopyelotomy include functionally significant obstruction, as defined earlier. Contraindications include relatively long areas of obstruction and upper tract stones, which are best managed simultaneously with alternative approaches, usually percutaneously or laparoscopically.** Another consideration is that in patients with significant hydronephrosis there is evidence that an antegrade endopyelotomy may be more efficacious (Lam et al, 2003b).

Technique. The instrument that allows the most straightforward retrograde access to the UPJ, as well as providing an effective working channel, is a small caliber (<7 Fr) semirigid ureteroscope. In women, the UPJ can often be reached with a No. 6.9 Fr semirigid ureteroscope. In men, typically small caliber (<7.5 Fr) actively deflecting flexible ureteroscopes are utilized, and today with availability of improved ureteral access sheaths and improved flexible ureteroscopes, many retrograde endopyelotomies are done using the flexible ureteroscope.

General anesthesia is used to minimize patient movement during ureteroscopy and the subsequent incision of the UPJ. In preparation for the endopyelotomy, a retrograde pyelogram is performed under fluoroscopic control at the outset of the procedure. A hydrophilic guide wire is passed cystoscopically under fluoroscopic control and coiled in the pyelocalyceal system. The cystoscope is then withdrawn and exchanged for the semirigid ureteroscope. The ureteroscope is passed alongside the guide wire to the level of the UPJ (Fig. 38–10). If the distal ureter is too narrow to allow easy passage of the ureteroscope, the intramural ureter can be dilated using a 5-mm balloon or a No. 9 or 10 Fr "introducing" catheter. If the ureter is still too narrow at any point to easily accommodate the ureteroscope, then an internal stent is placed and the procedure is postponed for 5 to 10 days to allow "passive" ureteral dilatation.

Once the UPJ is reached with the ureteroscope, the renal pelvis is drained to facilitate movement across the UPJ during the incision. When using a semirigid ureteroscope, the 200- or 365-μm holmium laser fiber is inserted through the working channel as the ureteroscope is positioned at the proximal extent of the UPJ or in the renal pelvis itself. At a setting of 0.8 to 1.2 J and a frequency of 10 to 15 Hz, the UPJ is incised, usually in a posterolateral direction, while the ureteroscope is withdrawn back down across the UPJ. This procedure is repeated and the incision gradually deepened to extend into the peripelvic and periureteral retroperitoneal space. Because this is done gradually and under direct vision, any visualized vessels, and thus potentially significant bleeding, are usually avoided.

The incision is carried caudally into normal ureteral tissue, until the UPJ is widely patent. Injection of contrast material through the ureteroscope can demonstrate extravasation and confirm an adequate depth of incision, although this is generally not necessary because the entire procedure has been performed under direct vision. Balloon dilation up to size No. 24 Fr can also be performed to complete the incision. If any small bleeding points are visualized ureteroscopically, they can be treated by defocusing the holmium laser. Similarly, the balloon can be reinflated to allow tamponade for 10 minutes to see if the bleeding will subside. The ureteroscope is then

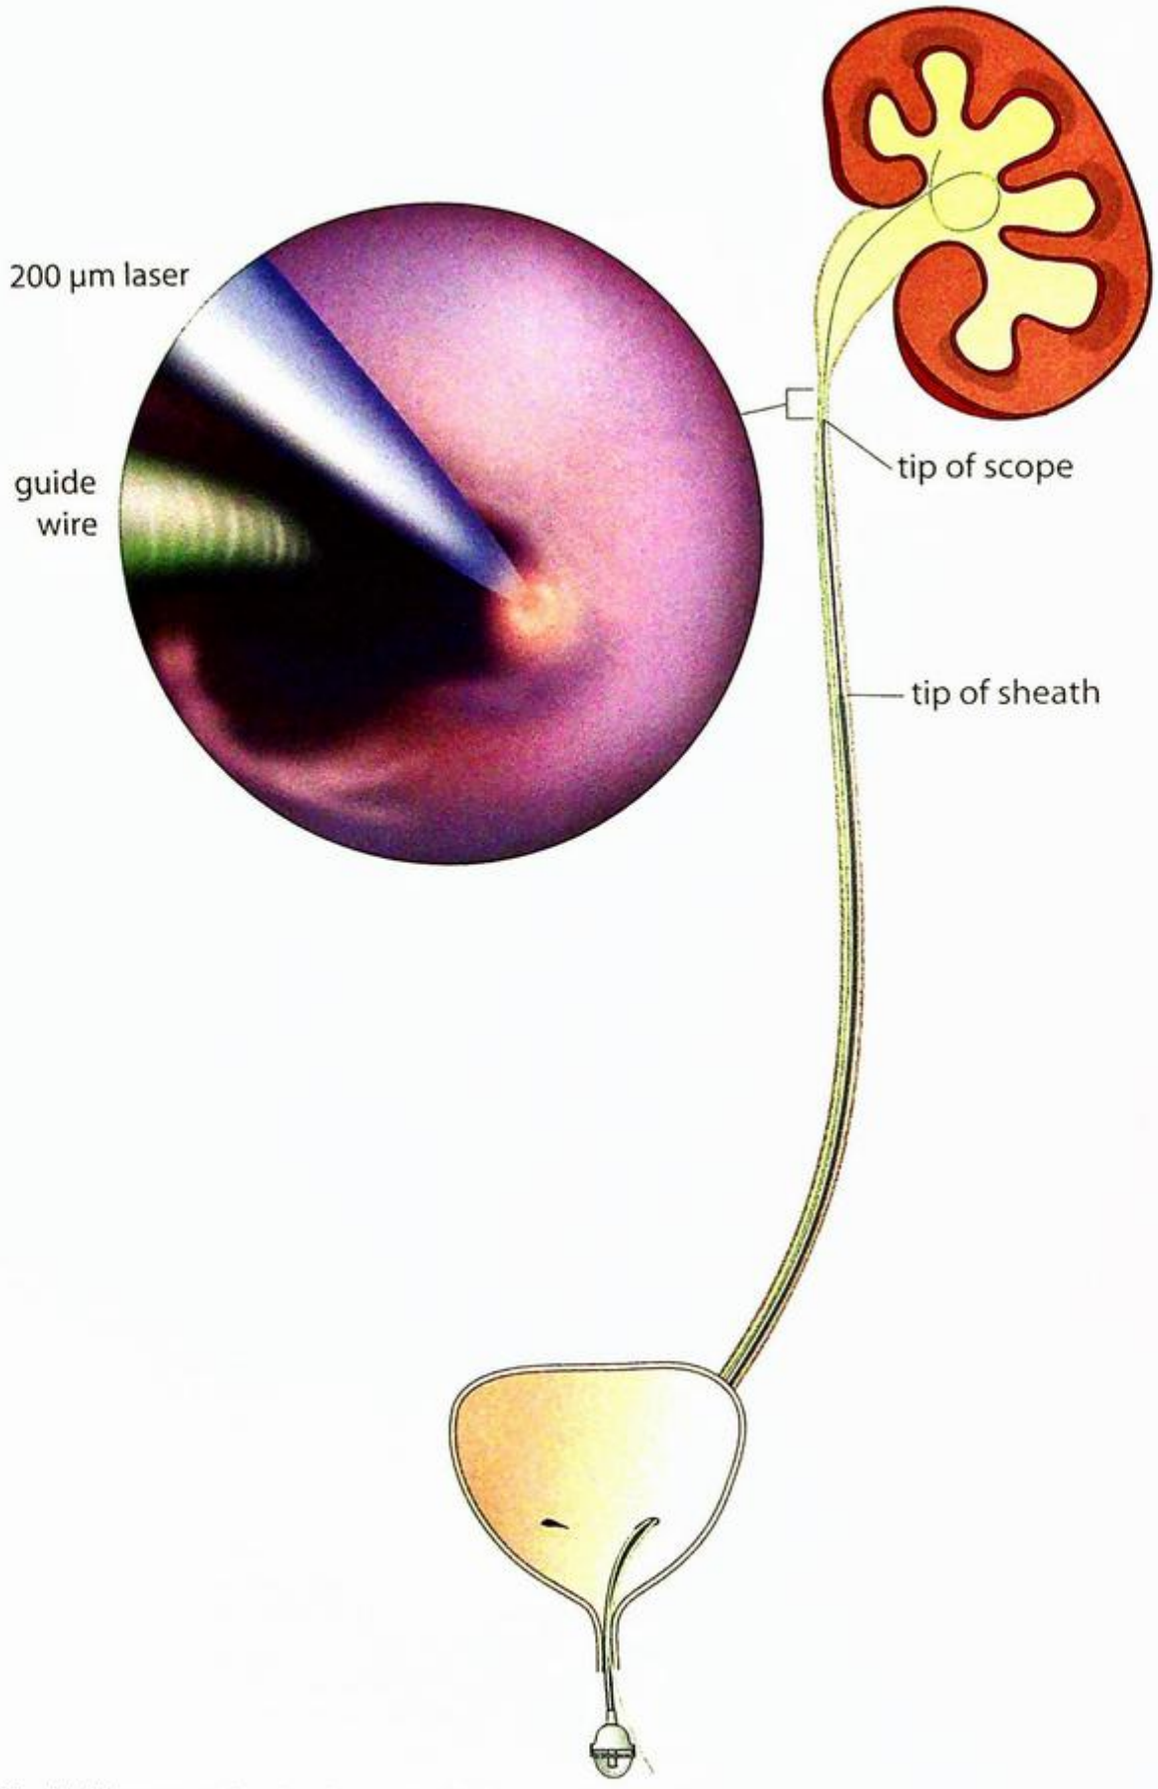

Figure 38–10. Flexible ureteroscopic endopyelotomy using holmium laser demonstrating endoscopic view of the UPJ *(inset)*. A safety wire is in place, and the ureteroscope is passed through a ureteral access sheath as a lateral incision is being made under endoscopic view, using holmium laser fiber. A properly sited, complete incision is straightforward with this direct visualization technique.

withdrawn from the ureter while the safety wire is left in place in the renal pelvis for subsequent passage of a stent. Experimental studies have shown that dilation with a No. 36 Fr balloon alone can create linear incisions in the UPJ (Pearle et al, 1994). **Although retrograde balloon dilation alone has been reported for treatment of UPJ obstruction, most recent long-term follow-up studies have shown a diminishing success rate over time, as low as 42%** (McClinton et al, 1993; Webber et al, 1997).

When flexible ureteroscopy is used, a ureteral access sheath is quite useful. The sheath allows for rapid transfer of the ureteroscope for assessment of the UPJ. Once the flexible ureteroscope is passed to the UPJ, a 200-μm holmium fiber is placed through the working channel and the UPJ incised in the appropriate location, as suggested by the radiographic studies.

Once the ureteroscope has been removed, a stent is advanced over the remaining wire using fluoroscopic guidance. A Foley catheter is left indwelling, again to obviate the risk of reflux and extravasation at the site of the endopyelotomy incision and to rapidly identify any significant bleeding. Diuretic renography is performed 4 weeks after stent removal to assess results. Clinical and radiographic follow-up is then continued at 6- to 12-month intervals for 24 to 32 months.

Results. Biyani and colleagues (1997) described their initial experience with a ureteroscopic approach using holmium laser energy. With a mean follow-up of just over 12 months, they achieved a success rate of 87.5% in a small group of patients. One patient developed a urinoma, which was managed conservatively. In 1998, Renner and coworkers reported a larger series of patients undergoing ureteroscopic laser endopyelotomy. By using a semirigid ureteroscope, the UPJ was incised at a posterolateral location unless vessels were visualized in that area, in which case a contralateral incision was made. Tawfiek and associates (1998) reported the Jefferson Medical College experience with ureteroscopic endopyelotomy. They combined endoluminal ultrasound with their ureteroscopic approach to definitively identify crossing vessels or a ureteropelvic septum, which is present in patients with high-inserting ureters. They believed this helped them definitively site their endopyelotomy incision. Different modalities were used for the endopyelotomy itself, including electrocautery and holmium laser. An 87.5% success rate was achieved in 32 patients. There were no significant bleeding complications, and all patients were discharged within 24 hours of the procedure.

Gerber and Kim (2000) **and Matin and associates** (2003) **reported contemporary experiences with ureteroscopic holmium laser endopyelotomy, demonstrating success rates of 70% to 80% with follow-up to 5 years.** Improved results were reported by Conlin (2002) (91% success rates) with retrograde endopyelotomy in patients when culling patients with crossing vessels greater than 4 mm using preoperative ultrasonography. Giddens and Grasso (2000) also published excellent results when culling patients with anterior and posterior crossing vessels from retrograde endopyelotomy using endoluminal ultrasound. To date, the use of endoluminal ultrasound to identify crossing vessels has been controversial, and although it may play a role in preoperative decision-making, similar data can be obtained using the less invasive spiral CT angiography. Yet despite this additional information, the best endopyelotomy success rates still lag behind those of open or laparoscopic pyeloplasty.

Complications. Complications of this approach have diminished in frequency and severity with the refinement of ureteroscopic instrumentation and the introduction of small-caliber holmium laser fibers. Postprocedural ureteral strictures are rare in contemporary series, and angiographic embolization or nephrectomy is rare using the retrograde approach. Most complications are minor and relate primarily to urinary leak, stent migration, and infection (Tawfiek et al, 1998; Gerber and Kim, 2000). As more long-term follow-up becomes available, the complication rates may evolve.

KEY POINTS: ENDOUROLOGIC MANAGEMENT OF UPJ OBSTRUCTION

- Contemporary indications for intervention for UPJ obstruction include the presence of symptoms associated with the obstruction, impairment of overall renal function or progressive impairment of ipsilateral function, development of stones or infection, or, rarely, causal hypertension.
- When intervention is indicated, the procedure of choice has historically been open operative repair of the UPJ, usually dismembered pyeloplasty. However, endopyelotomy has gained a proven role as an initial procedure of choice in many centers.
- The advantages of endourologic approaches include a significantly reduced hospital stay and postoperative recovery. However, the success rate does not approach that of standard open or laparoscopic pyeloplasty. Furthermore, whereas open or laparoscopic operative intervention can be applied to almost any anatomic variation of UPJ obstruction, consideration of any of the less invasive alternatives requires that the surgeon take into account the degree of hydronephrosis, ipsilateral renal function, concomitant calculi, and, possibly, the presence of crossing vessels.
- Generally, the urologist should have a low threshold to proceeding to angiography in patients with bleeding after endopyelotomy to minimize the need for transfusion and potential exploration. Successful angiographic embolization often obviates the need for operative "exploration" that can lead to nephrectomy.

Open Operative Intervention

General Surgical Principles. Several types of surgical incisions have been utilized for a pyeloplasty in the management of UPJ obstruction. An anterior extraperitoneal approach is chosen by some because it allows surgical repair with minimal mobilization of the pelvis and proximal ureter. Alternatively, a posterior lumbotomy provides direct exposure to the UPJ and again allows repair with minimal mobilization of the surrounding structures. Like the anterior extraperitoneal approach, posterior lumbotomy is best suited to relatively thin

patients without previous ipsilateral surgery. Our preference for most patients undergoing primary surgical repair of UPJ obstruction is an extraperitoneal flank approach. This incision may be subcostal but usually is performed through the bed of the 12th rib or carried anteriorly off its tip. The extraperitoneal flank approach is advantageous in that it is familiar to all urologists and provides excellent exposure without regard to body habitus. In the presence of other renal anomalies associated with the UPJ, such as horseshoe or pelvic kidney, anterior extraperitoneal approaches are often preferable, although laparoscopic management may be considered in this setting.

Before the definitive surgical management, drainage of a kidney with UPJ obstruction is recommended only in select circumstances, including infection associated with the obstruction or azotemia resulting from obstruction in a solitary kidney or bilateral disease. Procedural drainage may be of value in the uncommon scenario of severe, unrelenting pain requiring emergent relief of obstruction. For any of these situations, such drainage can be achieved by placement of an internal ureteral stent or a percutaneous nephrostomy tube.

The clinical indications for placement of stents or nephrostomy tubes intraoperatively remain controversial and vary among the urologists. For adults, our preference is for routine placement of a soft, inert, self-retaining internal ureteral stent, which is removed 4 to 6 weeks postoperatively. Such stents in adults can be easily removed in an outpatient office setting under local anesthesia. Routine use of internal ureteral stents offers several advantages, especially in the early postoperative period. Such practice appears to decrease the amount and length of time of urinary extravasation at the surgical repair site, thereby decreasing the risk of secondary fibrosis. Decreased urinary extravasation also allows earlier removal of external drains. For the uncomplicated pyeloplasty in adult patients, there appears to be no advantage to using both a nephrostomy tube and a stent, because this may result in a prolonged hospital stay and an increased incidence of infection (Wollin et al, 1989). Instead, nephrostomy tubes may be reserved for complicated procedures such as those required for secondary UPJ obstruction or those associated with active inflammation. However, if a percutaneous nephrostomy tube had been placed preoperatively, it is generally left in place to allow proximal diversion and access for antegrade radiographic studies during the postoperative period.

Although the use of internal stents and nephrostomy tubes remains somewhat controversial, provision of external drainage from the site of surgical repair is absolutely necessary. Such external drainage may be achieved with a Penrose or closed suction drain placed near, but not on, the suture line and brought out through a separate stab incision. This practice helps to minimize the risk of urinoma formation leading to possible disruption of the suture line, scarring, or sepsis.

Historical Notes. The historical aspects of UPJ repair were previously examined by Kay in 1989 and by Schaeffer and Grayhack in 1986. The first reconstructive procedure was performed by Trendelenburg in 1886; however, the patient died of postoperative complications. In 1891, Kuster divided the ureter and reanastomosed it to the renal pelvis, thus apparently performing the first successful dismembered pyeloplasty. Kuster's technique, however, was prone to recurrent stricture. In 1892, Fenzer applied the Heineke-Mikulicz principle to UPJ repair. This surgical technique involves transverse closure of a longitudinal incision. However, this technique can cause shortening of the suture line on one side, resulting in buckling or kinking of the UPJ with recurrent obstruction. In 1916, Schwyzer introduced the YV-pyeloplasty, which was subsequently modified by Foley in 1937. However, this technique was best applied to high ureteral insertions and was essentially unsuitable when the UPJ itself was already in a dependent position. Later on, flap techniques were developed that were more universally applicable, including the spiral flap of Culp and DeWeerd (1951) and the vertical flap of Scardino and Prince (1953). Thompson and associates (1969) reported the use of a renal capsular flap for complex cases in which an adequate amount of renal pelvis is not available for repair.

In 1949, Nesbit followed the principle of Kuster's dismembered procedure and further modified it by creating an elliptical anastomosis to decrease the likelihood of stricture formation at the site of repair. Also in 1949, Anderson and Hynes described their modifications of this dismembered technique that involved anastomosis of the spatulated ureter to a projection of the lower aspect of the pelvis after a redundant portion was excised. Use of healing by secondary intention was also investigated in the similar time period. The techniques of intubated ureterotomy were popularized by Davis in 1943, but they had been previously described by Fiori in 1905, Albarran in 1909, and Keyes in 1915.

Although a variety of techniques have been described for the management of UPJ obstruction, several basic principles must always be applied to maximize the success of surgical repair. **For any procedure, the resultant anastomosis should be widely patent and completed in a watertight fashion without tension. In addition, the reconstructed UPJ should allow a funnel-shaped transition between the pelvis and the ureter that is in a position of dependent drainage.**

Dismembered Pyeloplasty

Indications. **At present, a dismembered pyeloplasty is preferred by most urologists in the surgical repair of UPJ obstruction because this procedure is almost universally applicable to the different clinical scenarios.** This approach can be used regardless of whether the ureteral insertion is high on the pelvis or already dependent. It also permits reduction of a redundant pelvis or straightening of a tortuous proximal ureter. Furthermore, **anterior or posterior transposition of the UPJ can be achieved when the obstruction is due to accessory or aberrant lower pole vessels.** In addition, unlike the flap techniques, **only a dismembered pyeloplasty allows complete excision of the anatomically or functionally abnormal UPJ itself. It is important to note that a dismembered pyeloplasty is not well suited to UPJ obstruction associated with lengthy or multiple proximal ureteral strictures or to patients in whom the UPJ obstruction is associated with a small, relatively inaccessible intrarenal pelvis.**

Technique. Surgical exposure to the UPJ is achieved by first identifying the proximal ureter in the retroperitoneum. The proximal ureter is then dissected cephalad to the renal pelvis, leaving a large amount of periureteral tissue to preserve the ureteral blood supply. A marking stitch of fine suture is then placed on the lateral aspect of the proximal ureter, below the level of the obstruction, to facilitate proper orientation for the subsequent repair. In a similar fashion, the medial and lateral

aspects of the dependent portion of the renal pelvis are marked with traction sutures (Fig. 38–11*A*). The UPJ tissue is excised, and the proximal ureter is then spatulated on its lateral aspect. The apex of this lateral, spatulated aspect of the proximal ureter is brought to the inferior border of the renal pelvis, whereas the medial side of the ureter is brought to the superior aspect (see Fig. 38–11*B*). The anastomosis is then performed with fine interrupted or running absorbable sutures, placed full thickness through the ureteral and renal pelvic walls in a watertight manner (see Fig. 38–11*C*). As discussed earlier, our preference for adult patients is to routinely perform the anastomosis over an internal ureteral stent, which is left indwelling.

If the renal pelvis is exceptionally redundant, a "reduction" pyeloplasty can be performed by excising the redundant portion of the pelvis (Fig. 38–12). The cephalad aspect of the pelvis is then closed with running absorbable sutures down to the dependent portion, which will subsequently be anastomosed to the ureter. In the event that aberrant or accessory lower pole vessels are found in association with the UPJ obstruction, a dismembered pyeloplasty allows transposition of the UPJ in relation to these vessels (Fig. 38–13).

Results. The overall success of open dismembered pyeloplasty has been very favorable in the literature. In a retrospective review, Persky and coworkers (1977) noted that none of their 109 dismembered pyeloplasties for UPJ obstruction required subsequent nephrectomy. In another retrospective review involving 111 patients with UPJ obstruction undergoing open surgical repair over a 15-year-period, Clark and Malek (1987) found 95% success in resolution of clinical symptoms and 91% success in decompression of pelvicalyceal system on urography after one surgical repair. Of the 111 patients with open pyeloplasty, 95 (86%) patients underwent dismembered pyeloplasty. Examining the functional outcomes based on the split-function analysis from preoperative and postoperative renal scans, O'Reilly (1989) found that open Anderson-Hynes dismembered pyeloplasty arrests functional deterioration in almost every case and improves function significantly in the majority in 26 consecutive patients with UPJ obstruction.

Flap Procedures

Foley YV-Plasty. **The Foley YV-plasty was originally designed for repair of a UPJ obstruction secondary to a high ureteral insertion.** Like other flap techniques, however, its use has generally been replaced by the more versatile dismembered pyeloplasty. Like other flap techniques, the Foley YV-plasty is specifically contraindicated when transposition of lower pole vessels is necessary. In situations requiring concomitant reduction of redundant renal pelvis, this technique is also of little value.

In Foley YV-plasty, the renal pelvis and proximal ureter are first exposed and a widely based triangular or V-shaped flap is outlined with methylene blue or fine stay sutures. The base of the V is positioned on the dependent, medial aspect of the ipsilateral renal pelvis and the apex at the UPJ. The incision from

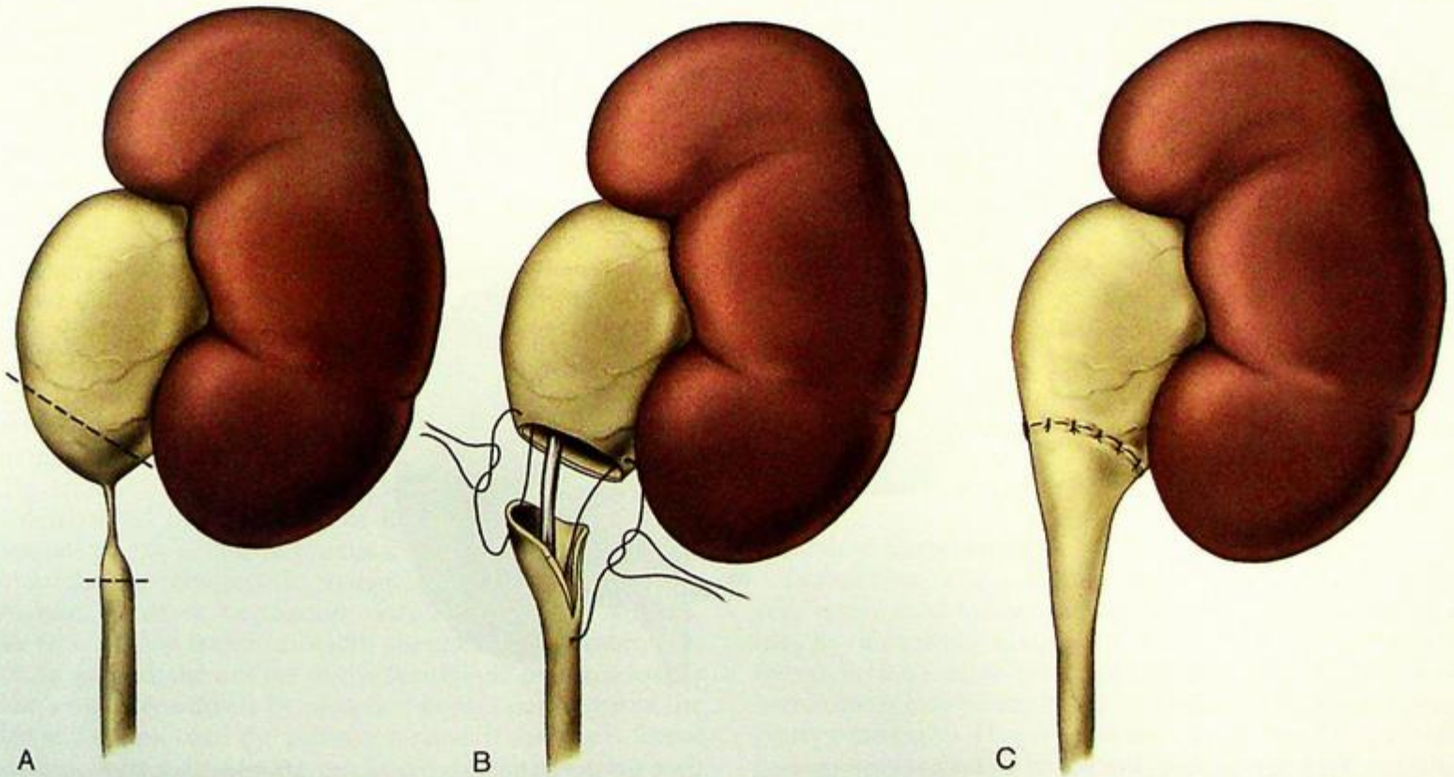

Figure 38–11. **A,** Traction sutures are placed on the medial and lateral aspects of the dependent portion of the renal pelvis in preparation for dismembered pyeloplasty. A traction suture is also placed on the lateral aspect of the proximal ureter, below the level of obstruction. This will help maintain proper orientation for the subsequent repair. **B,** The UPJ is excised. The proximal ureter is spatulated on its lateral aspect. The apex of this lateral, spatulated aspect of the ureter is then brought to the inferior border of the pelvis while the medial side of the ureter is brought to the superior edge of the pelvis. **C,** Anastomosis is then performed with fine interrupted or running absorbable sutures placed full thickness through the ureteral and renal pelvis walls in a watertight fashion. In general, we prefer to leave an indwelling internal stent for adult patients. The stent is removed 4 to 6 weeks later.

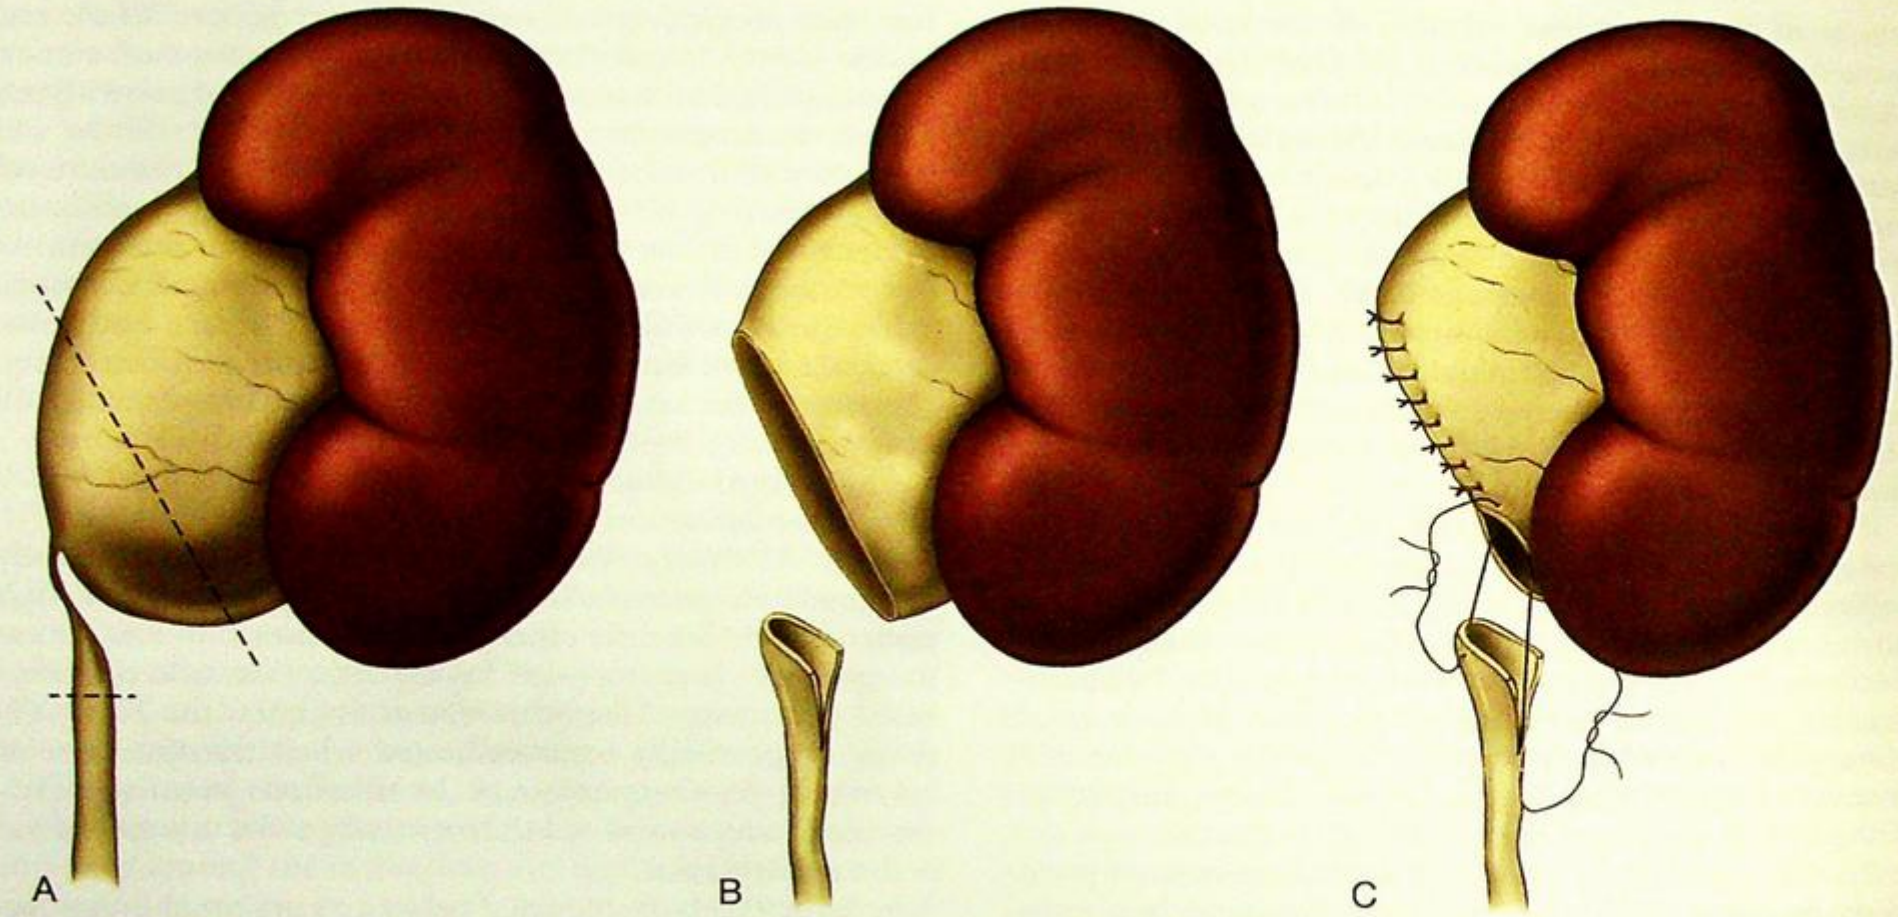

Figure 38–12. **A,** For large or redundant renal pelves, a reduction pyeloplasty is performed by excising the redundant portion between traction sutures. **B,** The cephalad aspect of the pelvis is then closed with running absorbable suture down to the dependent portion. **C,** The dependent aspect of the pelvis is then anastomosed to the proximal ureter.

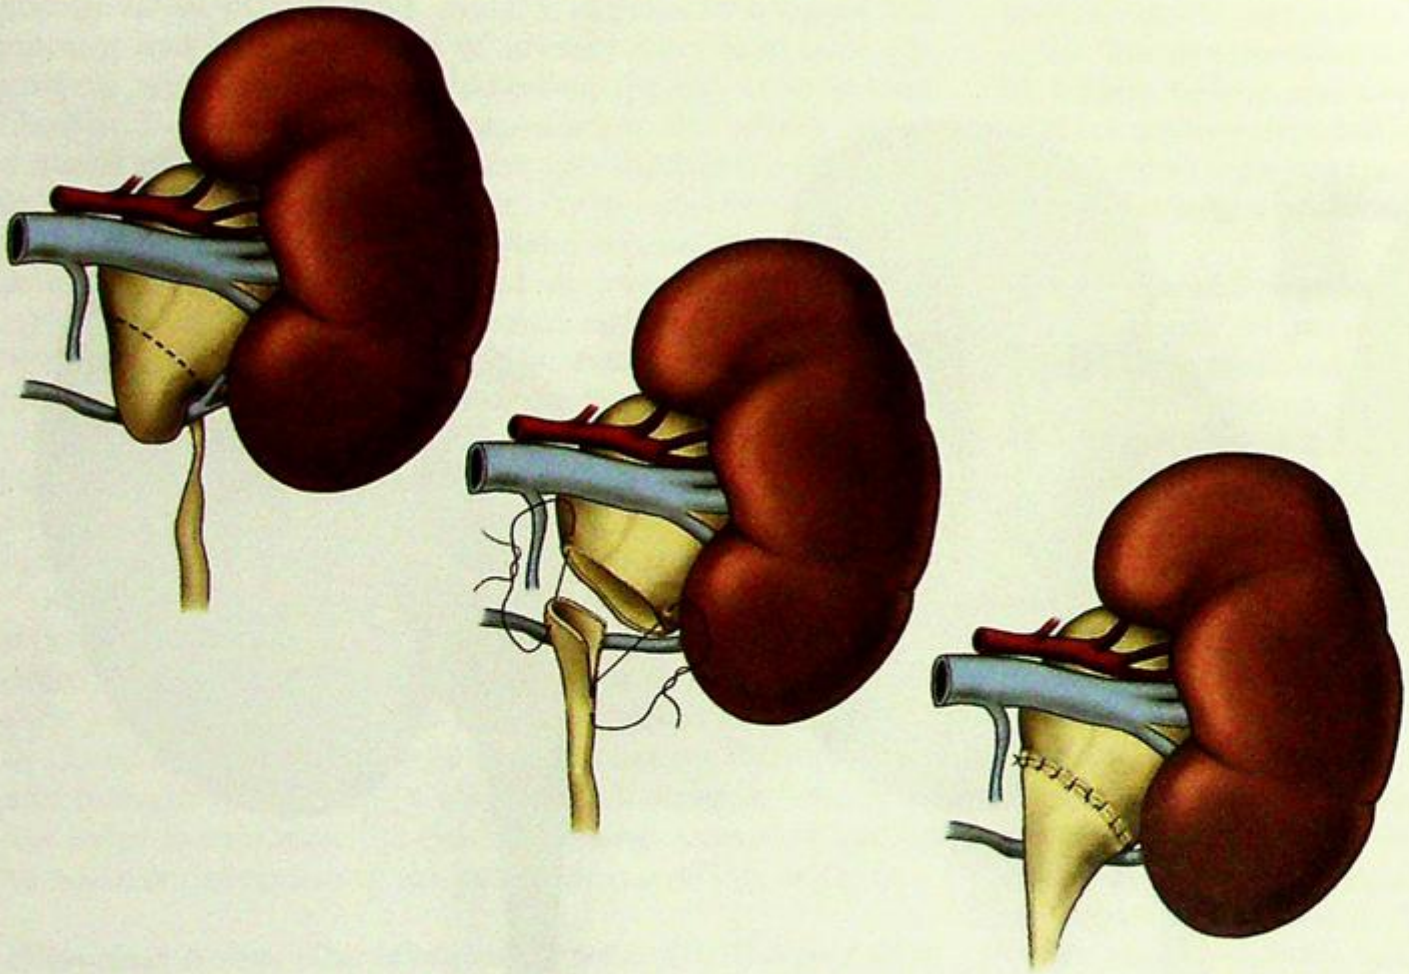

Figure 38–13. When aberrant or accessory lower pole vessels are found in association with the UPJ obstruction, a dismembered pyeloplasty allows transposition of the UPJ in relation to the vessels.

the apex of the flap (the stem of the Y) will then be performed along the lateral aspect of the proximal ureter. The surgical incision in the ureter should be long enough to completely traverse the area of stenosis and extend for several millimeters into the normal-caliber ureter (Fig. 38–14*A*). The renal pelvic flap and ureterotomy are then created. A fine scalpel blade is used for the initial pelvic incision, after which a Potts or a fine Metzenbaum scissors is used to complete the flap and ureterotomy (see Fig. 38–14*B*). An internal ureteral stent is now placed and the repair performed over it. First, the apex of the pelvic flap is approximated to the apex (inferior aspect) of the ureterotomy incision using fine absorbable suture. The

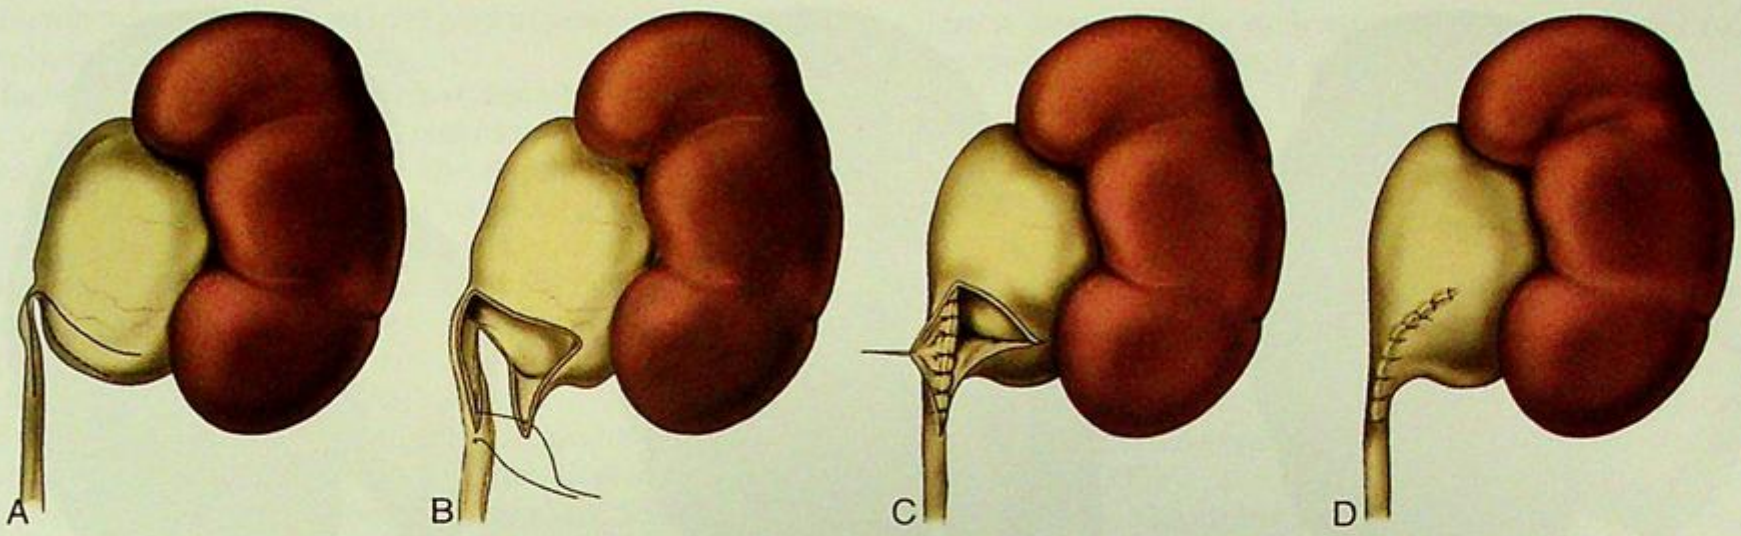

Figure 38–14. **A,** Foley YV-plasty is best applied to a UPJ obstruction associated with a high insertion of the ureter. The flap is outlined with tissue marker or stay sutures. The base of the V is positioned on the dependent, medial aspect of the renal pelvis and the apex at the UPJ. The incision from the apex of the flap, which represents the stem of the Y, is then carried along the lateral aspect of the proximal ureter well into an area of normal caliber. **B,** The flap is developed with fine scissors. The apex of the pelvic flap is then brought to the most inferior aspect of the ureterotomy incision. **C,** The posterior walls are then approximated using interrupted or running fine absorbable suture. **D,** The anastomosis is completed with approximation of the anterior walls of the pelvic flap and ureterotomy.

posterior walls are then approximated using fine interrupted or running suture (see Fig. 38–14*C*). Interrupted technique is likely to minimize pursing or buckling of the suture line as well as local tissue ischemia. Anastomosis of the anterior walls is then performed, thereby completing the surgical repair (see Fig. 38–14*D*).

Culp-DeWeerd Spiral Flap. **The Culp-DeWeerd spiral flap is generally best suited for large, readily accessible extrarenal pelves in which the ureteral insertion is already in a dependent, oblique position.** Although most of these patients are also good candidates for a standard or reduction dismembered pyeloplasty, the spiral flap may be of significant value when both UPJ obstruction and a relatively long segment of proximal ureteral narrowing or stricture occur in the same setting.

The spiral flap is first outlined with a broad base positioned obliquely on the dependent aspect of the renal pelvis. To maximize preservation of the flap blood supply, the base is placed in a position anatomically lateral to the UPJ, that is, between the ureteral insertion and the renal parenchyma. The pelvic flap itself may be spiraled posteriorly to anteriorly or vice versa. In either case, the anatomically medial line of incision (farthest from the parenchyma) is carried down the proximal ureter, completely traversing through the obstructed segment (Fig. 38–15*A*). Appropriate placement of the apex of the flap is determined by the length of flap needed. This, in turn, depends on the length of proximal ureter to be bridged. The longer the flap required, the farther away the apex will be from the base. However, to preserve vascular integrity of the flap, the ratio of flap length to width should not be greater than 3:1. In general, the outline of the flap should be made longer than what may initially be perceived as necessary because the flap will shrink once the pelvis is incised. If the flap is found to be too long, excess length can be reduced by trimming back the apex, thereby preserving its blood supply. Once the flap is created, the apex is rotated down to the most inferior aspect of the ureterotomy (see Fig. 38–15*B*). The anastomosis with fine absorbable sutures is subsequently performed over an internal stent (see Fig. 38–15*C*).

Scardino-Prince Vertical Flap. The Scardino-Prince vertical flap technique generally has limited clinical application, because it may be used appropriately only when a dependent UPJ is situated at the medial margin of a large, square ("box-shaped") extrarenal pelvis (Fig. 38–16*A*). Its use in most instances has been replaced by a standard dismembered pyeloplasty, although the vertical flap may be preferable for relatively long areas of proximal ureteral narrowing. **The vertical flap technique generally cannot produce as long a flap as the spiral flap.**

The Scardino-Prince vertical flap is similar to the spiral flap technique except that the base of the flap is positioned more horizontally on the dependent aspect of the renal pelvis, between the UPJ and the renal parenchyma. The flap itself is created by straight incisions converging from the base vertically to the apex on either the anterior or the posterior aspects of the renal pelvis. The site of the apex and the length of the flap are determined by the length of proximal ureter to be bridged. The medial incision is carried down the proximal ureter, completely traversing through the stenotic area and into normal-caliber ureter, using fine scissors (see Fig. 38–16*B*). The apex of the flap is then rotated down and approximated to the most inferior aspect of the ureterotomy. Finally, the flap is closed with interrupted or running fine absorbable sutures (see Fig. 38–16*C*).

Intubated Ureterotomy

Indications. The Davis intubated ureterotomy, which is very rarely used today, was developed for surgical repair of lengthy or multiple ureteral strictures. If these strictures are found in association with UPJ obstruction, the intubated ureterotomy may be combined with any of the standard pyeloplasty procedures. However, in such situations, the intubated ureterotomy would be best combined with a spiral flap procedure. Compared with the vertical flap, the spiral flap can be made longer, which allows more of the strictured area to be bridged by a pelvic flap, thereby leaving a shorter area to rely on healing by "secondary intention." In fact, in this specific clinical setting, any flap technique would be preferable to a

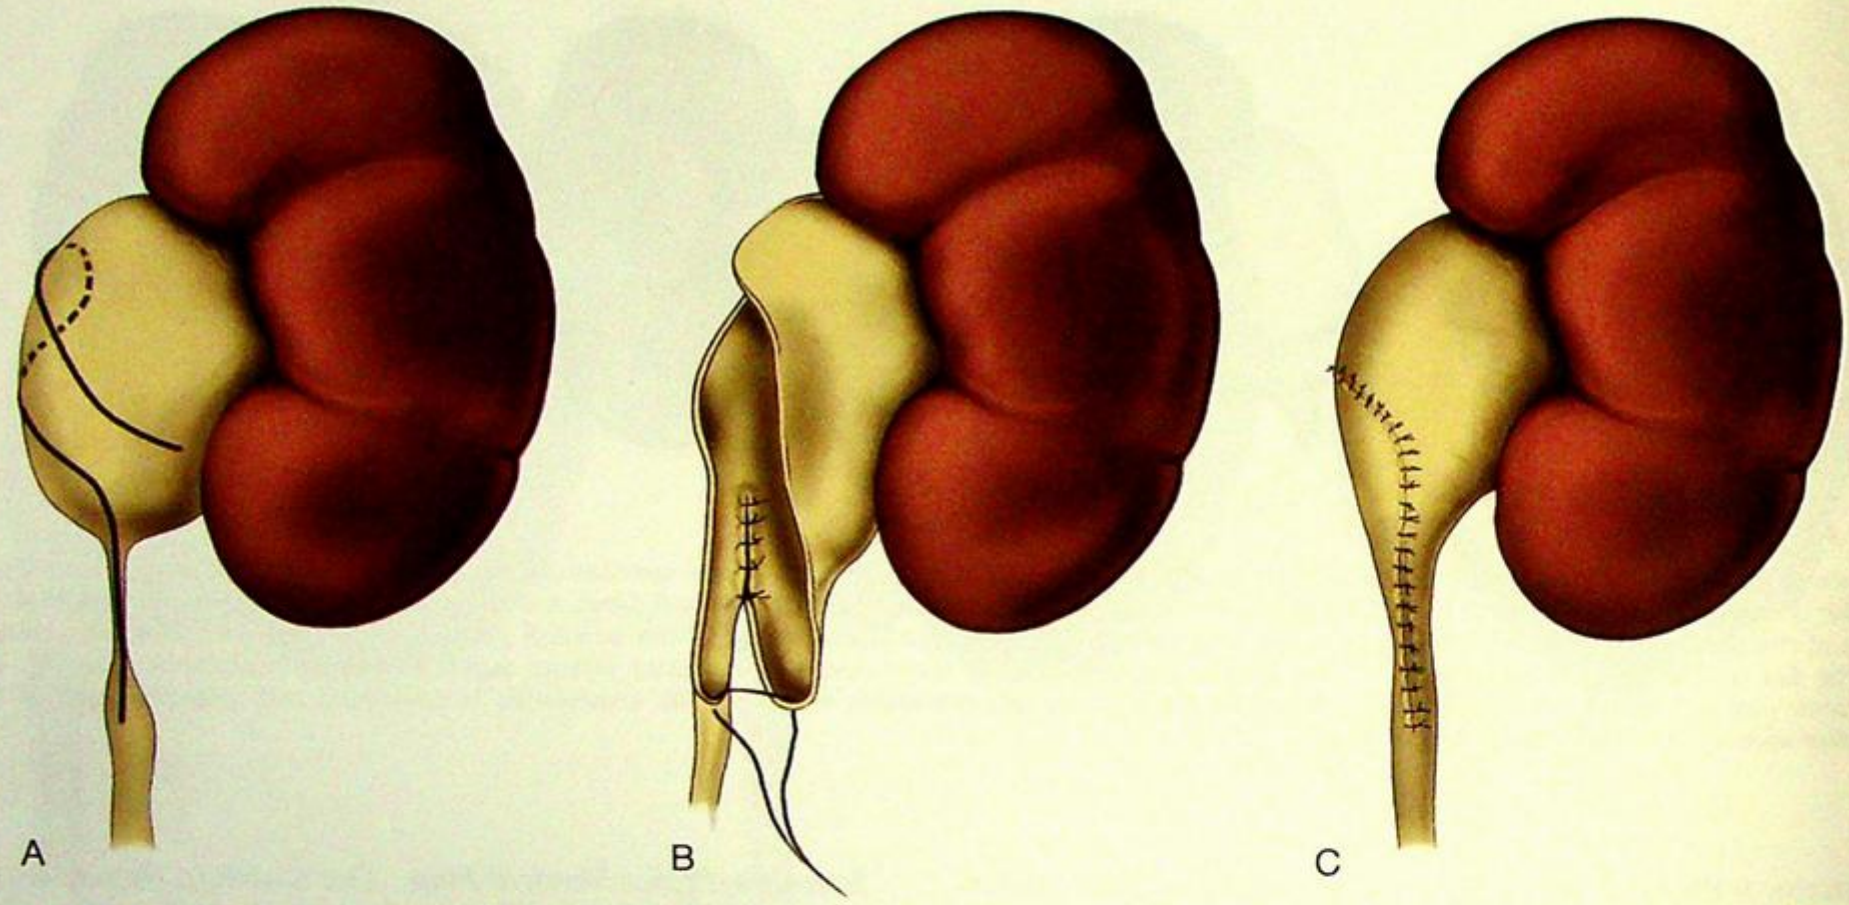

Figure 38–15. **A,** Spiral flap may be indicated for relatively long areas of proximal ureteral obstruction when the UPJ is already in a dependent position. The spiral flap is outlined with the base situated obliquely on the dependent aspect of the renal pelvis. The base of the flap is positioned anatomically lateral to the UPJ, between the ureteral insertion and the renal parenchyma. The flap is spiraled posteriorly to anteriorly or vice versa. The anatomically medial line of incision is carried down completely through the obstructed proximal ureteral segment into normal-caliber ureter. The site of the apex for the flap is determined by the length of flap required to bridge the obstruction. The longer the segment of proximal ureteral obstruction, the further away is the apex, because this will make the flap longer. However, to preserve vascular integrity to the flap, the ratio of flap length-to-width should not exceed 3:1. **B,** Once the flap is developed, the apex is rotated down to the most inferior aspect of the ureterotomy. **C,** The anastomosis is then completed, usually over an internal stent, again utilizing fine absorbable sutures.

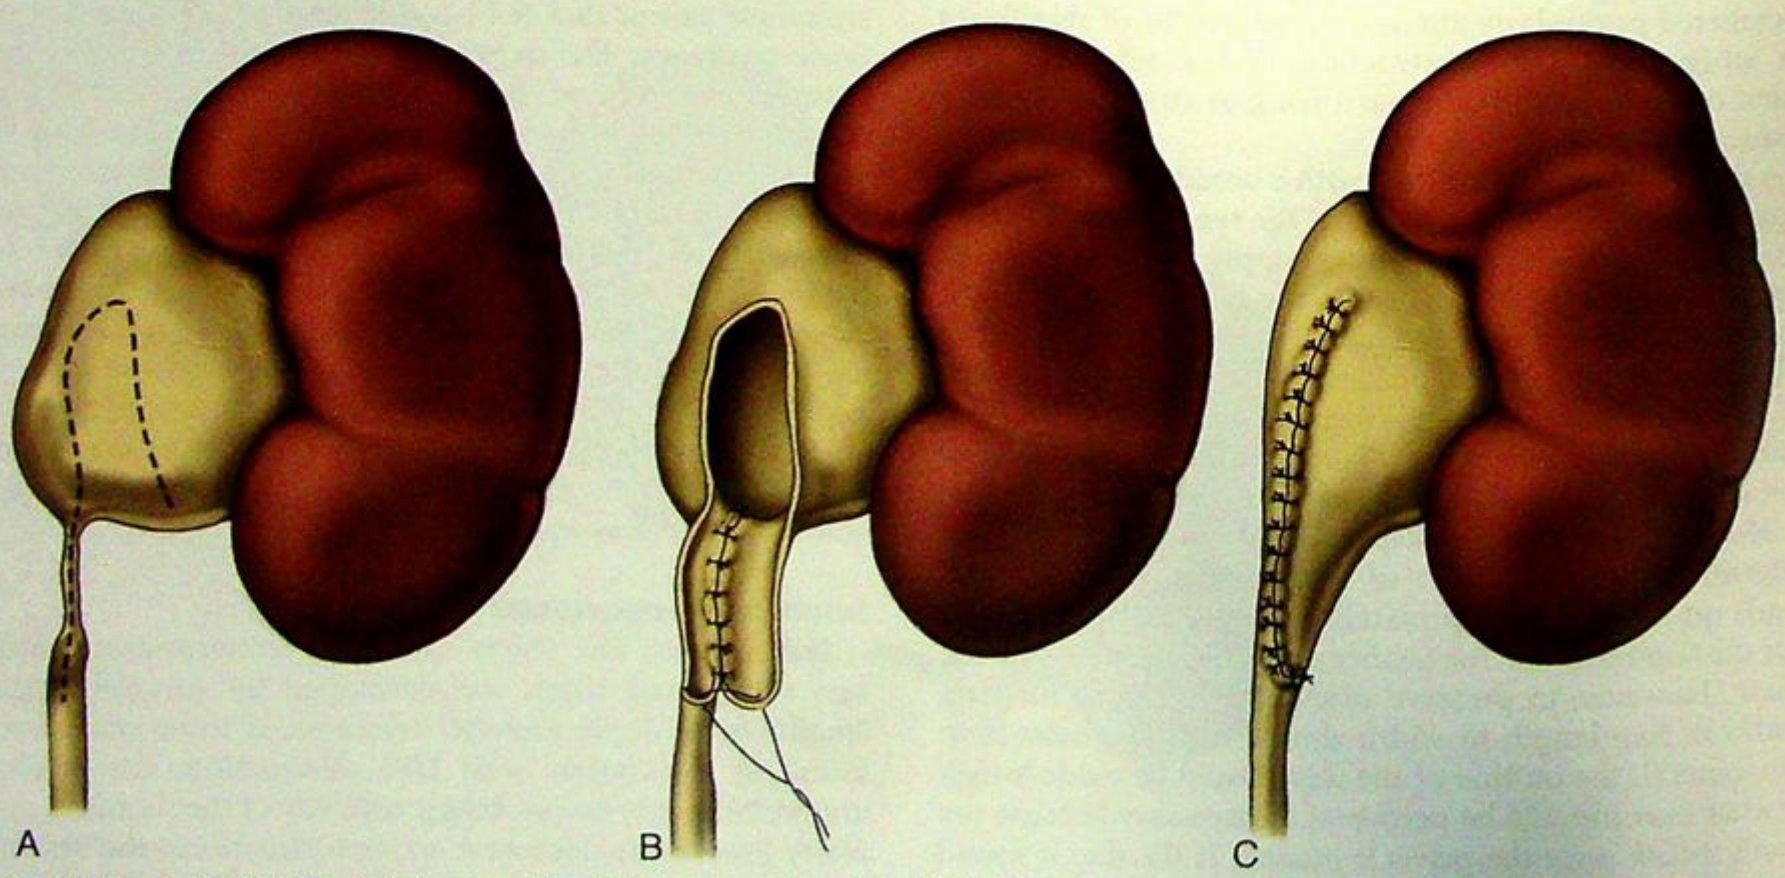

Figure 38–16. **A,** Vertical flap technique may be utilized when a dependent UPJ is situated at the medial margin of a large, box-shaped extrarenal pelvis. In contrast to the spiral flap, the base of the vertical flap is situated more horizontally on the dependent aspect of the renal pelvis, between the UPJ and the renal parenchyma. The flap itself is formed by two straight incisions converging from the base vertically up to the apex on either the anterior or the posterior aspect of the renal pelvis. As for the spiral flap, the position of the apex determines the length of the flap, which should be a function of the length of proximal ureter to be bridged. The medial incision of the flap is carried down the proximal ureter completely through the strictured area into normal-caliber ureter. **B,** The apex of the flap is rotated down to the most inferior aspect of the ureterotomy. **C,** The flap is then closed by approximating the edges with interrupted or running fine absorbable sutures.

dismembered repair, at least in regard to preservation of blood supply and subsequent healing.

Technique. A flap is outlined as described previously, with the ureterotomy to be made completely through the long, strictured area (Fig. 38–17*A*). The flap is then created, with minimal dissection of the ureter to preserve its blood supply. Unlike the uncomplicated pyeloplasties, these cases require routine nephrostomy tube drainage to prevent postoperative formation of a urinoma. Nephrostomy drainage in these cases also allows access for subsequent antegrade radiographic studies during the postoperative period.

Based on the original description, the ureteral intubation is achieved with a stenting catheter that is placed across the stenotic area to the distal ureter or bladder. Proximally, it is brought out through the renal cortex alongside a nephrostomy tube. Currently, most urologists use a self-retaining, soft, inert, internal ureteral stent instead. The apex of the flap is brought over the stent as far down as possible on the ureterotomy, and the flap is closed with either interrupted or running absorbable suture (see Fig. 38–17*B*). The distal aspect of the ureterotomy is then left open for secondary healing via ureteral regeneration (see Fig. 38–17*C*).

An antegrade nephrostogram is usually obtained 6 weeks after the surgery. If there is no extravasation, the ureteral stent is removed cystoscopically and an antegrade radiographic study is repeated. When ureteral patency without extravasation is ensured with such study, the nephrostomy tube is clamped and subsequently removed.

Ureterocalycostomy

Indications. Ureterocalycostomy may be used as a primary reconstructive procedure whenever a UPJ obstruction or proximal ureteral stricture is associated with a relatively small intrarenal pelvis (Fig. 38–18*A*). When the UPJ is associated with rotational anomalies such as horseshoe kidney (Levitt et al, 1981), ureterocalycostomy may be useful to provide completely dependent drainage. Furthermore, ureterocalycostomy is a well-accepted salvage technique for the failed pyeloplasty (Ross et al, 1990).

Technique. The ureter is first identified in the retroperitoneum and dissected proximally with a generous amount of periureteral tissue. For secondary procedures, however, extensive scarring may preclude adequate identification and dissection of the renal pelvis itself (see Fig. 38–18*B*). The kidney is then mobilized to gain access to the lower pole. An important technical point in ureterocalycostomy is that the parenchyma overlying the lower pole calyx must be resected rather than simply incised, because a simple nephrotomy may lead to a secondary stricture (Couvelaire et al, 1964).

The proximal ureter is first spatulated laterally, and the ureterocalyceal anastomosis is completed over an internal stent. Leaving an indwelling nephrostomy tube should also be

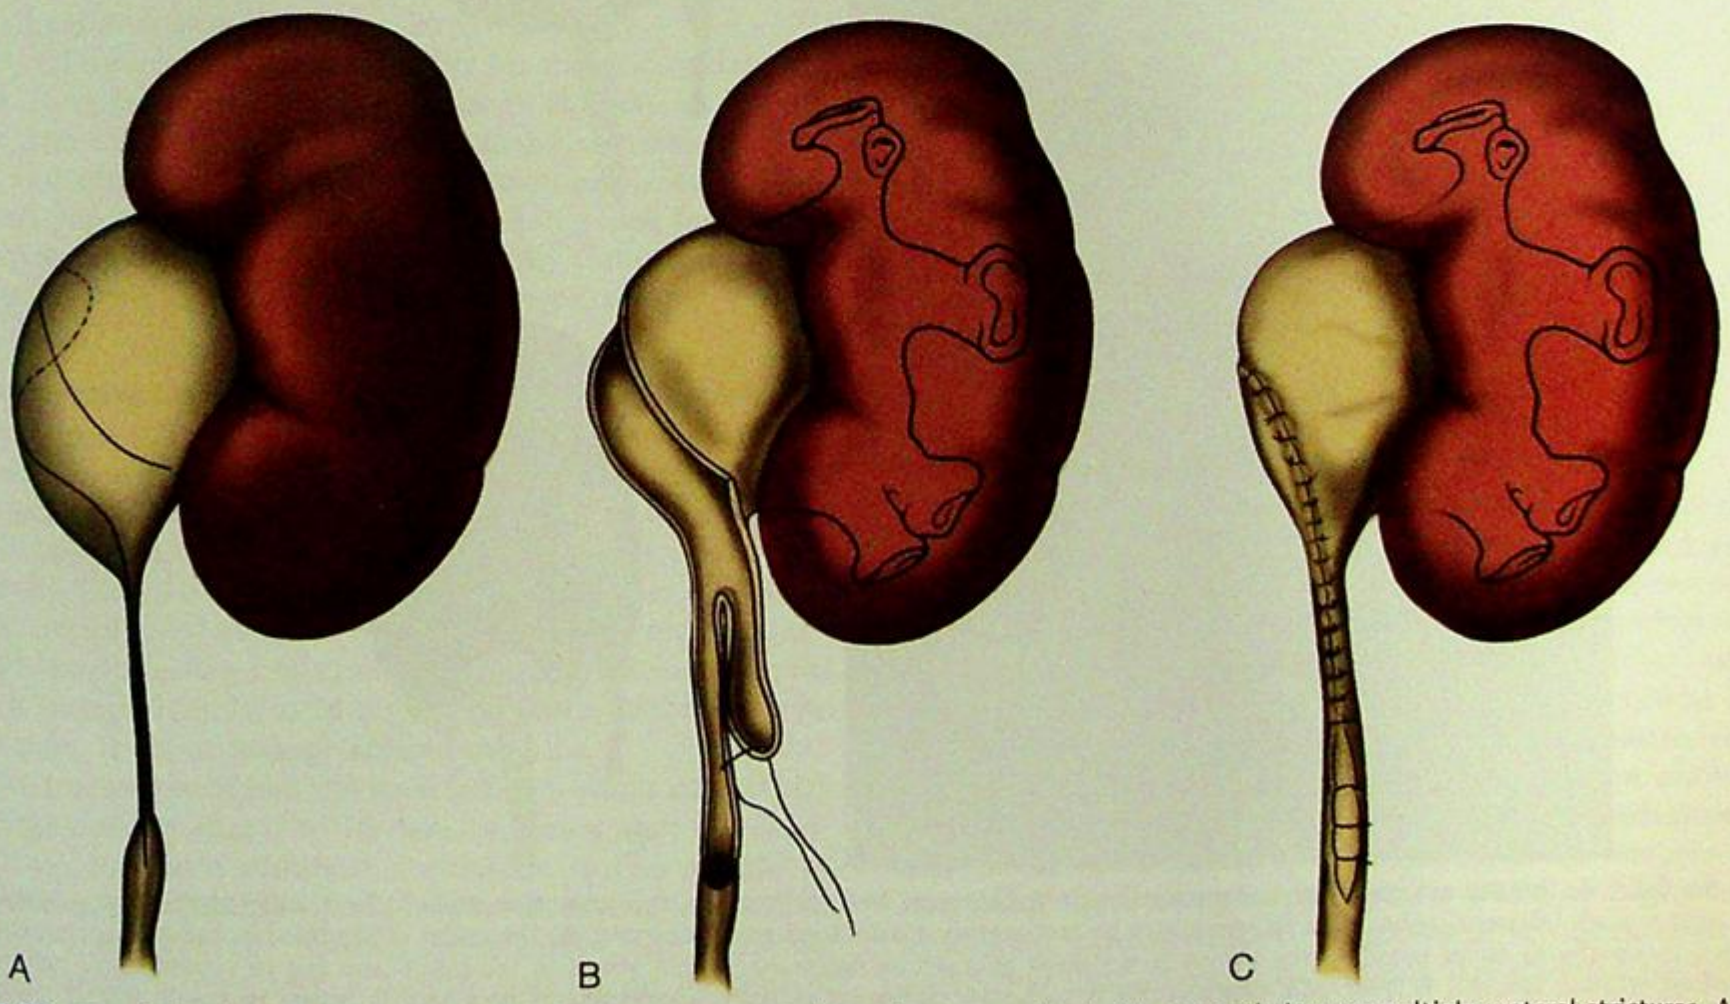

Figure 38–17. **A,** Intubated ureterotomy may be of value when a UPJ obstruction is associated with extremely long or multiple ureteral strictures. A spiral flap is outlined and developed as described in Figure 38-15. The ureterotomy incision will be carried completely through the long strictured areas or through each of the multiple areas of stricture. **B,** The flap is developed, taking care to use minimal dissection of the ureter to preserve its blood supply. In contrast to uncomplicated repairs, nephrostomy tube drainage is utilized routinely. A self-retaining, soft, inert internal ureteral stent is then placed and positioned proximally in the renal pelvis or lower infundibulum and distally in the bladder. The apex of the flap is then brought as far down as possible over the stent on the ureterotomy, and the flap is closed with interrupted or running absorbable suture. **C,** The distal aspect of the ureterotomy is left open to heal secondarily by ureteral regeneration. A few fine absorbable sutures may be loosely placed to keep the sides of the ureter in apposition to the stent.

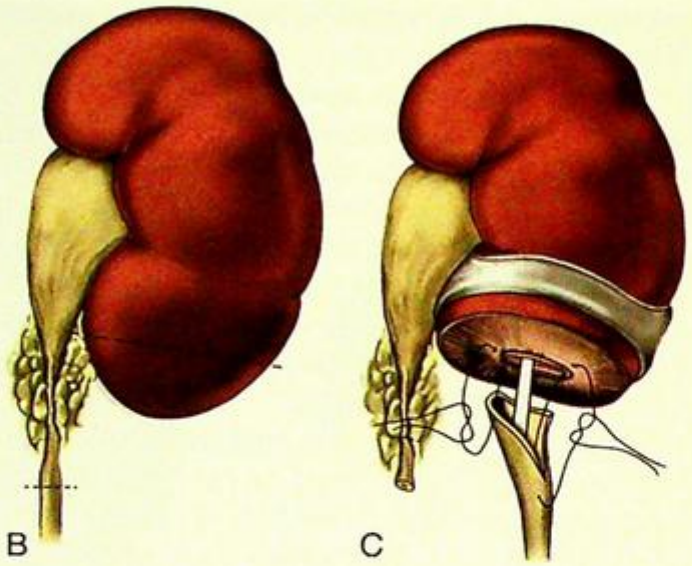

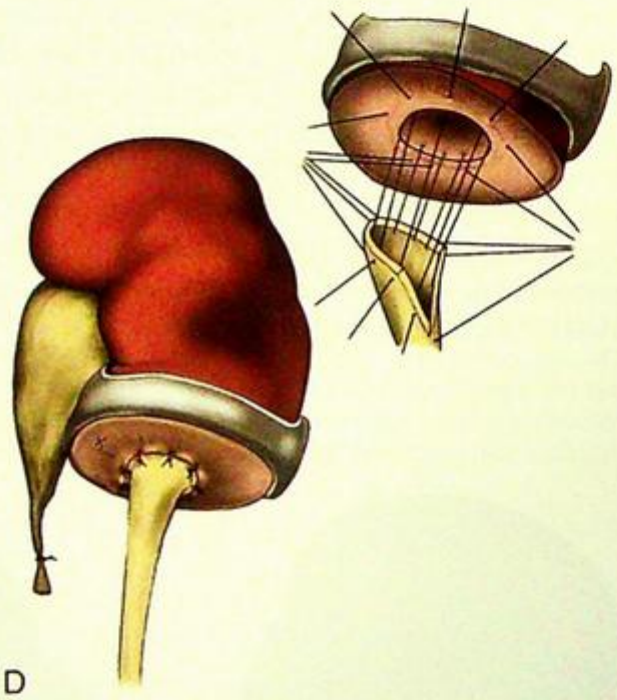

Figure 38–18. **A,** This patient complained of progressive right flank pain and was found on this retrograde study to have a UPJ obstruction *(arrow)* associated with a small intrarenal pelvis. This situation may be best managed with a ureterocalycostomy. **B,** The ureter is identified in the retroperitoneum and dissected proximally as far as possible. The kidney is mobilized as much as necessary to gain access to the lower pole and to subsequently perform the anastomosis without tension. A lower pole nephrectomy is performed, removing as much parenchyma as necessary to widely expose a dilated lower pole calyx. **C,** The proximal ureter is spatulated laterally. The anastomosis should subsequently be performed over an internal stent, and consideration should also be given to leaving a nephrostomy tube. The initial sutures are placed at the apex of the ureteral spatulation and the lateral wall of the calyx with a second suture placed 180 degrees from that. **D,** Anastomosis is then completed in a "open" fashion, placing each suture circumferentially *(inset)* but not securing them down until the anastomosis has been completed. **E,** The renal capsule is closed over the cut surface of the parenchyma whenever possible. However, the capsule should not be closed near the anastomosis itself because that may compromise the lumen by extrinsic compression. Instead, the anastomosis should be protected with a graft of perinephric fat or a peritoneal or omental flap. **F,** Intravenous urogram 2 months after right ureterocalycostomy

considered in these cases. The first suture is placed at the apex of the ureteral spatulation and lateral wall of the calyx, and the second suture is placed 180 degrees apart. The remainder of the anastomosis is then performed utilizing an interrupted "open" suture technique. That is, each suture placed is left untied until the final one is in place (see Fig. 38–18*C*). This method seems to provide a more accurate anastomosis under direct vision. When the full set of circumferential sutures has been placed, the sutures are secured down together (see Fig. 38–18*D*). The renal capsule is closed over the cut surface of the parenchyma if possible. However, such closure should not be close enough to the anastomosis itself to cause extrinsic compression on the anastomosis. Instead, the anastomosis should be covered with perinephric fat or a peritoneal or omental flap (see Fig. 38–18*E*). A follow-up urogram is generally obtained at 1 month after the ureteral stent extraction (see Fig. 38–18*F*).

"Salvage" Procedures. Failed open pyeloplasty is a challenging problem that is usually best managed initially using an endourologic approach. In some cases, such approach may not be applicable. In these cases, successful reconstruction can at times be achieved utilizing one of the flap or dismembered techniques already described. The secondary open operative reconstruction may be significantly aided by the placement of a ureteral catheter to aid intraoperative identification and dissection of the ureter and renal pelvis. In these situations there is often a relatively long length of proximal ureteral stenosis to repair and wide mobilization of the kidney and ureter is generally a necessity. This helps to bridge the area of stenosis and allows a tension-free secondary pyeloplasty.

Several other options are available for these secondary and often complex repairs. These surgical alternatives include those generally available for any extensive ureteral problem, such as ileoureteral replacement and autotransplantation with a Boari flap pyelovesicostomy. For cases in which function of the involved kidney is already significantly compromised and the contralateral kidney is normal, nephrectomy can be considered.

Postoperative Care and Management of Complications. In general, external drains are advanced and removed 24 to 48 hours after urinary drainage has ceased. When internal stents have been placed, they remain in situ for 4 to 6 weeks. If a nephrostomy tube is present, a nephrostogram is obtained generally 7 to 10 days postoperatively, or even later for particularly complicated repairs. When that study demonstrates a patent anastomosis without obstruction or extravasation, the tube is clamped for 12 to 24 hours and removed if there is no flank pain, fever, or leakage around the tube.

If an internal stent had not been left indwelling and urinary drainage persists after 7 to 10 days, or recurs after the external drain has been removed, retrograde studies should be obtained and an attempt made to pass an internal stent. The problem then generally resolves immediately, and, again, the internal stent is removed 1 month later. If an attempt at passing an internal stent is unsuccessful, a percutaneous nephrostomy is placed and then managed as if it had been left intraoperatively. If drainage persists despite nephrostomy tube placement, an internal or internal/external stent should be placed in an antegrade fashion. At times, despite appropriate use of stents, drains, and nephrostomy tubes, urinary extravasation will result in urinoma formation. This is best managed with direct percutaneous drainage of the fluid collection, utilizing ultrasound or CT guidance.

Standard follow-up of the functional result is accomplished with a urogram or renogram obtained approximately 4 weeks postoperatively or 4 weeks after any stents or nephrostomy tubes have been removed. More urgent evaluation is indicated if the patient becomes symptomatic. Compared with preoperative studies, radiographic evaluation at this time should show improvement in the degree of hydronephrosis. If a question remains as to the functional significance of any residual calycectasis, further evaluation can be performed using intravenous urography, diuretic renography, or retrograde pyelogram as outlined earlier in the chapter.

KEY POINTS: OPEN OPERATIVE INTERVENTION OF UPJ OBSTRUCTION

- Dismembered pyeloplasty can be applied to high ureteral insertion, redundant renal pelvis, and/or crossing vessels. It also allows excision of abnormal UPJ itself. It is the most versatile form of pyeloplasty. However, it is not well suited for lengthy or multiple proximal ureteral strictures or small, relatively inaccessible intrarenal pelvis.
- Flap procedures can be useful in situations involving a relatively long segment of ureteral narrowing or stricture. Of the various flap procedures, a spiral flap can bridge a strictured or narrow area of longer length. The flap procedures are not appropriate in the setting of crossing vessels.
- Ureterocalycostomy may be used for UPJ obstruction or proximal ureteral stricture associated with a relatively small intrarenal pelvis. It may also be used as a salvage technique for the failed pyeloplasty.

Laparoscopic Operative Intervention

Laparoscopic Pyeloplasty. Laparoscopic approach to pyeloplasty was first introduced in 1993 by Schuessler and associates and has been developed worldwide as a viable minimally invasive alternative to open pyeloplasty and endopyelotomy. Relative to both open pyeloplasty and endopyelotomy, laparoscopic pyeloplasty is associated with greater technical complexity and a steeper learning curve. **In the hands of the experienced laparoscopic surgeons, it has been shown to provide lower patient morbidity, shorter hospitalization, and faster convalescence, with the reported success rates matching those of open pyeloplasty (90% or higher).** Following the similar surgical principles of anatomic dissection and repair used in open pyeloplasty, laparoscopic pyeloplasty has been shown to provide the success rates surpassing those of endopyelotomy by 10% to 30%.

Indications and Contraindications. **The indications and contraindications for a laparoscopic repair are similar to those for either an endourologic or an open operative procedure. Indications to intervene include the presence of**

clinical symptoms of UPJ obstruction, the progressive impairment of renal function, and the development of ipsilateral upper tract calculi or infection. Cases requiring the transposition of crossing vessels obstructing the UPJ or the size reduction for massively dilated renal pelvis are suitable for the laparoscopic approach. **Absolute contraindications to intervene include the presence of uncorrected coagulopathy, the absence of adequate treatment of active urinary tract infection, and the presence of cardiopulmonary compromise unsuitable for surgery. The objective of the laparoscopic surgery is to provide a tension-free, watertight repair with a funnel-shaped drainage product to relieve clinical symptoms and to preserve renal function.**

Techniques. Four laparoscopic techniques for pyeloplasty have been described in the literature, including the standard transperitoneal approach, retroperitoneal approach, anterior extraperitoneal approach, and robotic-assisted approach. For each approach, a dismembered Andersen-Hynes pyeloplasty, which is preferred by most surgeons, or one of the non-dismembered methods such as YV-plasty and flap pyeloplasty (Culp-DeWeerd) analogous to those described for the open pyeloplasty can be used.

Transperitoneal Laparoscopic Approach. The initial transperitoneal approach to laparoscopic pyeloplasty was first described by Schuessler and associates (1993) and Kavoussi and Peters (1993), and **this approach has been the most widely used laparoscopic method because of its associated large working space and familiar anatomy.** Prior to the laparoscopic portion of the procedure, cystoscopy with retrograde pyelography is performed to define the anatomy and confirm the diagnosis, followed by placement of a ureteral stent and a urethral Foley catheter. The patient is placed in a 45-degree lateral decubitus position, and access to the peritoneal cavity is obtained via either the Veress needle or the Hassan access technique. Three to five laparoscopic ports are placed after the creation of CO_2 pneumoperitoneum. Typically, the umbilical port is for the laparoscope use. After medial mobilization of the colon, the ureter is identified and dissected in the cephalad direction to achieve mobilization of the ipsilateral proximal ureter, UPJ, and renal pelvis (Fig. 38–19*A*). Extensive dissection of the ureter and excessive electrocautery use in close proximity to the ureter should be avoided to minimize injury to its vascular supply. At this time, the anatomy of the proximal ureter, renal pelvis, and nearby vasculature are carefully examined to determine the etiology of the UPJ obstruction and the appropriate type of surgical repair. The general methods and principles of various types of surgical repair for laparoscopic pyeloplasty are identical to those described for open pyeloplasty. If dismembered pyeloplasty is to be performed, which is suitable for the presence of crossing vessels, the renal pelvis is first transected circumferentially above the UPJ and the lateral aspect of the proximal ureter is spatulated (see Fig. 38–19*B*). The renal pelvis and proximal ureter are then transposed to the opposite side of the crossing vessel, if such vessel is present, and the ureteropelvic anastomosis is then completed with intracorporeal suturing techniques (see Fig. 38–19*C* and *D*). In the presence of redundant renal pelvis, reduction pelvioplasty may be performed by excising redundant renal pelvic tissue and closing the pyelotomy. The actual laparoscopic suturing maneuver can be accomplished either free-hand or with a semi-automated device (EndoStitch, U.S. Surgical Inc., Norwalk, CT). Either continuous running or simple interrupted suturing method may be used in the dismembered laparoscopic pyeloplasty, typically with 4-0 absorbable suture. A surgical drain is placed after the completion of the anastomosis, and one of the trocar sites is typically utilized as the drain exit site.

Retroperitoneal Laparoscopic Approach. The initial retroperitoneoscopic approach to pyeloplasty was first reported by Janetschek and colleagues (1996). Cystoscopy with retrograde pyelography and ureteral stent placement is first performed as described previously. For the retroperitoneal approach, the patient is usually positioned in a flank position with the use of flexion and elevation of the kidney rest of the operating table. By following the Hassan access technique to enter the retroperitoneum, a retroperitoneal working space can be created with balloon dilation. After creation of a CO_2 pneumoretroperitoneum, three to four laparoscopic ports are used to perform the laparoscopic pyeloplasty. The ureter is usually identified early in the procedure, and the dissection, mobilization, and UPJ repair steps are identical to those described for the transperitoneal approach (Fig. 38–20).

Anterior Extraperitoneal Laparoscopic Approach. The anterior extraperitoneal laparoscopic approach to pyeloplasty was first described by Hsu and Presti (2003). Cystoscopy with retrograde pyelography and ureteral stent placement are first performed as described previously. For the anterior extraperitoneal approach, the patient is placed in a 45-degree lateral decubitus position. Access to the preperitoneal space is obtained using open surgical techniques via a 10-mm incision, after which a large preperitoneal space is created with balloon dilation. After CO_2 insufflation and placement of four ports, the boundary between the retroperitoneal fat and peritoneal sac is identified and developed, allowing medial mobilization of the peritoneal sac containing the bowel contents en bloc. Subsequently, full exposure of the anterior aspects of the retroperitoneal structures including the ipsilateral ureter and kidney is attained. The proximal ureter, UPJ, and renal pelvis are identified, dissected, mobilized, and repaired as in transperitoneal laparoscopic pyeloplasty. The entire procedure is completed in an extraperitoneal manner. A surgical drain is placed at the end of the procedure.

Robotic-Assisted Laparoscopic Approach. The robotic-assisted laparoscopic pyeloplasty in the experimental setting was first reported by Sung and coworkers (1999). Its feasibility was subsequently confirmed with worldwide clinical application in recent years. Typically, the procedure is performed in a transperitoneal manner providing a larger working space for the robotic arms. After the initial laparoscopic access and trocar placement, the robotic system is placed in close proximity to the operating table and the robotic arms are attached to the laparoscope and specifically designed laparoscopic instruments. The surgeon at the console operates via the control of the robotic arms, while the assistant remains at the bedside and performs suction, retraction, exchange of laparoscopic instruments, suture needle introduction, and removal. The general surgical steps are identical to those described for non–robotic-assisted laparoscopic pyeloplasty.

Postoperative Care and Complications. Typically, a clear liquid diet is initiated on postoperative day 1 and advanced rapidly. Perioperative prophylactic antibiotic coverage is maintained [illegible] Foley catheter is usually removed after 24 to

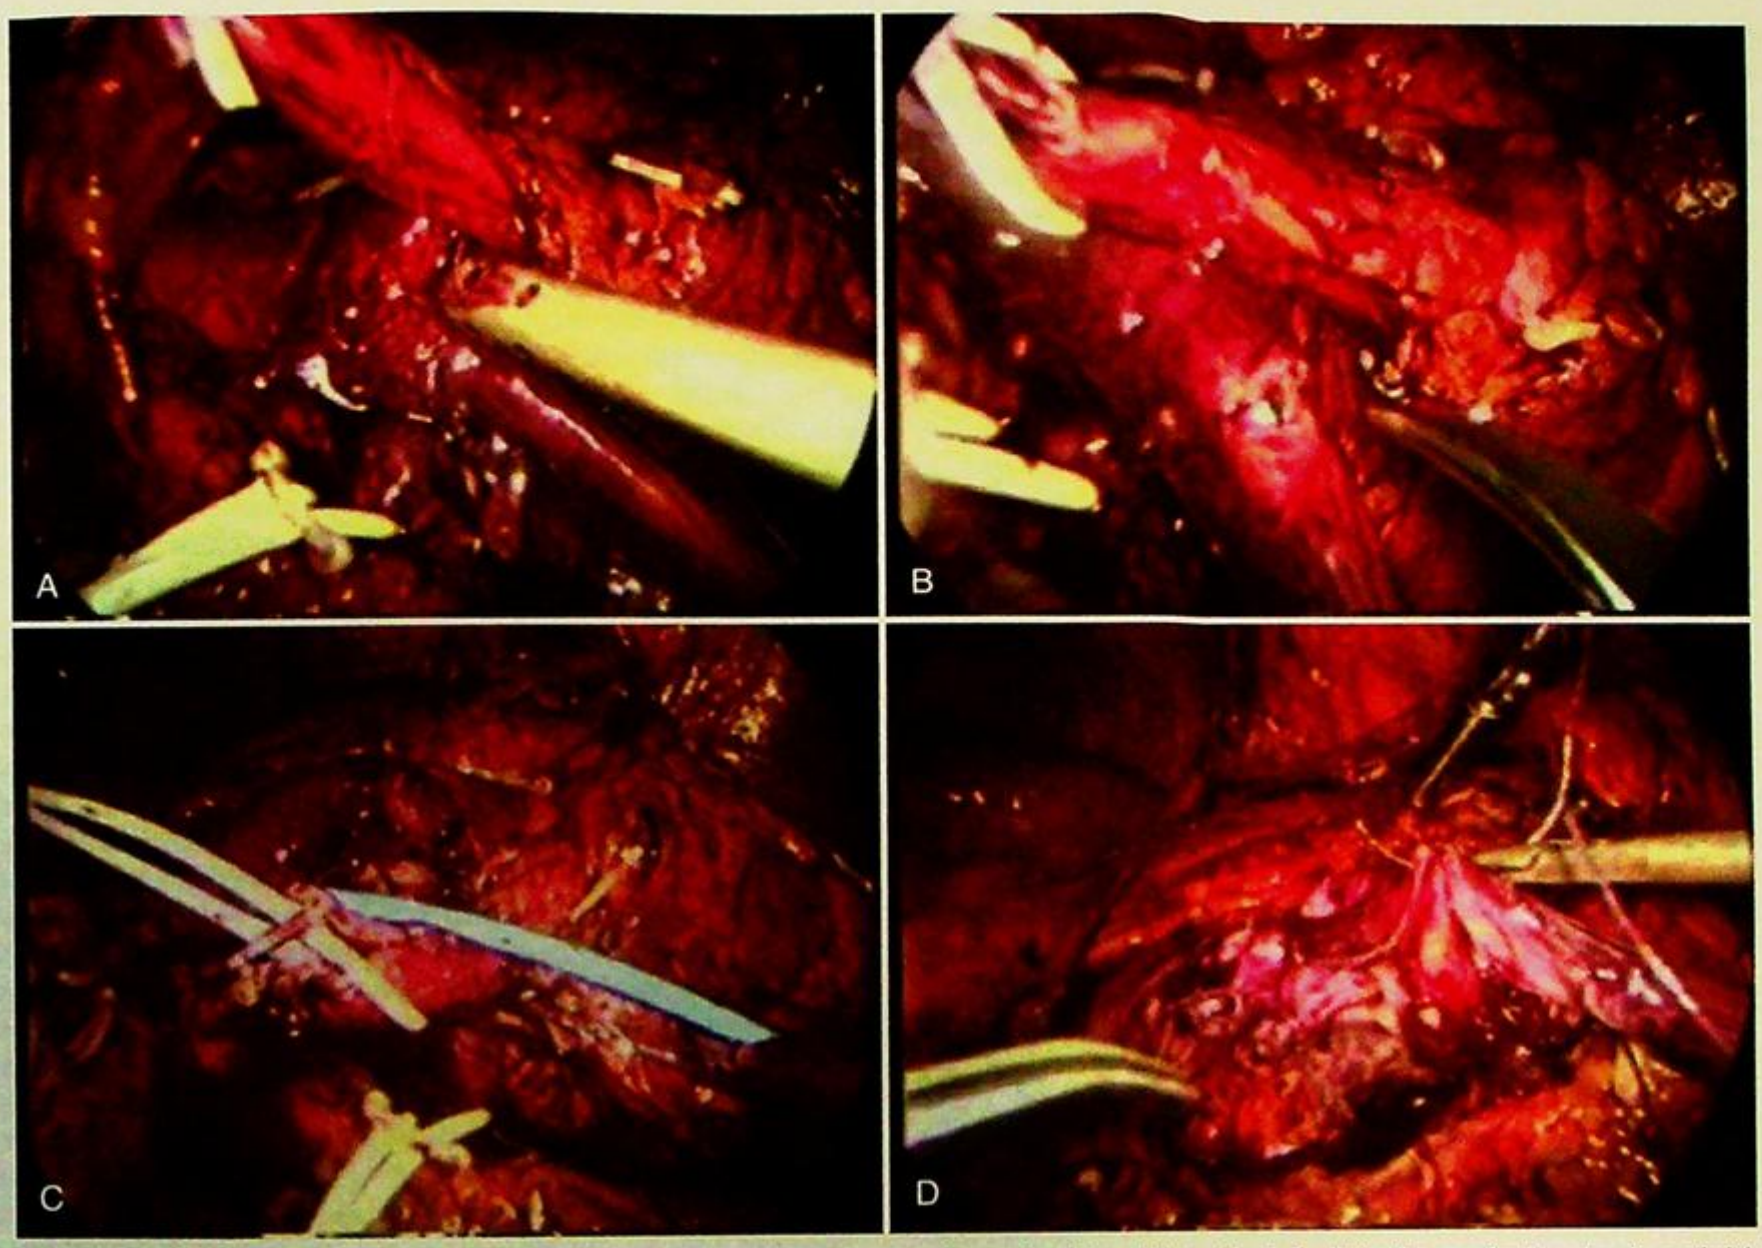

Figure 38–19. **A,** Transperitoneoscopic view of a patient with left pyeloplasty. The patient's head is to the left. Note the proximal ureter is sandwiched between an anterior crossing lower pole renal artery (wrapped with white vessel loop and retracted upward) and a posterior crossing lower pole vessel (wrapped with white vessel loop). The suction-irrigator tip points at the left UPJ. **B,** The left proximal ureter is being transected with laparoscopic scissors, revealing the preplaced ureteral stent within the ureteral lumen. **C,** The ureteral stent is transposed anterior to the anteriorly crossing vessel after circumferential transection of the proximal left ureter. **D,** Ureteropelvic anastomosis is completed with intracorporeal suturing techniques.

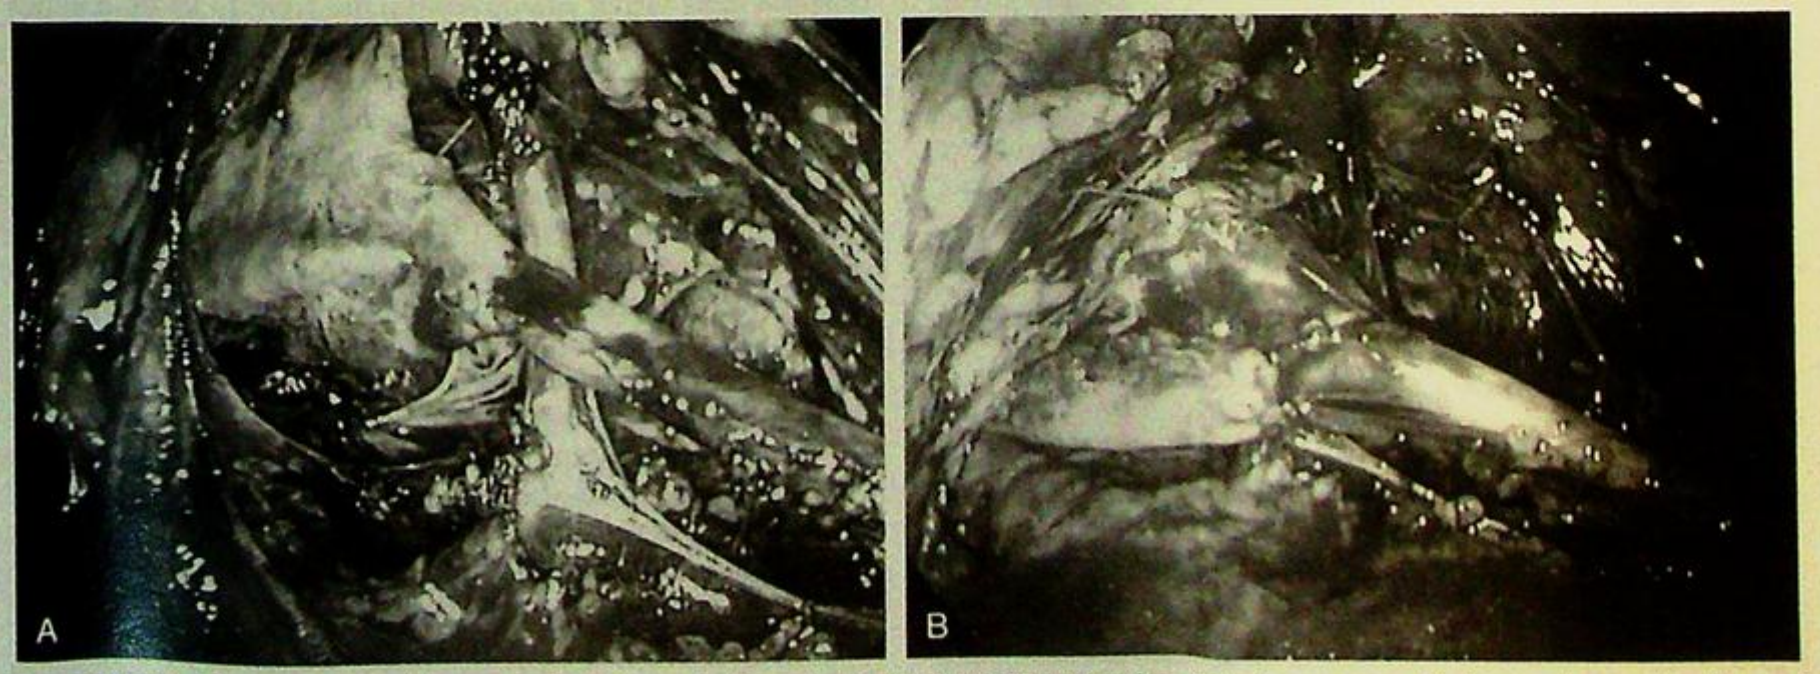

Figure 38–20. **A,** Retroperitoneal laparoscopic photograph of a patient with right UPJ obstruction. Note the presence of a lower pole crossing the renal vessel anterior to the UPJ. **B,** Intraoperative view of completed ureteropelvic anastomosis after retroperitoneal laparoscopic dismembered pyeloplasty.

36 hours, and the surgical drain is removed before hospital discharge if the drain output remains negligible. If the drain output increases after the Foley catheter removal, the Foley catheter should be replaced for 7 days to eliminate urinary reflux along the stent in the treated ureter and decrease urinary extravasation at the ureteropelvic anastomosis. The ureteral stent is typically removed 4 to 6 weeks later in an outpatient setting, and follow-up including the use of imaging studies such as diuretic renal scan is performed as for any open pyeloplasty. Most of the complications of laparoscopic pyeloplasty are similar to those of general laparoscopic procedures, including colonic injury, hemorrhage, ileus, pneumonia, congestive heart failure, thrombophlebitis, and urinoma formation. In the first 100 cases of laparoscopic pyeloplasty performed at Johns Hopkins Medical Institutions (Jarrett et al, 2002), such complications occurred in 12% of the patients. A typical postoperative appearance of a laparoscopic pyeloplasty patient is illustrated in Figure 38-21.

Results. Most of the published laparoscopic pyeloplasty reports have utilized the classic Andersen-Hynes dismembered technique, because most laparoscopic surgeons attempt to duplicate the well-established principles of open surgery (Janetschek et al, 2000; Eden et al, 2001; Soulie et al, 2001; Jarrett et al, 2002; Turk et al, 2002). The overwhelming majority of the patients in these recent series had primary laparoscopic pyeloplasties, and the mean operative times are in the range of 119 to 252 minutes. In experienced hands, the entire procedure can be consistently performed in less than 3.5 hours (Jarrett et al, 2002), reflecting greater confidence in intracorporeal suturing and knot-tying. Perioperative complication rates are low, ranging from 2% to 12%, demonstrating the safety of the laparoscopic procedure. Open conversion rates are also low, less than 5%. Furthermore, blood transfusion risks are low, being limited to anecdotal reports. Postoperative analgesic use is generally minimal. Mean length of hospital stay ranges from 2.6 to 4.5 days, and such average has decreased to 3.8 days in the series reported since 2000. With mean follow-up times of 14 to 26 months, the rates of surgical success (defined as durable clinical and/or radiographic success) reach the range of 87% to 99%, with the majority of contemporary series reporting success rates of greater than 95%. For the patients who fail laparoscopic pyeloplasty, most cases can be well managed with endoscopic intervention such as endopyelotomy, with success rates of approximately 70% (Varkarakis et al, 2004). Additional current concerns for the robotic-assisted laparoscopic pyeloplasty include cost, limited instrumentation, and need for experienced bedside laparoscopic assistance (Peschel et al, 2004).

Figure 38–21. Postoperative photograph of the abdomen of a patient with left-sided laparoscopic dismembered pyeloplasty. Note the four small scars from the laparoscopic procedure.

No prospective randomized trial has been successfully completed to compare laparoscopic with open pyeloplasty to date. The unwillingness of the patients to undergo randomization due to the different levels of perceived invasiveness appears to be the most significant barrier to completing such studies. In a retrospective study, Bauer and colleagues (1999) compared 42 laparoscopic pyeloplasties and 35 open pyeloplasties. With a minimal follow-up of 12 months for each of the patients, the two groups were found to be equivalent in pain relief (90% vs. 91%, respectively) and relief of obstruction (98% vs. 94%, respectively). In another retrospective study, Soulie and associates (2001) examined 26 laparoscopic pyeloplasties and 28 open pyeloplasties. The two groups were found to be equivalent in mean operating time (165 vs. 145 minutes, respectively), mean blood loss (92 vs. 84 mL, respectively), perioperative complication rate (11.5% vs. 14.3%, respectively), mean hospital stay (4.5 days vs. 5.5 days, respectively), and radiologic success (89% vs. 89%, respectively). However, more laparoscopic patients were found to have return to normal activity by postoperative day 15 (90% vs. 70%, respectively). In a third retrospective study, Klingler and colleagues (2003) compared 40 laparoscopic pyeloplasties with 15 open pyeloplasties. In this series, the laparoscopic group was found to have lower mean postoperative visual analog scale score (day 1, 3.5 vs. 5.4; day 5, 0.9 vs. 3.1) and shorter mean hospital stay (5.9 vs. 13.4 days).

Primary UPJ obstruction associated with renal anomalies such as horseshoe kidneys and pelvic kidneys has also been managed with laparoscopic pyeloplasty safely and successfully (Janetschek et al, 1996; Hsu and Presti, 2003; Bove et al, 2004). Furthermore, secondary UPJ obstruction has similarly been managed with success. In a retrospective review, Sundaram and colleagues (2003) identified 36 cases of laparoscopic transperitoneal pyeloplasty for secondary UPJ obstruction, mostly following failed retrograde or antegrade endopyelotomies. Mean operative time was 6.2 hours, longer than the reported times associated with primary UPJ obstruction. Open conversion was necessary in 1 patient, and postoperative complication occurred in 8 patients. With a mean follow-up of 21.8 months, the overall success rate of a greater than 80% decrease in pain, a patent UPJ, and stable or improved function of the affected renal unit was 83% (30 of 36 patients).

Special Situations of Laparoscopic Management of UPJ Obstruction

Laparoscopic Ureterocalicostomy. The clinical experience with laparoscopic ureterocalicostomy has been limited to one report to date. Gill and colleagues (2004) successfully performed laparoscopic ureterocalicostomy in two patients with UPJ obstruction associated with small renal pelvis and dilated lower pole calix. In both patients, a double-J ureteral stent was first placed into the ipsilateral ureter cystoscopically. With the patient in a 45- to 60-degree flank position, a transperitoneal approach using three or four ports was used to gain access to the ipsilateral renal unit laparoscopically. A circular rim of the tip of the thin lower pole renal parenchyma was identified and excised. The UPJ was transected, followed by ligation of the renal pelvic opening. The ureter was spatulated laterally, and end-to-end ureterocaliceal anastomosis with mucosa-to-mucosa apposition over the pre-placed double-J stent was performed with free-hand intracorporeal suturing and knot-tying techniques. The general reconstructive principles are identical to those of open ureterocalicostomy described previously, including the need to achieve tension-free, watertight, dependent drainage. Intravenous indigo carmine was administered to confirm no significant anastomotic leak. A Jackson-Pratt drain was then placed at the end of the laparoscopic procedure.

Laparoscopic Pyeloplasty with Concomitant Pyelolithotomy. Presence of calculi in the setting of UPJ obstruction can be managed laparoscopically with success. In a retrospective review, Ramakumar and colleagues (2002) reported 20 cases of laparoscopic pyeloplasty with concomitant extraction of renal stones through the pyelotomy site under laparoscopic guidance. In the series, extraction of the caliceal stones was facilitated by the use of flexible cystoscope introduced through a 10- to 12-mm port site. At a mean follow-up of 3 months, 90% of patients were stone free and 90% of patients had a patent UPJ radiographically.

Laparoscopic Dismembered Tubularized Flap Pyeloplasty. Presence of a significant upper ureteral defect after the excision of UPJ stricture may also be managed laparoscopically with success. Kaouk and coworkers (2002) described a case of laparoscopic pyeloplasty for secondary UPJ obstruction, in which a 3-cm upper ureteral defect was found after excision of the long stricture. By using a four-port transperitoneal approach, a wide-base renal pelvic flap was created and tubularized to bridge the defect, using intracorporeal freehand suturing techniques. At a 2-month follow-up, excretory urography and diuretic renal scan confirmed a widely patent upper ureter.

Laparoscopic Calicovesicostomy. Presence of a large-capacity bladder in the setting of UPJ obstruction associated with a low-lying obstructed renal unit can be managed successfully using an unconventional laparoscopic reconstructive strategy. Hsu and associates (2005) described a case of laparoscopic management of UPJ obstruction involving a horseshoe kidney with a unilateral hydronephrotic yet functioning lower pole moiety, ipsilateral ureteral duplication with high bifurcation, and complex anomalous renal vasculature. Rather than performing tedious anatomic dissection and complex ureteral reconstruction in such scenarios as required in conventional laparoscopic pyeloplasty, a nephrotomy was created at the most dependent portion of the hydronephrotic lower pole moiety and then laparoscopically anastomosed to the bladder dome vesicostomy using intracorporeal freehand suturing and knot-tying techniques. At the 4-month follow-up, patent calicovesicostomy was confirmed endoscopically and clinically.

KEY POINTS: LAPAROSCOPIC OPERATIVE INTERVENTION

- Transperitoneal laparoscopic approach is the most widely used method due to its associated large working space and familiar anatomy.
- Retroperitoneal laparoscopic approach and anterior extraperitoneal approach rely on creation of a working space using manual or balloon dilation.
- Laparoscopic management of UPJ obstruction has been shown to provide low perioperative complication rates, short hospital stay, and success rates over 95% in experienced hands.

RETROCAVAL URETER

Etiology and Diagnosis

Retrocaval ureter is a rare congenital urologic anomaly. It occurs as a consequence of the persistence of the posterior cardinal veins during embryologic development (Considine, 1966). Its presence should be suspected with the finding of a characteristic S-shaped deformity on intravenous or retrograde pyelography (Fig. 38–22*A*). Today, a definitive diagnosis can be made noninvasively utilizing three-dimensional CT (see Fig. 38–22*B*) (Pienkny et al, 1999). Procedural intervention is indicated in the presence of functionally significant obstruction leading to pain or renal function deterioration.

Operative Intervention

Open Surgical Management

The standard repair of retrocaval ureter is open surgical pyelopyelostomy. In this procedure, the ureter, dilated renal pelvis, and inferior vena cava are identified and dissected using the standard open surgical techniques. The dilated renal pelvis is then transected, following which the ureter is transposed to its normal anatomic position anterior to the vena cava (Fig. 38–23). Pyelopyelostomy is then performed circumferentially with absorbable sutures in a tension-free, watertight manner. A surgical drain and internal ureteral stent are typically used.

Laparoscopic Surgical Management

Retrocaval ureter has been managed successfully with the laparoscopic approach in the clinical setting as shown by a series of sporadic case reports in recent years (Baba et al, 1994; Matsuda et al, 1996; Polascik and Chen, 1998; Salomon et al, 1999; Gupta et al, 2001; Ramalingam and Selvarajan, 2003). Either a transperitoneal or a retroperitoneal approach may be used laparoscopically. A double-J ureteral stent is first placed into the ipsilateral ureter cystoscopically. After transperitoneal or retroperitoneal laparoscopic access, the ipsilateral ureter is identified and mobilized off the inferior vena cava. The ureter

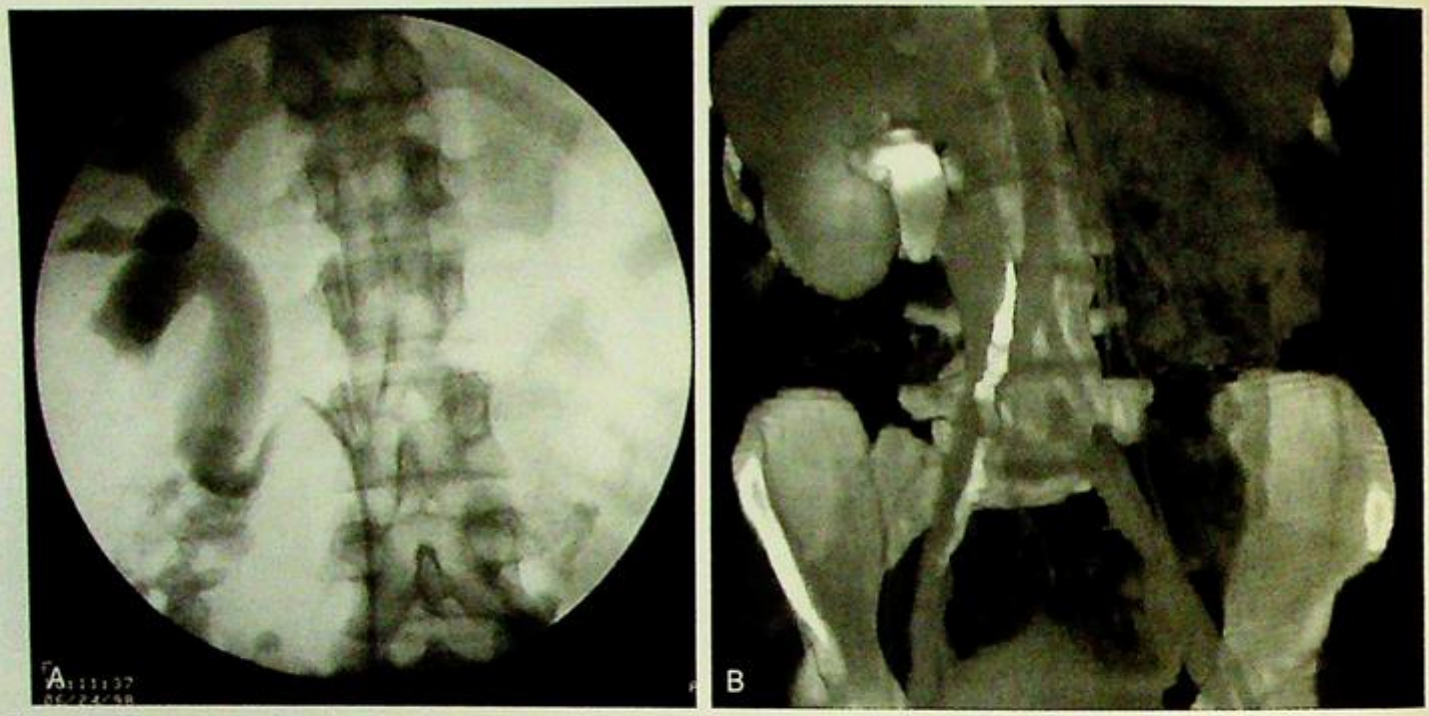

Figure 38–22. A, Retrograde pyelography in a patient with right-sided hydronephrosis. This study reveals a typical S-shaped deformity secondary to the ureter coursing laterally to medially posterior to the inferior vena cava. B, Three-dimensional spiral CT demonstrates the presence of a retrocaval ureter.

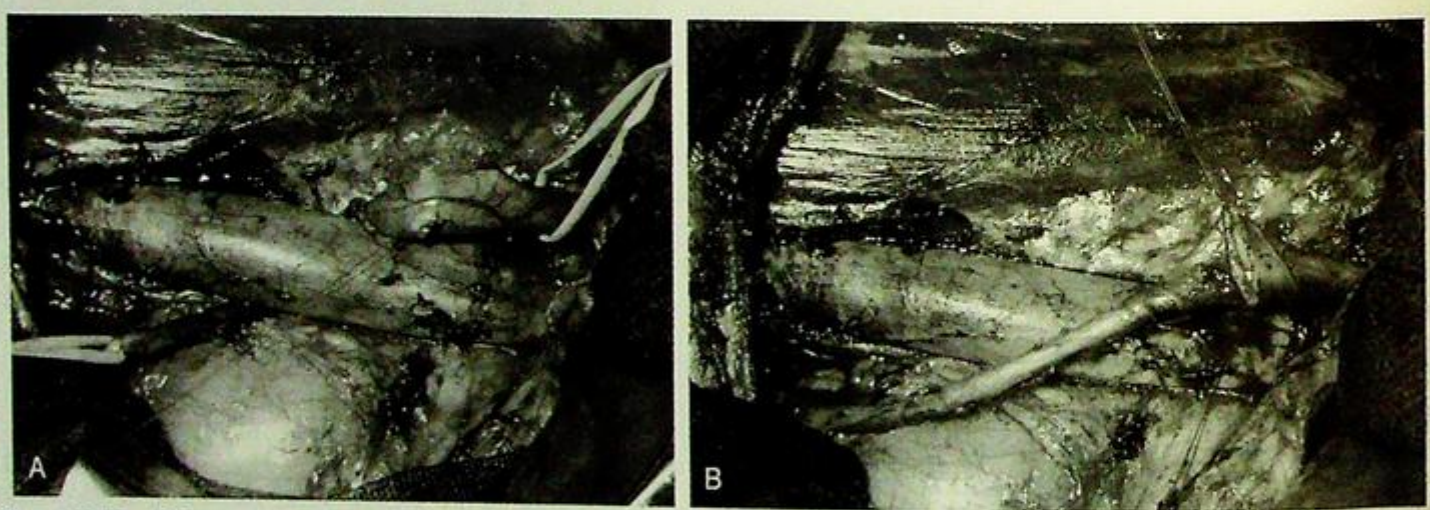

Figure 38–23. A, Intraoperative photograph of a patient with retrocaval ureter undergoing surgical repair via a retroperitoneal flank approach. Right side of the photograph represents the cephalad direction. Note the dilated proximal right ureter passing behind the inferior vena cava. B, Right ureteropelvic anastomosis has been completed after transection of the right renal pelvis and transposition of the ureter anterior to the inferior vena cava.

is then divided at the most distal segment of the dilated ureter. Redundant segment of dilated proximal ureter and stenotic segment of ureter are excised if present. The ureteral ends are positioned anterolateral to the vena cava, spatulated for 1.5 to 2 cm on opposite ends, and then anastomosed with absorbable sutures using intracorporeal suturing techniques over the stent. Tension-free, watertight anastomosis is the objective. A surgical drain is then left in place before formal laparoscopic exit. The surgical drain is typically removed within a few days postoperatively, and the ureteral stent is removed in 4 to 6 weeks. **The overall clinical results of the laparoscopic repair in the literature have been favorable, providing minimal postoperative patient morbidity, short convalescence, and anastomotic patency on short-term radiographic follow-up.**

KEY POINTS: RETROCAVAL URETER

- Retrocaval ureter results from the persistence of the posterior cardinal veins.
- Retrocaval ureter can be diagnosed using intravenous or retrograde pyelography or three-dimensional CT.
- Procedural intervention is indicated in the presence of functionally significant obstruction, and both open and laparoscopic approaches can be successfully applied.

Idiopathic

URETERAL STRICTURE DISEASE

Etiology

Common causes of ureteral stricture formation include ischemia, surgical and nonsurgical trauma, periureteral fibrosis, malignancy, or a congenital disorder (Table 38–1). **Proper evaluation and treatment of a ureteral stricture is essential to preserve renal function and rule out the presence of malignancy.** Although the classic radiographic presentation of a transitional cell carcinoma of the ureter is a radiolucent filling defect within the lumen with the characteristic goblet sign, it may appear as a benign stricture. In addition, metastatic tumors such as cervical, prostate, ovarian, breast, and colon cancer may appear as a ureteral stricture (Lau et al, 1998). Although the incidence of ureteral strictures in the general population is unknown, it is clear that the **presence of ureteral calculi and associated treatment of stones are risk factors.** Roberts and colleagues (1998) evaluated 21 patients with impacted ureteral stones and found that impaction for more than 2 months' duration was associated with a 24% incidence of stricture formation. Any ureteral instrumentation can lead to the development of a ureteral stricture. As advances in ureteroscopic technology have provided smaller, more flexible instruments with better optics, these endoscopic procedures have become less traumatic and are now associated with a long-term complication rate of less than 1% (Harmon et al, 1997). Other causes of benign ureteral strictures include radiation; abdominal aortic aneurysm; infections, such as tuberculosis and schistosomiasis; endometriosis; and trauma, including iatrogenic injury from previous abdominal or pelvic surgery (El Abd et al, 1996; Lacquet et al, 1997; Ramanathan et al, 1998; Oh et al, 2000). Patients with presumed idiopathic ureteral strictures should be evaluated utilizing CT to rule out the presence of an intrinsic ureteral malignancy or a lesion causing extrinsic compression.

Diagnostic Studies and Indications for Intervention

An intravenous pyelogram and retrograde pyelogram reliably define the location and length of the ureteral stricture. Subsequent ureteroscopy with biopsy or barbotage should be performed in any patient for whom the etiology of the stricture is not certain. Endoluminal ultrasound is an alternate approach that allows one to characterize a stricture and guide therapy, although it is not commonly utilized (Grasso et al, 1999). Diuretic renography will provide differential renal function and evaluate the renal unit for functional obstruction. **It is critical to assess the renal unit for function before starting treatment, because endourologic therapies generally require 25% function of the ipsilateral moiety to have reasonable success rates** (Wolf et al, 1997). Once a ureteral stricture is diagnosed, indications for intervention include the need to rule out malignancy, compromised renal function, recurrent pyelonephritis, and pain associated with functional obstruction.

Endourologic Options for Intervention

Ureteral Stent Placement

Ureteral stent placement is effective acutely in treating most ureteral strictures, in particular intrinsic ureteral strictures. Generally, select intrinsic ureteral strictures can be managed with endoscopic options, but cases of extrinsic ureteral compression are better suited to percutaneous drainage or surgical management. In cases in which the patient is not a candidate for definitive repair, or has a poor prognosis, chronic stent placement with periodic stent changes may be considered. **The use of chronic stent placement must be guarded, particularly when treating ureteral obstruction from extrinsic compression, because in many cases adequate drainage is short lived** (Docimo and Dewolf, 1989; Chung et al, 2004). Some urologists have placed two stents to maintain ureteral patency in cases in which a single stent did not provide adequate drainage (Yohannes et al, 2001).

Retrograde Balloon Dilation

Retrograde dilatation of ureteral strictures has historically been part of the urologic armamentarium. The technique was rarely definitive and usually required repeated dilatations on a regular basis. In the early 1980s, angiographic and vascular balloons were introduced into urologic practice, and the technique of balloon dilatation with temporary internal stenting became an accepted mode of treatment (Banner et al, 1983; Finnerty et al, 1984).

As for any patient with a ureteral stricture, the indications to intervene include functionally significant obstruction. Contraindications to this approach include active infection or a stricture longer than 2 cm, because dilatation alone will rarely be successful in this setting.

A retrograde approach is indicated whenever access across the strictured area is easily accomplished using transurethral techniques. The procedure generally begins with a retrograde pyelogram performed under fluoroscopic control to precisely delineate the site and length of stricture. A floppy-tipped guide wire is passed in a retrograde fashion across the strictured area and coiled proximally in the pyelocalyceal system. This is most easily accomplished by passing an open-end catheter up to the level of the stricture to use as a guide for the hydrophilic or floppy-tipped wire. Passage of the open-end catheter through the strictured area over the wire will then aid subsequent passage of a balloon catheter. Techniques for bypassing difficult areas of obstruction have been described in detail (Mata et al, 1994).

At this point, the open-end catheter is withdrawn and replaced with a high-pressure, 4-cm-long, 5- to 8-mm balloon. Under fluoroscopic control, the balloon catheter is positioned across the strictured area with proper position

ensured by visualization of radiopaque markers at the tip of the balloon. Balloon inflation is then begun, and a waist will be visualized at the strictured area that will disappear with progressive balloon inflation (Fig. 38–24). After 10 minutes of tamponade, the balloon is deflated and withdrawn. A guide wire is still in place, and this is used to pass an internal stent, which is left indwelling for 2 to 4 weeks. Follow-up radiographic studies including intravenous urography, ultrasonography, or diuretic renography, are generally performed approximately 1 month after stent extraction and at 6- to 12-month intervals thereafter.

Occasionally, access across the involved area cannot be obtained using fluoroscopic control alone. In such cases, direct ureteroscopic visualization can aid initial passage of the guide wire and the procedure can be continued as described. Alternatively, a low-profile balloon can be passed through the ureteroscope and the stricture dilated under direct vision.

Antegrade Balloon Dilation

At times, retrograde access across a strictured area is impossible. In such cases, access can be obtained using an antegrade approach and fluoroscopic control (Mitty et al, 1983; Banner and Pollack, 1984), with or without direct antegrade ureteroscopic visualization (De Jonge et al, 1986). **Percutaneous nephrostomy drainage is established, and, in cases associated with infection or compromised renal function, percutaneous drainage alone is instituted to allow resolution of infection and return to baseline renal function.** Once that is accomplished, the percutaneous tract is used for access for a fluoroscopically or ureteroscopically guided approach. The procedure is then analogous to a retrograde approach. Under fluoroscopic guidance, an antegrade contrast agent study is used to definitively define the site and length of the stricture. A floppy-tipped guide or glide wire is passed antegrade across the level of obstruction, following which a balloon catheter is passed; and the balloon is progressively inflated until the waist disappears. The balloon catheter is withdrawn over a wire and replaced with an internal stent, and a nephrostomy tube is also left indwelling. A follow-up nephrostogram is obtained within 24 to 48 hours to ensure proper positioning of a functional internal stent, and, at that time, the nephrostomy tube can be removed. Alternatively, access can be maintained by the use of an internal/external stent, which can be capped to allow internal drainage.

Results. Initial reports of retrograde and antegrade balloon dilatation of ureteral strictures suggested that results were better when the stricture was anastomotic and of relatively short duration and length (King et al, 1984b; Chang et al, 1987; Netto et al, 1990). **Goldfischer and Gerber (1997) reviewed the literature in regard to results of balloon dilatation of ureteral strictures and found reported success rates ranging from 50% to 76%. In that review, the best results were obtained in patients with iatrogenic, nonanastomotic strictures such as those following ureteroscopic instrumen-**

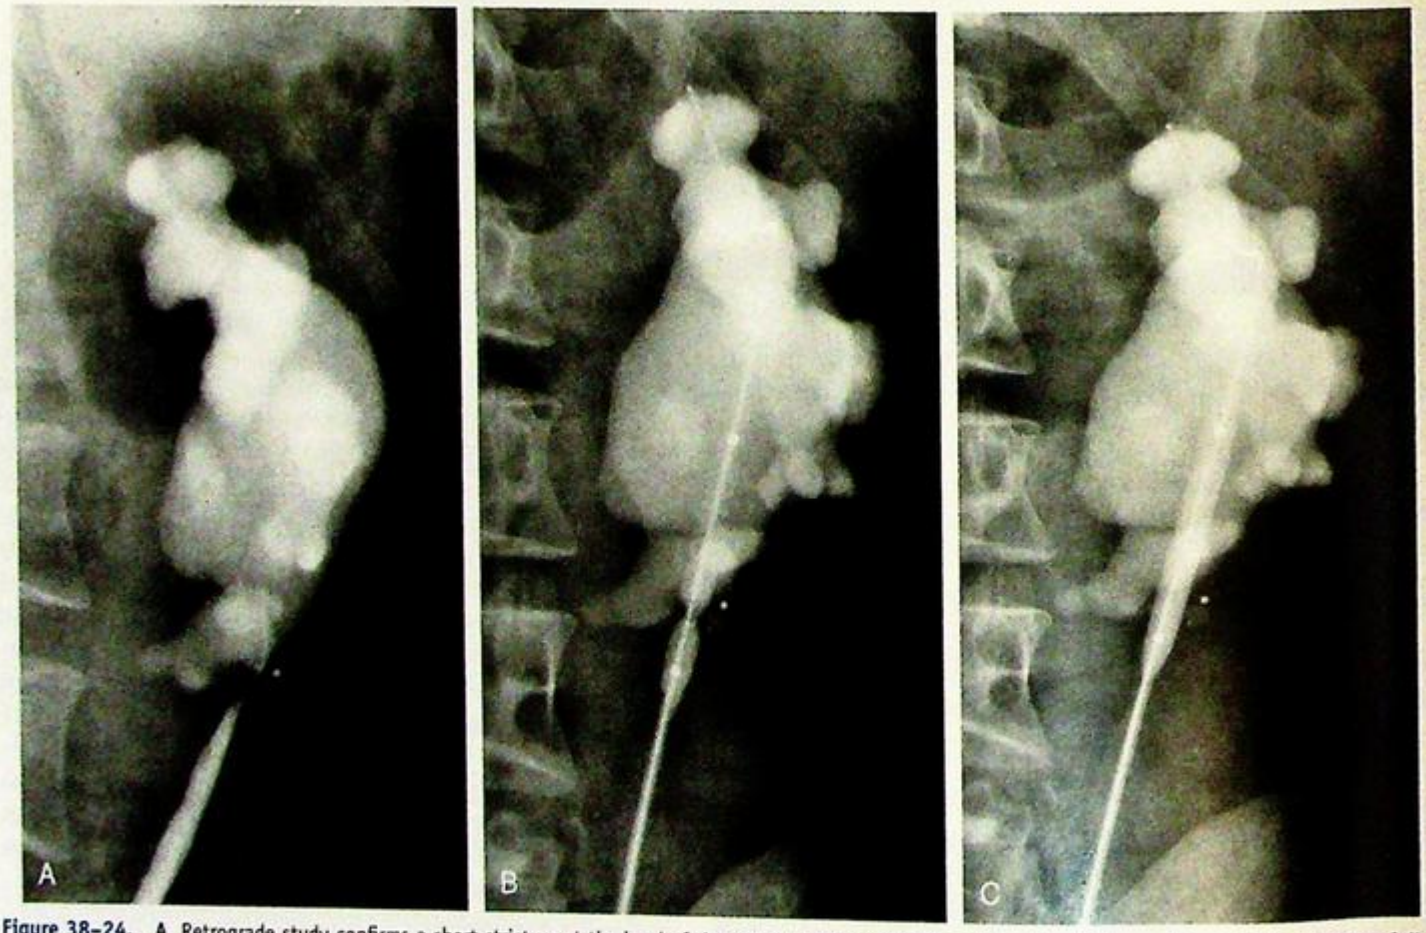

Figure 38–24. A, Retrograde study confirms a short stricture at the level of the UPJ in this patient with a horseshoe kidney who was referred after failed ureteroscopic management of a ureteral calculus impacted at that level. B, The stricture has been traversed with a guide wire, over which a high-pressure balloon has been passed. A waist is evident at the level of the stricture during initial balloon inflation. C, Balloon inflation and stricture dilatation are complete with disappearance of the waist.

tation. In that setting, a success rate of 85% was achieved compared with a rate of 50% for anastomotic strictures. Alternatively, Ravery and associates (1998) found a 40% success rate utilizing retrograde balloon dilation in treating inflammatory ureteral strictures at 16 months follow-up. Richter and coworkers (2000) reviewed their results with balloon dilatation in 114 patients with a minimal 2-year follow-up. As in other series, balloon dilatation was more successful for patients with relatively short strictures. In addition, these authors noted the significance of an intact vascular supply on the success of this procedure. For longer ureteral strictures and those associated with compromised vascular supply, an incisional approach (endoureterotomy) was recommended as a more successful endourologic alternative to balloon dilatation. Of note, in experimental models, balloon dilation created longitudinal incisions similar to endoureterotomy, possibly explaining some of the success seen using balloon dilation in ureteral strictures (Nakada et al, 1996).

Endoureterotomy

Endoluminal ureteral incision is a logical extension of balloon dilatation for "minimally invasive" management of ureteral strictures. As for balloon dilatation, access to and across the strictured area can be obtained in a retrograde or antegrade fashion, although a retrograde approach is preferable whenever possible because it is less invasive. The procedure is performed under direct vision using ureteroscopic control, or it can be guided fluoroscopically using the hot wire cutting balloon catheter. Generally, radiographic follow-up using diuretic renography is recommended for up to 3 years to detect most late failures (Wolf et al, 1997).

Retrograde Ureteroscopic Approach. A retrograde study is performed under fluoroscopic control at the outset of the procedure. Whenever possible, a floppy-tipped guide wire or hydrophilic glide wire is passed across the level of obstruction, as outlined earlier. If a wire cannot be passed across the strictured area using fluoroscopic control alone, a semirigid or flexible ureteroscope is passed to the level of obstruction and the guide wire advanced through the ureteroscope across the involved area under direct vision. The ureteroscope is then withdrawn, but a safety wire is always left in place across the stricture. The ureteroscope is then reintroduced and passed alongside the guide wire to the level of obstruction.

The position for the endoureterotomy incision is chosen as a function of the level of the ureter involved. In general, lower ureteral strictures are incised in an anteromedial direction, taking care to stay away from the iliac vessels. In contrast, upper ureteral strictures are incised laterally or posterolaterally, again away from the great vessels (Meretyk et al, 1992) (Fig. 38–25).

The ureterotomy incision itself can be performed using a cold knife (Schneider et al, 1991; Yamada et al, 1995), a cutting electrode (Conlin et al, 1996), or a holmium laser (Fig. 38–26). In all cases, the incision is made from the ureteral lumen out to periureteral fat in a full-thickness fashion. Proximally and distally, the endoureterotomy should encompass 2 to 3 mm of normal ureteral tissue. In certain instances, the stricture must be balloon dilated to gain access across the stricture. Similarly, the strictures may be balloon dilated after endoincision, to enlarge the incision. Once the endoureterotomy incision is complete, the remaining guide wire is used to pass an internal stent. In general, the larger diameter stents should be considered, because larger stents (12 Fr) have been associated with improved results in some series (Hwang et al, 1996; Wolf et al, 1997). Similarly, Wolf and associates (1997) found benefit in the injection of triamcinolone ureteroscopically after endoureterotomy. Corticosteroids and other biologic response modifiers may have a role in the future in managing select strictures.

Cautery Wire Balloon Incision. Cautery wire balloon incision has been used for ureteral strictures in the same manner as it has for UPJ obstruction. The procedure requires safety

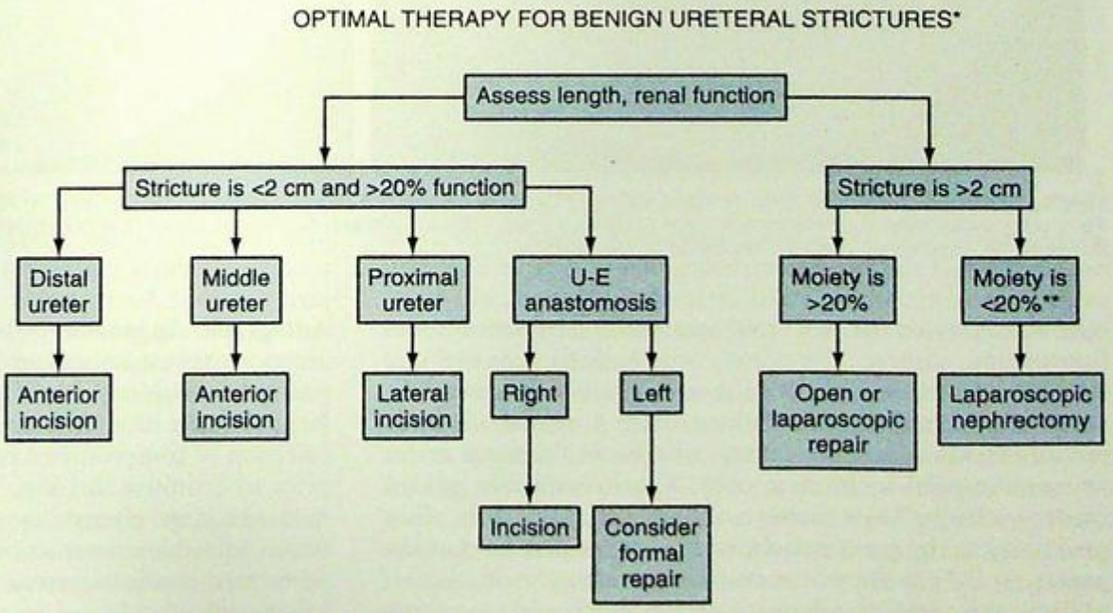

Figure 38–25. Algorithm for management of benign ureteral and ureteroenteric stricture disease.

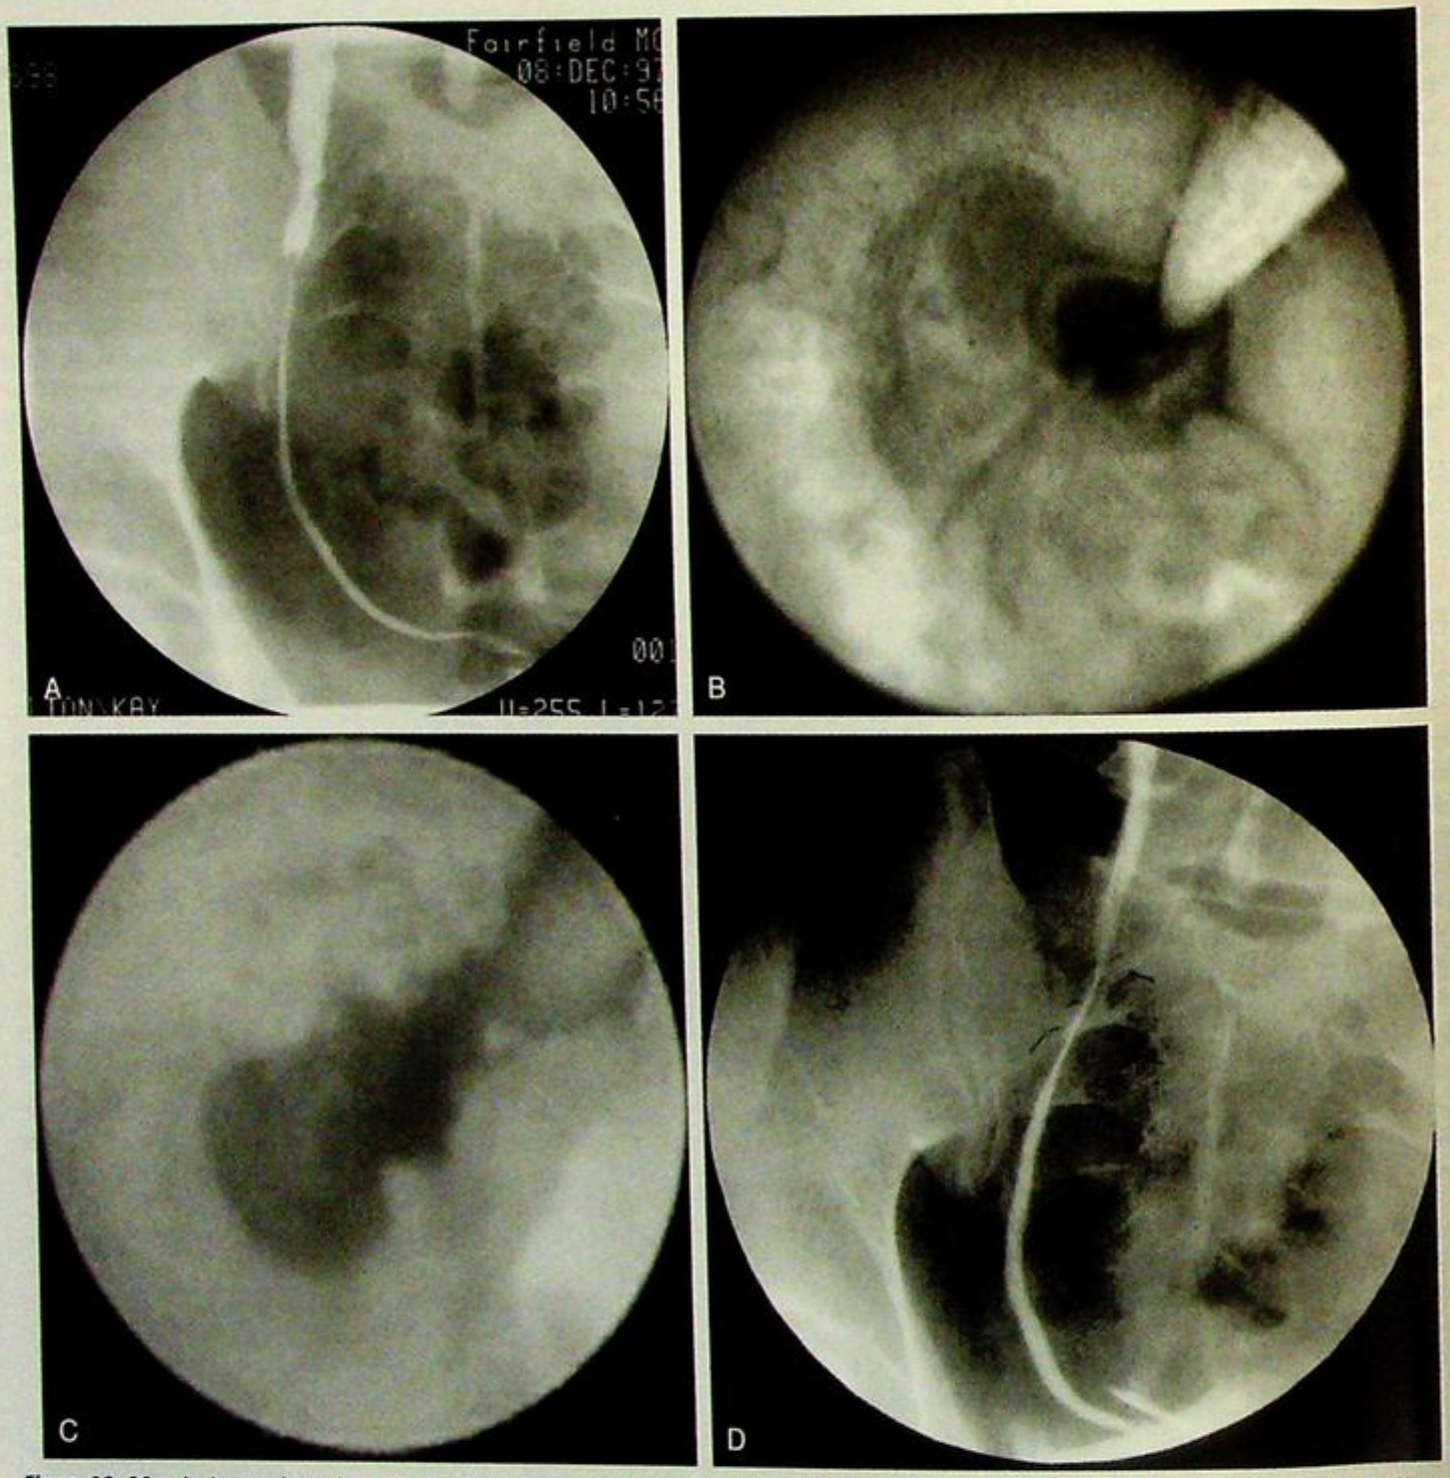

Figure 38–26. **A,** Antegrade study confirms hydronephrosis at the level of the iliac ureter in this patient referred for management after a complicated open ureterolithotomy. **B,** Ureteroscopic view confirms a tight ureteral stricture. **C,** Ureteral lumen is widely patent after holmium laser endoureterotomy. **D,** Follow-up ureterogram confirms resolution of the stricture.

wire access across the strictured area and is performed under fluoroscopic control. The cautery wire balloon is passed in a retrograde or antegrade fashion and positioned across the stricture using radiopaque markers. In the proximal ureter the incision should be posterolateral, whereas in the distal ureter an anteromedial incision is used. **Fluoroscopically guided cautery wire balloon incision should not be used in close proximity to the great vessels, such as at the iliac level of the ureter.** As for any form of endourologic management, success utilizing this technique depends on the length and vascularity of the involved segment (Chandhoke et al, 1993b; Cohen et al, 1996; Wolf et al, 1997).

Antegrade Approach. When direct visual ureteroscopic access to the strictured area cannot be accomplished in a retrograde fashion, an antegrade approach may be used. Nephrostomy tube drainage is instituted and any associated infection or compromised renal function is allowed to resolve prior to definitive incision. The percutaneous tract is dilated to a size large enough to allow a working sheath through which a flexible ureteroscope is passed. The procedure is then performed in a fashion analogous to a retrograde approach. A safety wire should be in place at all times alongside the ureteroscope, across the obstructed area and coiled distally in the bladder.

Combined Retrograde/Antegrade Approach. Rarely, a ureteral stricture is associated with an area of complete ureteral obliteration across which a wire cannot be passed to allow subsequent balloon dilatation or ureteroscopic endoureterotomy. In such cases, a combined retrograde/antegrade approach has been described (Cardella et al, 1985; Conlin et al, 1996; Beaghler et al, 1997; Knowles et al, 2001). The obstructed area is defined radiographically with a simultaneous antegrade and retrograde pyelogram. Ureteroscopes are passed simultaneously in both a retrograde and an antegrade manner, and the two opposing ureteral ends are localized under fluoroscopic guidance. A working guide wire is then passed from one end of the ureter, through and through to the other lumen, utilizing a combination of fluoroscopic and direct visual control. For completely obliterated ureteral segments, this is most easily accomplished using the stiff end of a guide wire passed through a semirigid ureteroscope via the retrograde approach, although when a semirigid ureteroscope cannot be placed, a flexible ureteroscope or even an open-end ureteral catheter can be used to stabilize the wire from above or below. A "cut to the light" technique can be helpful in this setting. The ureteral segments are aligned as closely as possible under endoscopic and fluoroscopic guidance and with the light source to one of the ureteroscopes turned off. The light from the opposite ureteroscope is then used to aid incisional restoration of urinary continuity. The strictured area is then recannulated using the stiff end of a guide wire, a small electrocautery electrode, or a holmium laser. Once through-and-through control is obtained with a guide wire, a stent is passed and left in place for 8 to 10 weeks. As for other endourologic approaches to ureteral strictures, success rates are inversely related to the length of the strictured area. **Although success rates may be uncertain, internalization of urinary flow, even when dependent on long-term stent placement, can be a quality-of-life advantage for certain high-risk patients.** Knowles and associates (2001) reported a 90% patency rate in 10 patients treating obliterated distal ureteral segments using cautery wire balloon incision at 36 months follow-up, 3 of whom required the combined approach.

KEY POINTS: ENDOUROLOGIC MANAGEMENT OF URETERAL STRICTURE

- Proper evaluation and treatment of a ureteral stricture is essential to preserve renal function and rule out the presence of malignancy. It is critical to assess the renal unit for function before starting treatment, because endourologic therapies generally require 25% function of the ipsilateral moiety to have reasonable success rates.
- The use of chronic stent placement for ureteral obstruction must be guarded, particularly when treating ureteral obstruction from extrinsic compression, because in many cases adequate drainage is short lived.
- As for any patient with a ureteral stricture, the indications to intervene include functionally significant obstruction. Contraindications to this approach include active infection or a stricture longer than 2 cm.
- The position for the endoureterotomy incision is chosen as a function of the level of the ureter involved. In general, lower ureteral strictures are incised in an anteromedial direction, taking care to stay away from the iliac vessels. In contrast, upper ureteral strictures are incised laterally or posterolaterally, again away from the great vessels.

Surgical Repair

Before any surgical repair, it is essential to conduct careful evaluation of the nature, location, and length of the ureteral stricture. Preoperative assessment typically includes an intravenous pyelogram (or antegrade nephrostogram) and a retrograde pyelogram if indicated. Other studies such as a nuclear medicine renogram to assess renal function and ureteroscopy, ureteral barbotage, or brushing to rule out carcinoma should be individualized. Based on such information, the appropriate surgical procedure can then be planned for the patient (Table 38–2).

Table 38–2. Bridging Various Ureteral Defect Lengths with Different Reconstructive Surgical Techniques

Technique	*Ureteral Defect Length (cm)*
Ureteroureterostomy	2-3
Ureteroneocystostomy	4-5
Psoas hitch	6-10
Boari flap	12-15
Renal descensus	5-8

Open Ureteroureterostomy

A short defect involving the upper ureter or midureter, either in the form of stricture or as a consequence of recent injury, is most appropriate for ureteroureterostomy. On the other hand, a lower ureteral stricture is usually best managed by ureteroneocystostomy with or without a psoas hitch or Boari flap. In the transplant setting, a donor ureteral stricture may be managed by a ureteroureterostomy to a healthy, native ureter. Because tension on the anastomosis almost always leads to stricture formation, only short defects should be managed by end-to-end ureteroureterostomy. Determination of whether enough ureteral mobility can be achieved to allow tension-free ureteroureterostomy usually cannot be made until the time of surgery.

The choice of surgical incision depends on the level of the ureteral stricture. A flank incision is appropriate for the upper ureter. A Gibson or a lower midline incision is suitable for the middle and lower ureter. If the patient has sustained an iatrogenic ureteral injury from a previous surgery performed through a Pfannenstiel incision, the same incision may be used for the ureteral reconstruction. In such a situation, proximal ureteral dissection may be difficult through the Pfannenstiel incision, requiring cephalad extension of the lateral portion of the incision in a "hockey stick" fashion.

Extraperitoneal dissection is usually performed except in cases of transperitoneal surgical ureteral injury.

After surgical incision, the retroperitoneal space is developed as the peritoneum is mobilized and retracted medially. Frequently, the ureter can be easily identified as it crosses the iliac vessels. A Penrose drain or vessel loop may be placed around the ureter to facilitate its atraumatic handling. Direct handling of the ureter with forceps should be minimized. Care should be taken to preserve its adventitia, which loosely attaches the blood supply to the ureter.

During ureteral dissection and mobilization, enough mobility must be achieved to avoid tension after the excision of the diseased ureter. With a gunshot injury, devitalized tissue and an adjacent segment of normal-appearing ureter should be excised to eliminate late ischemia and stricture formation from the blast effect. Once both ends of the ureter have been adequately trimmed to healthy areas, mobilized, and correctly oriented, they are spatulated for 5 to 6 mm. Spatulation is performed for both ureteral segments at 180 degrees apart. If a grossly dilated ureter is involved, it may be transected obliquely and not spatulated in order to match the circumference of the nondilated segment. A fine, absorbable suture is placed in the corner of one ureteral segment and the apex of the other, and the two ends of the suture are tied outside the ureteral lumen. The opposite corner and apex are similarly sutured and approximated. The anastomosis may then be completed by running these two sutures continuously and tying them to each other or in an interrupted fashion (Fig. 38–27). A double-J ureteral stent should be placed before completion of the anastomotic closure. Observation of reflux of methylene blue irrigant from the bladder to the ureterotomy can be used to verify the appropriate placement of the distal stent in the bladder. Retroperitoneal fat or omentum may be used to cover the anastomosis. A surgical drain is placed, and a Foley catheter is generally left indwelling for 1 to 2 days. The surgical drain may be removed if there is minimal output for 24 to 48 hours. If the surgical procedure is not performed entirely in a retroperitoneal manner, it is important to determine the nature of the fluid from the surgical drain, which can be achieved by checking the creatinine level of the fluid. If there is no urinary extravasation, the drain can then be removed. The double-J ureteral stent is removed endoscopically, usually 4 to 6 weeks postoperatively.

The success rate for a tension-free, watertight ureteroureterostomy is high, well over 90% (Carlton et al, 1969; Guiter et al, 1985). If a urinary fistula is suspected, a plain

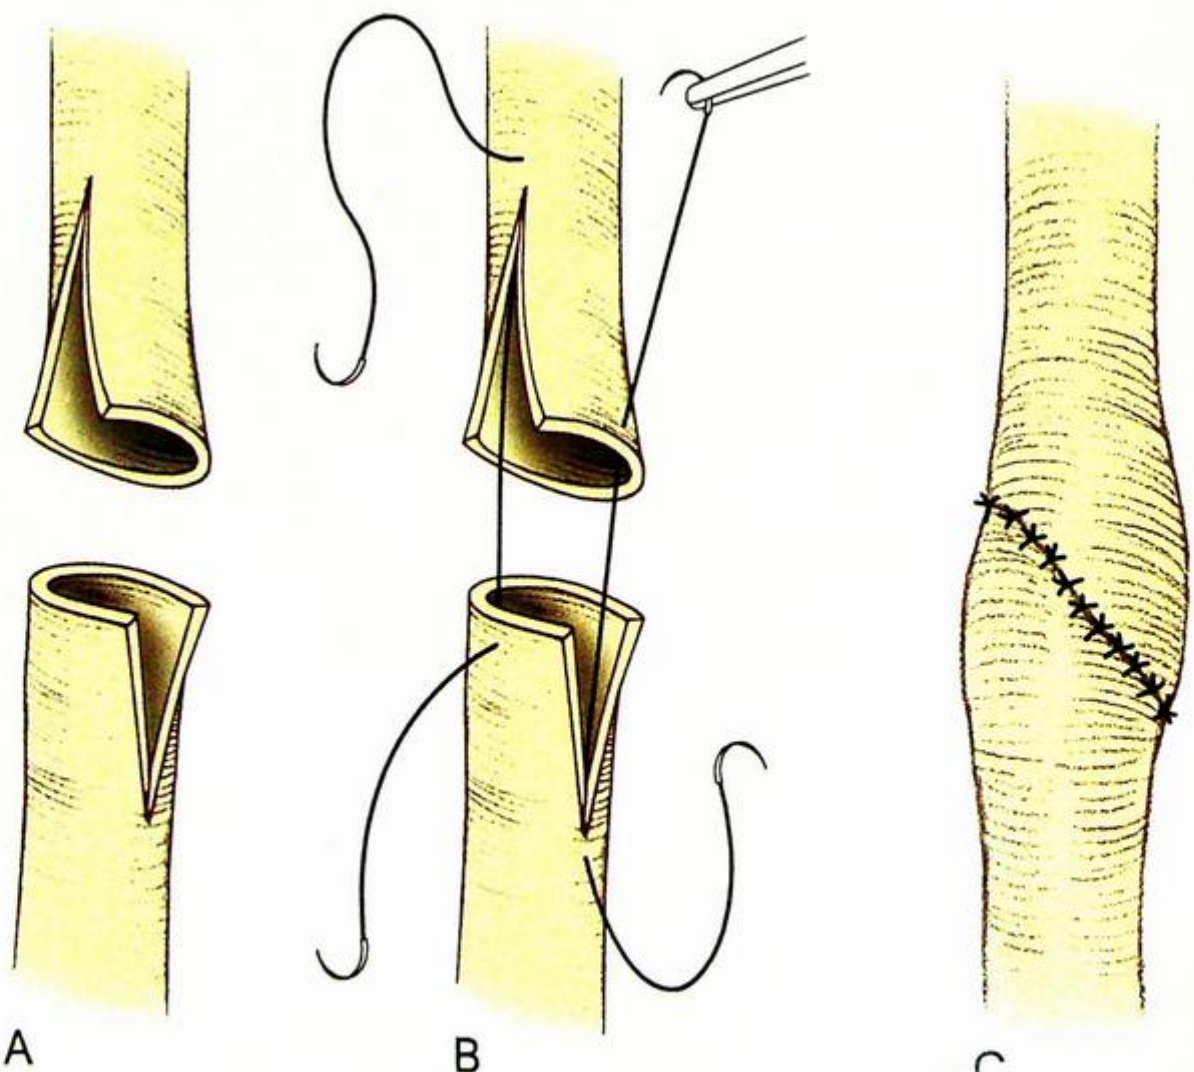

Figure 38–27. A, Spatulated ureteral ends. B, Placement of sutures. C, End-to-end ureterostomy.

abdominal radiograph should first be obtained to verify the position of the double-J stent. The proximity of a drain to the anastomosis should also be checked because it may exacerbate a leak. Suction should be stopped if a suction drain device is used, because straight drainage may facilitate closure of the ureteral leakage site. Reflux from voiding or bladder spasms may also contribute to prolonged urinary extravasation, and such problems can be managed by Foley catheter drainage and anticholinergics. Prolonged urinary leakage from the anastomosis may require the placement of a nephrostomy tube for proximal urinary diversion.

Laparoscopic Ureteroureterostomy

A laparoscopic approach may be offered to patients with ureteral stricture disease. Nezhat and colleagues (1992) first reported laparoscopic management of an obstructed ureter due to endometriosis. In this case, ureteroureterostomy was performed laparoscopically over a ureteral stent after resection of the obstructed ureteral site. In their more recent retrospective review involving eight laparoscopic ureteroureterostomy patients, seven were found to have patent anastomosis with relatively short follow-up, ranging from 2 to 6 months (Nezhat et al, 1998). The overall clinical experience in laparoscopic ureteroureterostomy is limited worldwide. However, in the hands of experienced laparoscopic surgeons, it appears to be a viable minimally invasive approach applicable to almost any patient with a relatively short area of obstruction.

Open Ureteroneocystostomy

Ureteroneocystostomy to manage vesicoureteral reflux is covered elsewhere in this text. Ureteroneocystostomy without a psoas hitch or Boari flap in an adult is appropriate for injury or obstruction affecting the distal 3 to 4 cm of the ureter. A lower midline, Pfannenstiel, or Gibson incision may be used, and the extraperitoneal approach is generally more preferable. After surgical incision, the ureter is usually identified as it crosses the iliac vessels, dissected distally, and transected at the level of the obstruction. After adequate proximal ureteral mobilization, direct ureteroneocystostomy is performed only if a tension-free anastomosis is possible. Otherwise, a psoas hitch or Boari flap should be used as an adjunct. A direct, nontunneled anastomosis may be performed if postoperative reflux is acceptable. Otherwise, a submucosal tunnel is created for antireflux anastomosis. A double-J stent and surgical drain are used as described for ureteroureterostomy (see earlier).

The issue of reluxing versus antirefluxing anastomosis in ureteroneocystostomy in adults has been examined previously. **In a retrospective review of adult patients with ureteroneocystostomy, no significant difference in the preservation of renal function or risk of stenosis was identified in the refluxing versus antirefluxing procedures** (Stefanovic et al, 1991). However, it is unclear if a nonrefluxing anastomosis decreases the risk of pyelonephritis in an adult patient.

Laparoscopic Ureteroneocystostomy

Successful laparoscopic application to ureteroneocystostomy has been reported by several investigators (Ehrlich et al, 1993; Reddy and Evans, 1994; Yohannes et al, 2001). In the management of distal ureteral stricture, laparoscopic ureteroneocystostomy is usually performed transperitoneally incorporating intracorporeal suturing techniques. Ureteral stenting is typically used postoperatively as in open surgery. The overall clinical experience for laparoscopic management of distal ureteral strictures is limited in the literature. However, the clinical outcomes have been reported to be favorable and comparable to those of open surgical data while providing minimal postoperative morbidity as in many other laparoscopic urologic procedures.

Open Psoas Hitch

The psoas hitch is an effective method to bridge a defect of the lower third of the ureter. However, a ureteral defect extending proximal to the pelvic brim usually requires more than a psoas hitch alone. Indications include distal ureteral stricture, injury, and failed ureteroneocystostomy (Prout and Koontz, 1970; Ehrlich et al, 1978; Rodo Salas et al, 1991). A psoas hitch may also be used in conjunction with other maneuvers such as a transureteroureterostomy in more complicated urinary tract reconstruction. **Generally, a small, contracted bladder with limited mobility is considered as a contraindication.** In addition to the preoperative radiographic and endoscopic evaluation described previously, urodynamic studies may provide information regarding detrusor capacity and compliance before the surgery. Bladder outlet obstruction or neurogenic dysfunction, if present, needs to be treated preoperatively.

To gain access to the distal ureter, a Pfannenstiel or lower midline incision is usually used. Extraperitoneal approach is preferred, if possible. In such a scenario, the space of Retzius is developed and the bladder mobilized by freeing its peritoneal attachments and dividing the vas deferens or round ligament. With traction, the ipsilateral dome of the bladder should be able to reach the level proximal to the iliac vessels. **Additional mobility can be achieved by dividing the contralateral superior vesical artery.** The ipsilateral ureter is identified as it crosses the iliac vessels, mobilized, and divided just above the diseased segment. An anterior cystotomy, generally created in a vertical or oblique fashion, is frequently made to facilitate manual displacement of the bladder toward the ipsilateral ureter. The ureter is delivered into the lumen of the bladder at the ipsilateral superolateral aspect of the dome, followed by the tension-free anastomosis with or without a submucosal tunnel. **The ipsilateral bladder dome is secured to the psoas minor tendon or the psoas major muscle using several absorbable sutures. Care should be taken to avoid injury to the genitofemoral nerve and the femoral nerve in the vicinity when placing these sutures.** Alternatively, psoas fixation may be performed before ureteroneocystostomy. A double-J stent is used usually, followed by closure of cystotomy with absorbable sutures (Fig. 38–28).

Relative to simple ureteroneocystostomy, psoas hitch can provide an additional 5 cm of length. Relative to the Boari flap, the advantages of psoas hitch include increased technical simplicity and decreased risk for vascular compromise and voiding difficulties. The success rate of ureteroneocystostomy with a psoas hitch is over 85% in both adults and children based on recent reports (Mathews and Marshall, 1997; Ahn and Loughlin, 2001). Complications occur uncommonly but have included urinary fistula, ureteral obstruction, bowel injury, iliac vein injury, and urosepsis (Fig. 38–29).

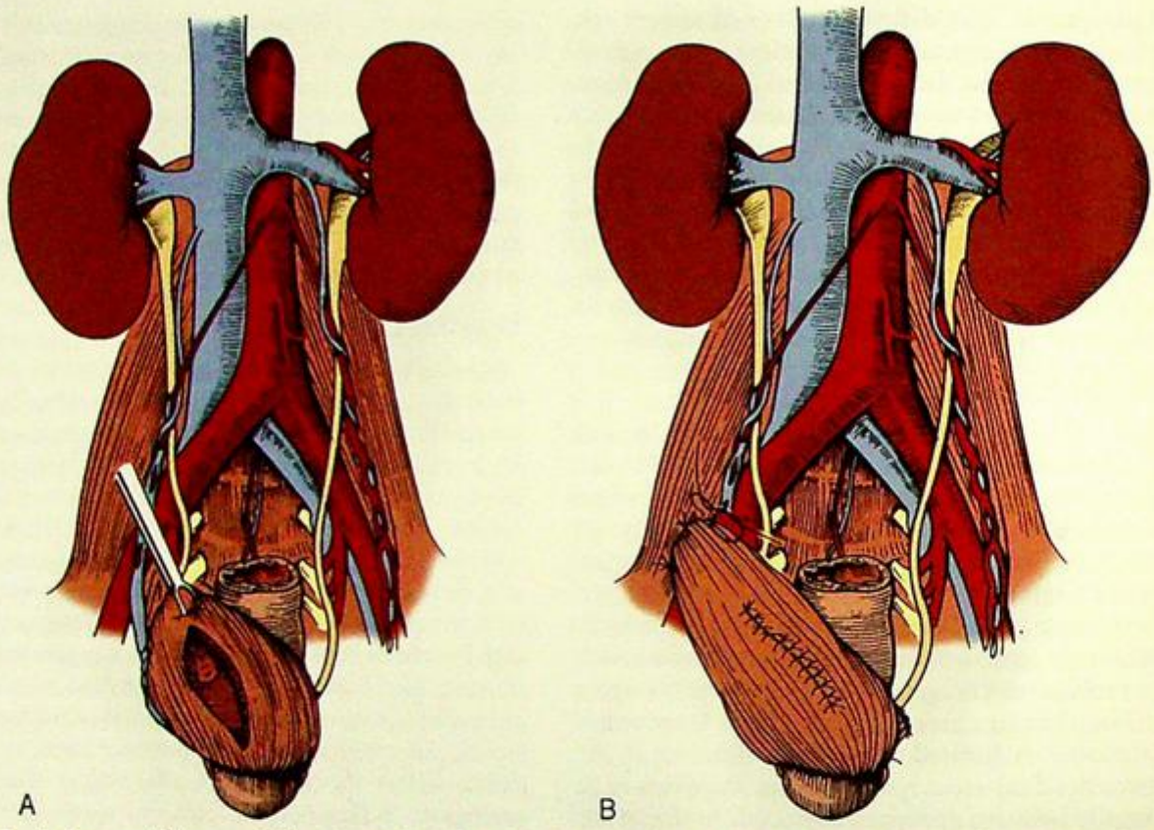

Figure 38–28. **A,** In psoas hitch, an anterior cystotomy is performed after bladder mobilization. **B,** The bladder dome is fixed to the ipsilateral psoas tendon, and the ureteral reimplantation is completed in a tension-free manner.

Laparoscopic Psoas Hitch

Ureteroneocystostomy with psoas hitch has been performed laparoscopically with success (Nezhat et al, 2004). Preoperative ureteral stenting is generally performed, and the procedure is typically completed via the transperitoneal approach. Overall, the clinical experience with such a procedure is quite limited in the literature. However, based on the short-term and intermediate-term follow-up data to date, the clinical outcomes appear to be satisfactory and equivalent in experienced hands.

Open Boari Flap

When the diseased ureteral segment is too long or when ureteral mobility is too limited to perform a tension-free ureteroureterostomy, a Boari flap may be a useful alternative. Boari first described the use of this technique in the canine model in 1894. **A Boari flap can be constructed to bridge a 10- to 15-cm ureteral defect, and a spiraled bladder flap can reach the renal pelvis in some circumstances, especially on the right side.** As in a psoas hitch, evaluation of bladder function should be performed preoperatively in addition to the ureteral evaluation. Bladder outlet obstruction and neurogenic dysfunction, if present, should be addressed preoperatively. **A small bladder capacity is likely to be associated with difficult or inadequate Boari flap creation, warranting consideration of alternative methods in the preoperative surgical planning.**

In the Boari flap procedure, a Pfannenstiel incision may be used at the time of surgery, although a midline incision is preferred and allows easier access to the upper ureter. The bladder is mobilized from its peritoneal attachments, and the umbilical ligaments are divided. The contralateral bladder pedicle is divided and ligated, allowing greater mobility toward the ipsilateral ureter, and the ipsilateral bladder pedicle including the superior vesical artery is preserved. The affected ureter is carefully mobilized, with care being taken to preserve its blood supply. The diseased segment is then excised. After the identification of the ipsilateral superior vesical artery or one of its branches, a posterolateral bladder flap is outlined based on this vascular supply. The flap continues obliquely across the anterior bladder wall, with the base of the flap being at least 4 cm in width and the tip of the flap being at least 3 cm in width. The flap length should equal the estimated ureteral defect plus an addition of 3 to 4 cm if a nonrefluxing anastomosis is planned. Furthermore, the ratio of flap length to base width should not be greater than 3:1 to help minimize flap ischemia.

After bladder flap creation, the distal end of the flap is pexed to the psoas minor tendon or psoas major muscle with several absorbable sutures. The ureter is delivered through a small opening created in the posterior flap, and a tension-free mucosa-to-mucosa refluxing anastomosis is performed after spatulation of the distal ureteral end. Alternatively, a nonrefluxing tunneled anastomosis can be used. The flap is then tubularized anteriorly and closed using absorbable suture. Furthermore, the ureteral adventitia may be secured to the distal aspect of the flap and then the base of the flap may be secured to the psoas (Fig. 38–30).

The number of reported patients treated with a Boari flap is small, yet the results are good if a well-vascularized flap is used (Ockerblad, 1957; Scott and Greenberg, 1972;

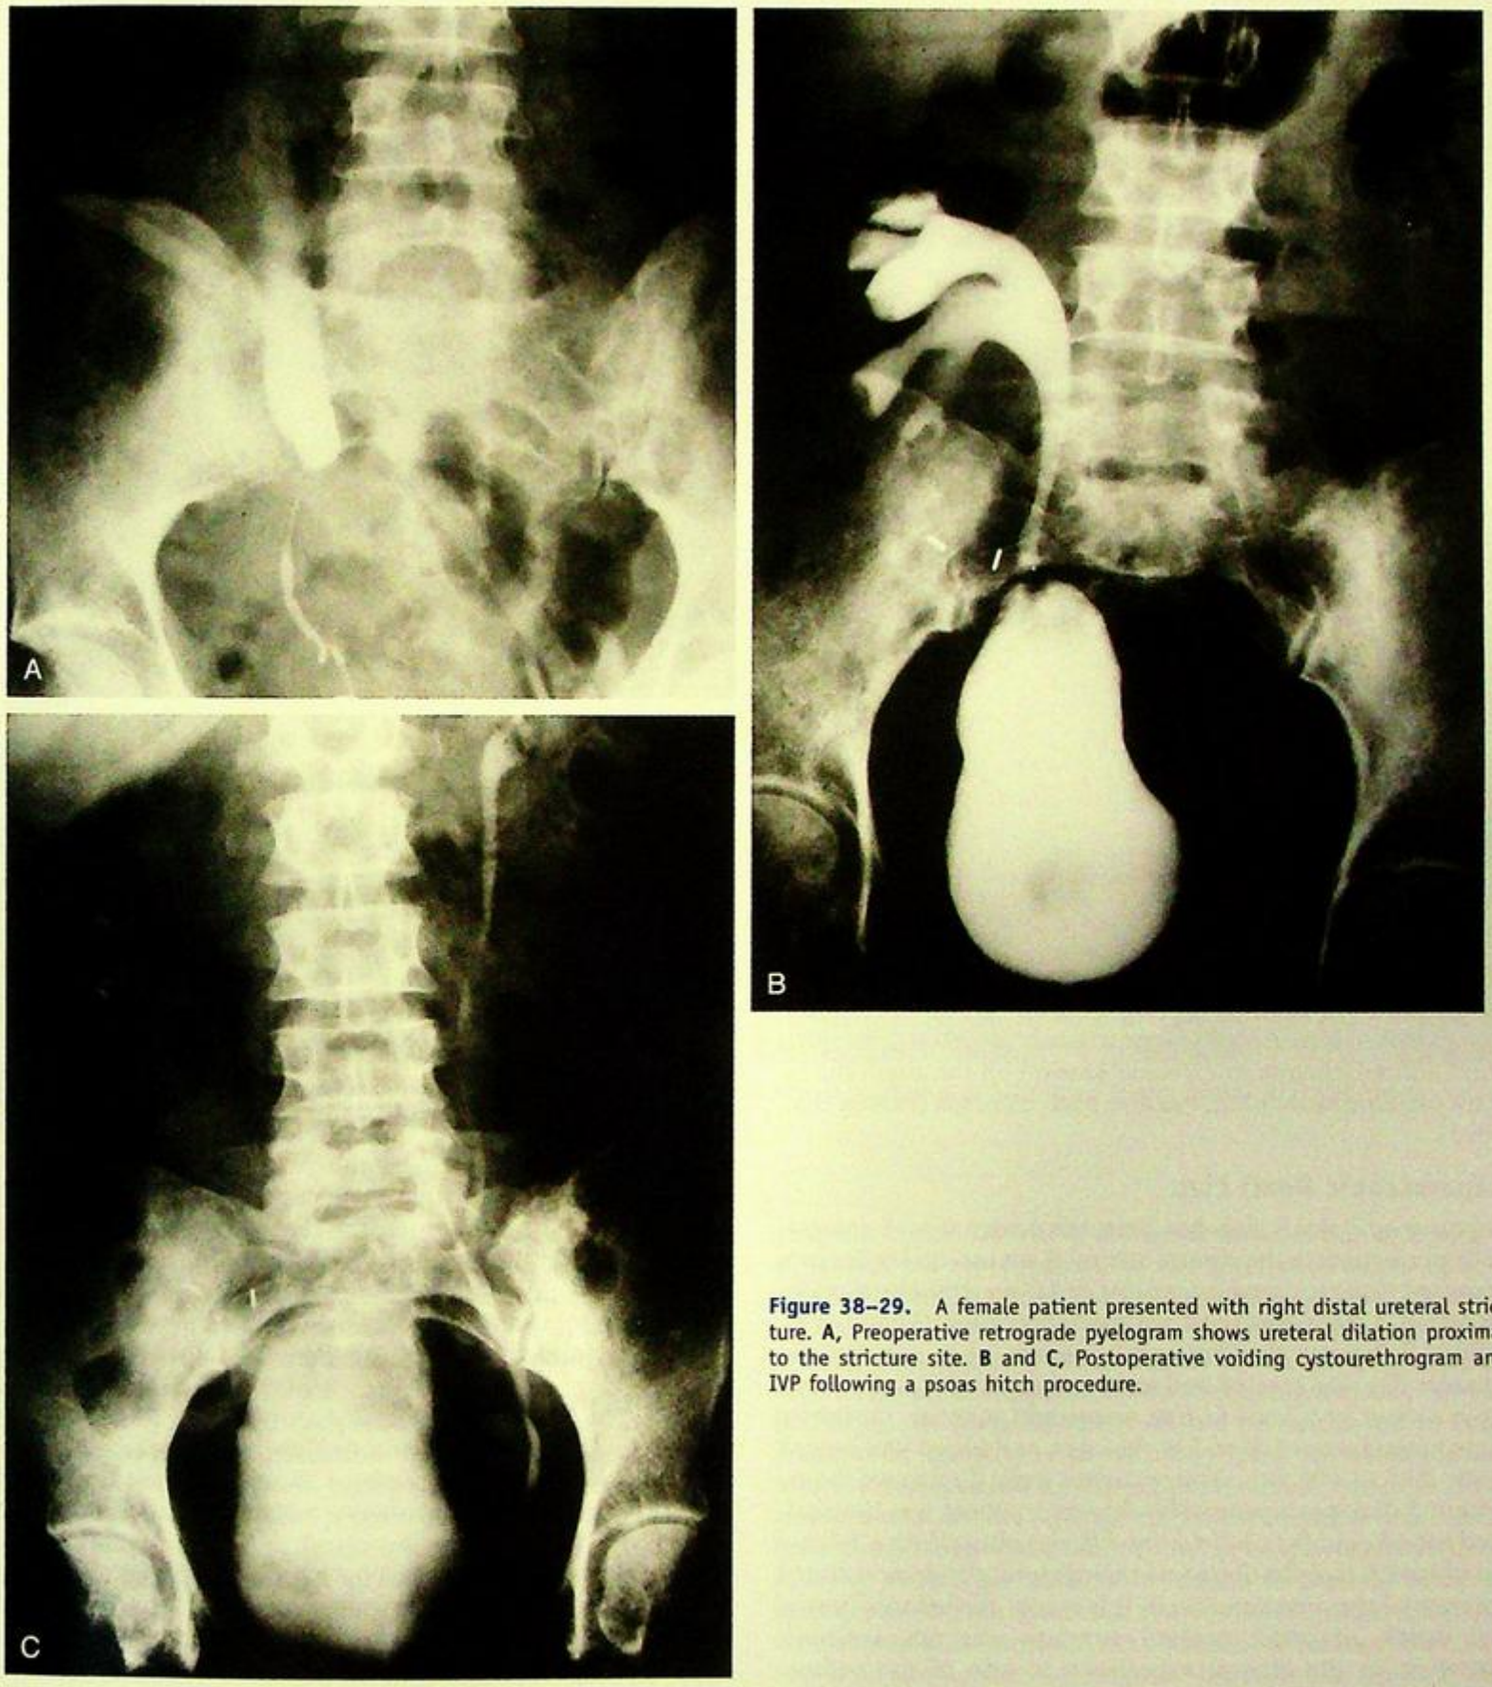

Figure 38–29. A female patient presented with right distal ureteral stricture. **A,** Preoperative retrograde pyelogram shows ureteral dilation proximal to the stricture site. **B** and **C,** Postoperative voiding cystourethrogram and IVP following a psoas hitch procedure.

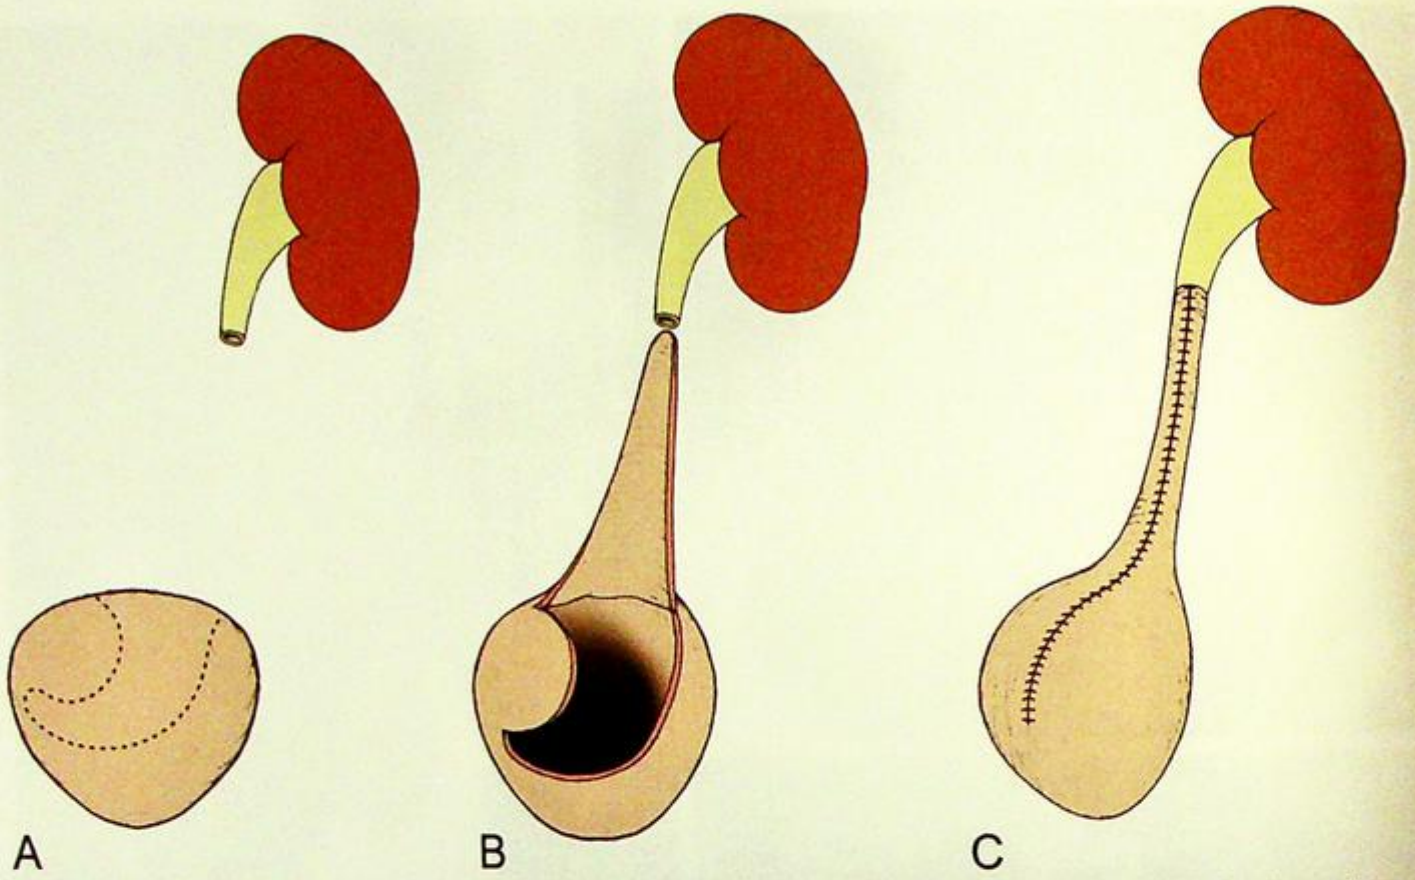

Figure 38–30. **A,** In Boari flap, the intended flap is first marked on the anterior and lateral aspects of the mobilized bladder. **B,** The flap is created, ensuring good vascular supply. **C,** Ureteroneocystostomy is completed, with the longitudinal bladder tube closure.

Thompson and Ross, 1974; Middleton, 1980; Benson et al, 1990; Motiwala et al, 1990) (Fig. 38–31). The most common complication is clearly recurrent stricture formation, resulting from either ischemia or excessive tension on the anastomosis. Rare pseudodiverticulum has also been reported (Berzeg et al, 2003).

Laparoscopic Boari Flap

Laparoscopic Boari flap has been uncommonly yet successfully performed in the clinical setting. Kavoussi and colleagues reported three successful cases for distal ureteral obstruction, in which a transperitoneal approach was used (Fugita et al, 2001). Following the same principles in open surgery, the bladder flap was created and anastomosed to the ureteral end over a stent in a tension-free, watertight manner. Operative time ranged from 120 to 330 minutes, and blood loss ranged from 400 to 600 mL. Two patients were discharged home within 3 days postoperatively whereas 1 patient was hospitalized for 13 days for *Clostridium difficile* colitis. With a follow-up of over 6 months there was radiographically demonstrated patency of the anastomosis. In this report the information of the length of distal ureteral stricture was not available. However, in the clinical experience of one of the authors (T.H.), ureteral loss of 8 to 12 cm can be comfortably bridged with Boari flap in the laparoscopic setting, as in open surgery.

Renal Descensus

Renal mobilization, which was originally described by Popescu in 1964, can provide additional length to bridge a defect in the upper ureter or decrease tension on a ureteral repair (Harada et al, 1964; Passerini-Glazel et al, 1994). A transperitoneal, subcostal, midline, or paramedian incision may be used to gain access to the kidney and the appropriate level of the ureter. After entry to Gerota's fascia, the kidney is completely mobilized and rotated inferiorly and medially on its vascular pedicle. The lower pole of the kidney is then secured to the retroperitoneal muscle using several absorbable sutures. Up to 8 cm of additional length may be gained using this technique. In such cases, the renal vessels, especially the renal vein, limit the extent to which the kidney can be mobilized. As a solution, the technique for division of the renal vein with reanastomosis more inferiorly to the inferior vena cava may be performed but rarely applied clinically.

Intubated Ureterotomy

The Davis intubated ureterotomy has been described previously in this chapter. Because of the development of more effective surgical treatment alternatives, this procedure is described primarily for historical interest. An intubated ureterotomy is generally used for a ureteral stricture too long for conventional ureteroureterostomy or ureteroneocystostomy and has been performed to treat stricture up to 10 to 12 cm in length. An innovative modification to this procedure has incorporated a buccal mucosal patch graft in a small number of patients with good results (Naude, 1999).

Transureteroureterostomy

The initial clinical application of transureteroureterostomy was described by Higgins in 1934. In the management of ureteral stricture, this procedure may be used when ureteral

length is insufficient for anastomosis to the bladder (Brannan, 1975). **The only absolute contraindication is insufficient length of the donor ureter to reach the contralateral recipient ureter in a tension-free manner. However, any disease process that may affect both ureters represents a relative contraindication. Absolute contraindications include the presence of a diseased recipient ureter or a donor ureter of inadequate length. Relative contraindications include history of nephrolithiasis, retroperitoneal fibrosis, urothelial malignancy, chronic pyelonephritis, and abdominopelvic radiation. Reflux to the recipient ureter, if present, needs to be identified and corrected simultaneously.** Therefore, a voiding cystogram should be performed preoperatively, in addition to the other imaging and endoscopic studies previously described for thorough evaluation of both ureters.

In performing a transureteroureterostomy, a midline, transperitoneal approach is used to gain access to both ureters. After medial colonic mobilization, the affected ureter is mobilized, preserving the adventitia with the ureteral blood supply, and divided just proximal to the level of obstruction. The contralateral colon is medially mobilized. Only the portion of recipient ureter needed for the anastomosis is exposed, which is generally 5 cm proximal to the level of division of the affected ureter. A tunnel under the sigmoid colon mesentery is created proximal to the inferior mesenteric artery to avoid ureteral tethering by this vessel, after which the donor ureter is then brought through the tunnel to the recipient side. Mobilization of the recipient ureter should be minimized to help preserve the integrity of its vascular supply. An anteromedial ureterotomy is made in the recipient ureter, which is then anastomosed to the spatulated donor ureteral end in a tension-free, watertight manner using either interrupted or running absorbable sutures. A double-J ureteral stent is usually passed from the donor renal pelvis, through the anastomosis and into the bladder. A second ureteral stent may also be placed throughout the length of the recipient ureter if the ureter is found to be adequately large in diameter.

The clinical success of transureteroureterostomy has been demonstrated by multiple investigators. Hendren and Hensle (1980) reported 75 cases of pediatric transureteroureterostomy without compromising a single recipient kidney. Hodges and associates (1980) reported a similar success in a large group of children and adults. However, two patients required

revision due to ureteral kinking by the inferior mesenteric artery. The successful application of transureteroureterostomy was further confirmed more recently by Pesce and colleagues (2001). In two other recent studies, nephrectomy for ureteral stenosis was found to be rarely necessary (Mure et al, 2000; Sugarbaker et al, 2003). Laparoscopic transureteroureterostomy has not been demonstrated in the human setting thus far.

Open Ileal Ureteral Substitution

Surgical management of long length of ureteral defect or loss, especially the proximal ureter, is particularly challenging (Benson et al, 1990). Reconstruction of the ureter with tissue lined with urothelium is most preferable because urothelium is not absorptive and is resistant to the inflammatory and potentially carcinogenic effects of urine (Harzmann et al, 1986). Incorporation of other tissue in ureteral repair is, therefore, reserved for situations in which a defect cannot be bridged by other methods or the bladder is unsuitable for reconstruction. In such a scenario, ileal interposition has been demonstrated to be a satisfactory option for very complicated ureteral reconstruction. On the other hand, the appendix and fallopian tube have been found to be unreliable ureteral substitutes.

Shoemaker reported the first ileal ureter in a woman with tuberculous involvement of the urinary tract in 1909. Later, the metabolic and physiologic effects of the ileal ureter have been investigated in the canine model (Hinman and Oppenheimer, 1958; Martinez et al, 1965). When an isoperistaltic segment of ileum is directly anastomosed to the bladder, reflux and renal pelvic pressure increase are generally seen only during voiding. The retrograde transmission of intravesical pressure is dependent on the length of ileum segment used in interposition and the voiding pressure. In patients with ileal segments longer than 15 cm, Waldner and colleagues (1999) found no reflux into the renal pelvis in a report involving 19 cases of ileal ureter with refluxing ileovesical anastomosis. Comparing dogs with tapered versus nontapered ileal segments, Waters and coworkers (1981) found no difference in renal perfusion pressure or metabolic derangements.

A large clinical experience in ileal ureter involving 89 patients was reported by Boxer and associates (1979). Only 12% of patients with normal preoperative renal function developed significant metabolic problems postoperatively, and preoperative renal function was identified to be an important prognostic factor. In a separate study, nearly half of those with a serum creatinine value of greater than 2 mg/dL developed hyperchloremic metabolic acidosis, requiring conversion to a conduit (Koch and McDougal, 1985). In the same study, patients with bladder dysfunction also experienced more complications. There are no sufficient clinical data to establish the superiority of a tapered segment, a nonrefluxing anastomosis, or a shorter, segmental replacement over a standard ileal substitution (Waters et al, 1981). **Given the above, the general contraindications to an ileal ureteral substitution are baseline renal insufficiency with a serum creatinine value of greater than 2 mg/dL, bladder dysfunction or outlet obstruction, inflammatory bowel disease, or radiation enteritis.**

Before the surgical procedure, a full mechanical and antibiotic bowel preparation is often used. A long midline incision is made. The ipsilateral colon is mobilized medially, and the affected ureter is dissected proximally to the level of healthy tissue. The proximal anastomosis may be performed at the level of the renal pelvis if the entire upper ureter is unhealthy. The length of the ureteral defect is measured, and an appropriate segment of distal ileum is chosen. The segment should be at least 15 cm away from the ileocecal valve, and adequate blood supply should be confirmed before harvesting. The mesentery is usually divided more extensively than with a standard ileal conduit to provide greater mobility. Occasionally, a segment of colon may be more accessible than ileum and is harvested using the similar surgical principles. **In the presence of a scarred or intrarenal pelvis, ileocalycostomy may be performed** (McQuitty et al, 1995). In this circumstance, excision of a piece of lower pole renal parenchymal tissue is helpful in preventing stenosis at the anastomosis, as in a typical ureterocalicostomy. After bowel division, the distal end of the ileal segment is marked for orientation and bowel-to-bowel continuity is reestablished. A small window is made in the colonic mesentery, through which the segment of ileum is delivered laterally. Alternatively, the cecum and ascending colon can be reflected superiorly to avoid mesenteric window creation in performing right ureteral reconstruction. The orientation of the ileal segment is checked to ensure isoperistalsis, and the anastomoses are performed at the level of the renal pelvis or lower pole calyx and at the bladder (Fig. 38–32). Bilateral ileal ureteral substitution may be achieved by using a longer segment that travels intraperitoneally from one kidney to the other and then to the bladder. An alternative is to use two separate bowel segments.

Perioperative complications associated with ileal ureter include early urinary extravasation or urinoma formation and obstruction from edema, a mucus plug, or a kink in the segment. Ischemic necrosis of the ileal segment may occur and should be considered if signs of an acute abdomen are present. Significant electrolyte abnormalities and renal insufficiency are unusual if preoperative renal function is normal. **Patients with worsening metabolic abnormalities associated with a progressively dilating ileal ureter should be evaluated for vesicourethral dysfunction. Furthermore, malignancy arising from an ileal ureter segment has been reported in four cases in the literature** (Austen and Kalble, 2004), **and it is recommended that regular endoscopic examination should be performed starting at the third postoperative year for early detection of such malignancy.** However, Matiaga and colleagues (2003) have confirmed the safety and reliability of ileal ureter creation for complex ureteral stricture/loss in 18 patients with a mean follow-up of 18.6 months. This conclusion was further supported by Bonfig and associates (2004) in another contemporary series involving 43 patients with a mean follow-up of 40.8 months.

Laparoscopic Ileal Ureteral Substitution

The clinical experience in laparoscopic ileal ureteral substitution is limited worldwide, yet this procedure appears to hold significant promise. Gill and coworkers (2000) reported successful laparoscopic ileal ureter replacement using a transperitoneal, three-port approach. The entire procedure, including free-hand suturing and knot tying, was performed using the intracorporeal laparoscopic technique. Although the operative procedure was relatively long, at 8 hours, there was minimal

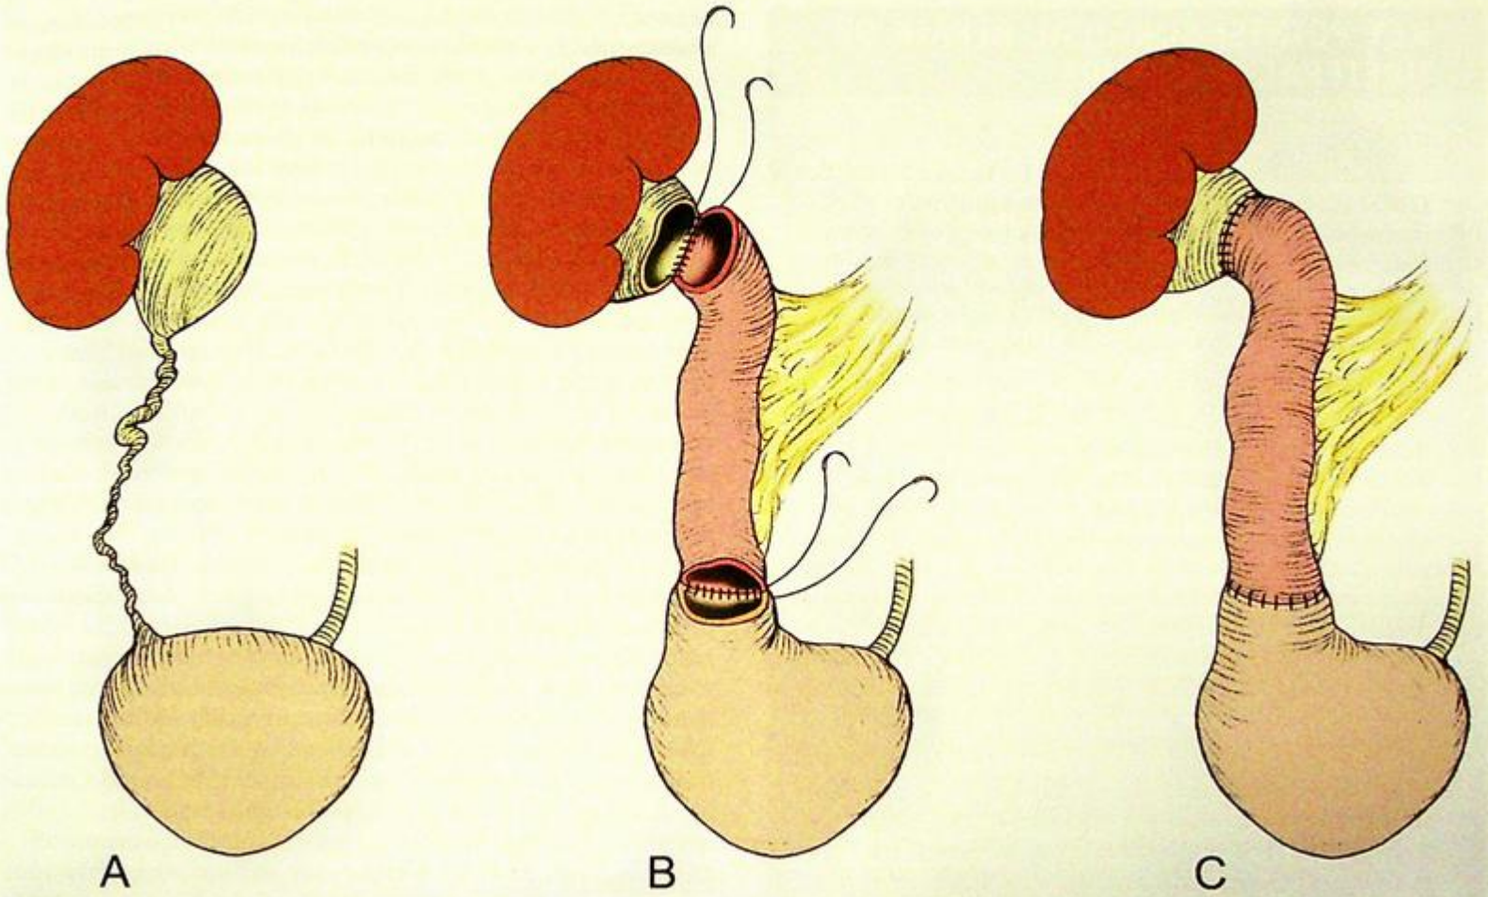

Figure 38–32. **A,** In ileal ureteral substitution, the affected ureter is first identified and dissected, which is followed by removal of the diseased portion. **B,** A piece of ileum is brought through the colonic mesentery to bridge the renal pelvis and the bladder. **C,** Both proximal and distal anastomoses are completed in a full-thickness, watertight, tension-free manner.

postoperative morbidity and a short hospital stay (of 4 days) as in most other laparoscopic procedures.

Autotransplantation

In 1963, Hardy performed the first autotransplantation for a patient with proximal ureteral injury. Since then, clinical autotransplantation has been performed for a variety of problems, including extensive ureteral loss or stricture (Hardy, 1963; Novick and Stewart, 1981; Chuang et al, 1999; Wotkowicz and Libertino, 2004). Generally, autotransplant is considered when the contralateral kidney is absent or poorly functioning or when other methods for ureteral substitution or repair are not feasible. The kidney is harvested with maximal vessel length as in a typical live donor nephrectomy for allotransplantation, and the renal vessels are anastomosed to the iliac vessels to reestablish renal perfusion. A healthy segment of the proximal ureter is anastomosed to the bladder (Bodie et al, 1986). Alternatively, the ipsilateral renal pelvis may be anastomosed directly to the bladder (Kennelly et al, 1993).

Recently, laparoscopy has been successfully incorporated in autotransplantation for severe ureteral loss. Nephrectomy can be performed laparoscopically as in any typical laparoscopic donor nephrectomy, followed by renal graft retrieval, bench preparation, and autotransplantation in the ipsilateral iliac fossa via a Gibson incision using the standard open surgical techniques (Fabrizio et al, 2000; Meng et al, 2003; Bluebond-Langner et al, 2004). The use of laparoscopy in autotransplantation has been shown to provide reduced postoperative analgesic need and faster recovery because a large open upper abdominal or flank incision for renal harvest is avoided. Laparoscopic nephrectomy in autotransplantation is most commonly performed transperitoneally. However, retroperitoneal approach for such purpose has been applied successfully by Gill and colleagues (2000).

URETEROENTERIC ANASTOMOTIC STRICTURE

Incidence and Etiology

Several factors determine the incidence of stricture formation at the anastomosis of the ureter and intestine at the time of urinary diversion. The longest follow-up data available are for urinary conduits, in which the stricture rate is between 4% and 8% and more common on the left (Schmidt et al, 1973; Skinner et al, 1980). Factors potentially influencing outcome in this population include the technique used for ureteral dissection, the segment of bowel used for the diversion, and the type of anastomosis performed. Because ureteral ischemia is central to the etiology of ureteroenteric strictures, careful attention to dissection is necessary to prevent complications. The ureteral blood supply runs parallel to the ureter in the

KEY POINTS: SURGICAL REPAIR OF URETERAL STRICTURE

- Only short ureteral defects may be managed by end-to-end ureteroureterostomy.
- Distal ureteral stricture may be managed with ureteroneocystostomy with a psoas hitch or Boari flap.
- In psoas hitch, additional mobility can be achieved by dividing the contralateral superior vesical artery. Care should be taken to avoid injury to the genitofemoral nerve or femoral nerve.
- Boari flap may be used to bridge a 10- to 15-cm ureteral defect. Small bladder capacity is a contraindication to such flap creation. Care should be taken to ensure adequate vascular supply to the flap.
- Transureteroureterostomy is contraindicated in the presence of any disease process that may affect both ureters. It is also contraindicated if there is insufficient length of the donor ureter to reach the contralateral recipient ureter in a tension-free manner.
- Ileal ureter is useful in the presence of extensive ureteral loss. It is contraindicated in cases of baseline renal insufficiency with a serum creatinine value of greater than 2 mg/dL, bladder dysfunction or outlet obstruction, inflammatory bowel disease, or radiation cystitis.
- Autotransplantation is considered when the contralateral kidney is absent or poorly functioning or when other methods for ureteral substitution or repair are not feasible.

adventitia. Although ureteral mobilization is necessary to approximate the ureter and bowel and prevent tension on the anastomosis, stripping the ureter of its surrounding adventitia can lead to distal ureteral ischemia and stricture formation. **When performing an ileal conduit, the left ureter is brought underneath the sigmoid mesentery just overlying the aorta. The additional length and dissection needed on the left and the possibility of angulation around the inferior mesenteric artery may lead to a higher incidence of stricture formation on the left** (Mansson et al, 1989).

Much controversy exists over the choice of bowel segment employed for conduit diversion. One theoretical advantage to the use of colon is the feasibility of performing a nonrefluxing anastomosis. However, the reported incidence of renal deterioration with a nonrefluxing versus a refluxing ureterocolonic anastomosis has been mixed, and there does not appear to be a clear advantage with respect to renal function and colonization to a nonrefluxing anastomosis. The issues influencing stricture formation in continent urinary diversions become even more complex, owing to the variety of bowel segments, reservoir configurations, and types of anastomoses available for reconstruction. **The reported rate of ureteroenteric anastomotic stricture after continent diversion is 4% to 25%, with the majority presenting within the first 2 years** (Lugagne et al, 1997; Weijerman et al, 1998). Despite the paucity of randomized studies, there is a growing body of evidence in the literature that the risk of obstruction with a nonrefluxing anastomosis is significantly higher than that of a refluxing anastomosis. Pantuck and associates (2000) compared 60 nonrefluxing ureteroenteric anastomoses with 56 direct, refluxing anastomoses and found the long-term stricture rate to be 13% and 1.7%, respectively. With a mean follow-up of 41 months, there was no significant difference in the two groups with respect to hydronephrosis, pyelonephritis, nephrolithiasis, or renal insufficiency. Similarly, Roth and colleagues (1996) found a greater than fivefold increase in ureteral strictures in the group undergoing a nonrefluxing anastomosis. Their data also indicated that the risk of obstruction was unrelated to surgical expertise.

Studer and coworkers (1995) have reported a randomized study evaluating a nonrefluxing versus a refluxing anastomosis into an isoperistaltic afferent ileal limb. Thirteen percent of nonrefluxing anastomoses resulted in stricture formation, as compared with 3% of refluxing anastomoses. Although there is no clear evidence that reflux into an adult kidney is detrimental, it is clear that obstruction is quite harmful to renal function. These studies and others support the use of a refluxing anastomosis in low-pressure continent reservoirs.

Evaluation

A minimally invasive means of screening the upper tracts in patients who have undergone any type of urinary diversion is a renal ultrasound. In addition, patients with renal colic, recurrent urinary tract infection, or loss of renal function will require evaluation. In patients with hydronephrosis on ultrasound, an intravenous pyelogram and contrast study of the conduit or reservoir will provide information on the length and location of the stricture. If a stone or recurrent tumor is suggested, CT or MRI may be helpful. Diuretic renography is indicated in patients with chronic hydronephrosis to assess differential renal function and to confirm the presence of functional obstruction. If hydronephrosis is present but renal function is insufficient for intravenous urography or renography, placement of a nephrostomy tube and performance of an antegrade nephrostogram is both diagnostic and therapeutic. This approach is also useful before endoscopic intervention and clarifies stricture length, which aids in surgical planning.

Indications for Intervention

Not all patients with urinary diversion and hydronephrosis require intervention. **Most patients with a long-term urinary conduit will have an element of chronic hydronephrosis that is not secondary to obstruction. In this population, a decrease in renal function or loss of reflux on a routine loopogram should prompt diuretic renography to quantitatively assess for functional obstruction.** Indications for intervention in patients with diversions and hydronephrosis include pain, infection, and renal insufficiency associated with functional obstruction. Although recurrence of transitional cell carcinoma at the level of the anastomosis is uncommon,

the radiographic picture of an irregular mass at the level of the stricture and the rapid progression of obstruction and loss of renal function should prompt further evaluation and intervention (Tsuji et al, 1996).

A particularly challenging subset of patients includes those undergoing urinary diversion as part of a pelvic exenteration for gynecologic malignancy. Penalver and coworkers (1998) reported on 66 patients, 95% of who had undergone previous pelvic irradiation. Early and late complications at the ureteroenteric anastomosis were 22% and 10%, respectively. Eighty-five percent of their postoperative complications were managed successfully by conservative measures such as percutaneous nephrostomy.

Endourologic Management

Endourologic management of ureteroenteric strictures has evolved in a manner analogous to that for ureteral stricture disease. Whereas the initial procedures involved simple balloon dilatation and stent placement, unsatisfactory results led to incisional techniques using electrocautery, and more recently, lasers were applied utilizing both fluoroscopic and direct endoscopic control. The present-day state-of-the-art incisional technique for endoureterotomy includes small-caliber flexible ureteroscopic instrumentation along with holmium laser incision (Siegel et al, 1982; Muench et al, 1987; Cornud et al, 1992; Delvecchio et al, 2000; Laven et al, 2001, 2003).

Endourologic management of ureteroenteric or ureterocolic strictures, unlike the management of ureteral strictures, favors antegrade management. As such, endourologic procedures typically begin with antegrade percutaneous access. Simple percutaneous drainage is continued to allow relief of any associated infection- or obstruction-related renal dysfunction. Once the patient is clinically stable, fluoroscopic control is utilized to pass a guide wire in an antegrade fashion across the anastomotic stricture, over which a balloon catheter can be positioned and inflated until the waist disappears. Stents are a routine part of the endourologic management, and these are generally inserted in this same antegrade fashion. However, because of difficulty with mucus plugging of stents in this setting, many centers routinely utilize an internal/external stent, which can be easily flushed or changed over a wire. In addition, retrograde looposcopic access can be combined with percutaneous access and antegrade passage of a wire. With through-and-through control, the anastomosis can be visualized fluoroscopically or, preferably, with direct ureteroscopic, looposcopic, or trans-stomascopic visualization. Any number of procedures can then be utilized for the dilatation itself, including balloon dilatation alone, electroincision with an electrode or hot wire cutting balloon, or holmium laser incision. In all cases, a stent is placed, usually for 4 to 8 weeks.

Balloon dilatation of ureteroenteric strictures was one of the first endourologic forms of management used, and fortunately long-term results are available. Notably, short-term reports using high-pressure balloon dilation have demonstrated success rates as high as 61% (Ravery et al, 1998). Alternatively, Shapiro and colleagues (1988) reported balloon dilatation for 37 benign ureteroenteric strictures in 29 patients. Only 6 (16%) were considered to have a successful result at least 1 year after interventional treatment, and repeat dilatations were often required to maintain ureteral patency. Similarly, Kwak and coworkers (1995) achieved an overall success rate of less than 30% at 9 months for patients undergoing antegrade balloon dilatation of ureteroenteric strictures. More recently, DiMarco and associates (2001) reported a 5% three-year success rate in 52 balloon dilations of ureteroenteric anastomotic strictures.

Results of cautery wire balloon incision have also been reported in patients treated for ureteroenteric strictures (Lin et al, 1999). For benign strictures, a stent-free long-term patency was achieved in only 30% of patients. Meretyk and colleagues (1991) reviewed the long-term results of endourologic management of ureteroenteric anastomotic strictures at Washington University. In that study, 15 patients with 19 ureteroenteric strictures were followed for an average of 2.5 years. An antegrade approach was used most frequently and was usually combined with electroincision. A 57% long-term stent-free patency rate was achieved, even with follow-up longer than 2 years. **Whereas long-term patency of most endoscopic procedures seems to be in the range of 50%, such approaches are still used preferentially as the initial intervention, reserving open operative management for those patients failing endourologic intervention** (Kramolowsky et al, 1987, 1988).

Cornud and associates (1996) reported their long-term results with percutaneous electroincision of ureterointestinal anastomotic strictures and specifically compared the results of fluoroscopic and endoscopic guidance. Twenty-seven patients were followed for longer than 1 year after stent removal, and an overall patency rate of 71% was reported. These investigators found better results when direct endoscopic control was combined with fluoroscopic guidance, compared with fluoroscopic guidance alone. In that report, right common iliac artery damage was reported during electroincision in one patient who had the procedure performed under fluoroscopic guidance alone. As a result, direct visual approaches have been favored for the management of ureteroenteric or ureterocolic anastomotic strictures, and the holmium laser has proven to be an excellent incisional tool. Endoureteromy is typically performed antegrade, and success rates ranging from 50% to 80% have been reported (Singal et al, 1997; Laven et al, 2001; Watterson et al, 2002). These reports suggest the left side is more resistant to management, because the majority of the failures occurred on the left side in one series (Laven et al, 2003). **When considering endoscopic incision of a left ureteroenteric stricture, the risk of hemorrhage is a consideration because the sigmoid mesentery can be in close proximity. This, taken with the lower success rates of all endoscopic approaches on the left side, supports serious consideration to open repair when treating left ureteroenteric strictures.**

Open Intervention

Open surgical management of ureterointestinal strictures is technically challenging and associated with a longer recovery than endoscopic options but is often necessary due to the low success rates of less invasive alternatives, in particular balloon dilatation (DiMarco et al, 2001). When undertaking open repair, it is optimal to sterilize the urine and prepare the bowel preoperatively. If a cutaneous stoma is present, it is prepared into the field and the conduit or reservoir is drained with a Foley catheter during the procedure. Placement of a

nephrostomy tube and ureteral stent is helpful. Through a midline incision, the conduit or reservoir is identified and preserved, the colon is reflected medially, and the proximal, dilated ureter is identified and traced down to the area of the previous anastomosis. Care is taken to preserve the adventitia and associated blood supply. If enough ureteral length is available, the ureter can be transected proximal to the stricture, spatulated, and anastomosed to a convenient area of the bowel. If the dissection is particularly difficult, there may be significant trauma to the conduit or reservoir, requiring major revision. In addition, insufficient ureteral length may require an additional segment of bowel to interpose between the ureter and the reservoir. The anastomosis is carried out over a No. 7 Fr stent, and a drain is left in situ. The stent remains for 4 to 6 weeks. Good long-term success rates have been reported with open repair, as high as 80% (Laven et al, 2003). As expected, strictures longer than 1 cm were more likely to recur and the left side had lower success rates (DiMarco et al, 2001; Laven et al, 2003) Major complications were encountered in 11% of cases in one series (DiMarco et al, 2001).

KEY POINTS: URETEROENTERIC STRICTURES

- Whereas long-term patency of most endourologic procedures for ureteroenteric strictures seems to be in the range of 50%, such approaches are still used preferentially as the initial intervention, reserving open operative management for those patients failing endourologic intervention.
- When considering endoscopic incision of a left ureteroenteric stricture, the risk of hemorrhage is a consideration because the sigmoid mesentery can be in close proximity. This, taken with the lower success rates of all endoscopic approaches on the left side, supports serious consideration to open repair when treating left ureteroenteric strictures.
- Good long-term success rates have been reported with open repair, as high as 80%. As expected, strictures longer than 1 cm were more likely to recur and the left side had lower success rates.

RETROPERITONEAL FIBROSIS

Presentation and Etiology

Retroperitoneal fibrosis (RPF) is typically characterized by the presence of an inflammatory, fibrotic process in the retroperitoneum causing compression of the retroperitoneal structures including the ureters. RPF most commonly affects patients who are 40 to 60 years of age. However, more than 30 cases of RPF have been reported in patients younger than 18 years of age (van Bommel, 2002). RPF cases have a male predominance, with a male-to-female ratio of 2 to 3:1. The true incidence is unknown but has been estimated to be 1:200,000 to 1:500,000 per year.

The retroperitoneal fibrotic mass generally centers around the distal aorta at L4-L5 and wraps around the ureters, leading to hydronephrosis via extrinsic compression on the ureters or interference with ureteral peristalsis (Lepor and Walsh, 1979; Koep and Zuidema, 1987). In most patients, the presenting symptom is pain in the lower back and/or flank. The pain, which is typically dull, noncolicky, and unchanged with posture, may radiate to the lower abdomen or groin. Furthermore, the pain is often relieved by aspirin rather than narcotics. Other symptoms include weight loss, anorexia, nausea, generalized malaise, fever, hypertension, and oliguria/anuria. The mass may compress the inferior vena cava, resulting in deep venous thrombosis and lower extremity edema (Rhee et al, 1994). The mass may extend proximally to the renal hilum and encase the renal vein, resulting in renal vein hypertension and subsequent gross hematuria (Powell et al, 2000). Aortic obstruction and involvement of the mediastinum, the biliary system, the mesentery, and the kidney itself are rare (Tripodi et al, 1998; Azuma et al, 1999; Dejaco et al, 1999; Klisnick et al, 1999). Distal extension to the bifurcation of the iliac vessels may occur, and extension to spermatic cord with scrotal involvement has been reported (Palmer and Rosenthal, 1999; Schulte-Baukloh et al, 1999). Duration of symptoms before diagnosis is usually 4 to 6 months, and approximately half of the patients present with fibrosis that has caused significant ureteral obstruction and symptoms secondary to uremia.

In approximately 70% of the cases, the disease is idiopathic. However, there is evidence that idiopathic RPF may be related to an immune-mediated periaortitis. Ceroid, a complex polymer of oxidized lipids and protein found in atherosclerotic plaques, has been suggested as the antigen initiating the inflammatory response (Parums et al, 1991). Indeed, a higher incidence of aortic aneurysms has been identified in patients with RPF recently (Breems et al, 2000).

RPF usually presents as an isolated disease entity. However, it may present as part of multifocal fibrosclerosis, a rare syndrome characterized by fibrosis involving multiple organ systems. In such a scenario, the clinical presentation may include RPF, sclerosing mediastinitis, sclerosing cholangitis, orbital pseudotumor, and Riedel's thyroiditis (Dehner and Coffin, 1998; Özgen and Cila, 2000). The pathogenesis of these disorders is unknown but appears to be autoimmune.

Among the 30% of RPF patients who have an identifiable cause, **drugs such as methysergide (Sansert) and other ergot alkaloids are most commonly associated with RPF.** β-Adrenergic blockers and phenacetin have also been implicated. The exact pathophysiology of drug-induced RPF remains unknown. Other causes of RPF include malignancies such as lymphoma, the most common malignancy in RPF cases, and multiple myeloma, carcinoid, pancreatic cancer, prostate cancer, and sarcoma (Webb and Dawson-Edwards, 1967; Usher et al, 1977). Radiation therapy for retroperitoneal malignancy is also known to produce a residual fibrotic mass leading to secondary ureteral obstruction. Abdominal aortic aneurysm may cause significant retroperitoneal inflammatory reaction, leading to fibrosis and ureteral obstruction. In addition, infectious causes such as tuberculosis, *Actinomyces*, gonorrhea, or schistosomiasis have been suggested in the pathogenesis of RPF.

Association of RPF with membranous glomerulonephritis has also been documented in the literature (Mercadal et al, 2000; Shirota et al, 2002). The exact etiology remains unclear,

although the association has been speculated to be secondary to an unknown antigen triggering a systemic immune response that leads to RPF. Association of RPF with ankylosing spondylitis and Wegener's granulomatosis have also been reported, further suggesting an underlying immune etiology in some patients (Izzedine et al, 2002; LeBlanc et al, 2002).

Pathologically, the typical gross appearance of RPF is that of a smooth, flat, tan-colored, dense mass enveloping the surrounding retroperitoneal structures. It is also known to invade the ureter or psoas muscle. Histologically, the appearance of RPF is that of a nonspecific inflammatory process that varies with stage of the disease. Early in the disease, affected tissue consists mainly of collagen bundles with capillary proliferation and inflammatory cells including lymphocytes, plasma cells, and fibroblasts. In the later stage, the mass becomes relatively acellular and avascular, consisting of sheets of hypocellular collagen. RPF secondary to malignancy is often histologically indistinguishable from idiopathic RPF, and it can be identified only based on the demonstration of small islands of tumor cells within the fibrotic mass.

Evaluation

In most RPF patients, the clinical symptoms are generally nonspecific and physical examination is usually unrevealing. Laboratory evaluation may reveal an elevated erythrocyte sedimentation rate, moderate leukocytosis, anemia, and variable renal insufficiency with associated electrolyte abnormalities. If the overall renal function is normal, an intravenous pyelogram (IVP) or CT with contrast medium enhancement may be performed. Typical IVP findings include hydronephrosis with medial deviation of the proximal ureter and midureter and a smoothly tapered ureter at the level of obstruction. Urinary obstruction is usually bilateral, but unilateral cases have been described. Uncommonly, there are patients with symptoms of urinary obstruction but very little hydronephrosis on imaging. CT typically reveals hydronephrosis associated with a well-delineated retroperitoneal soft tissue mass enveloping the great vessels and the ureters (Fig. 38–33). If the patient has significant renal impairment, a retrograde pyelogram may be performed, demonstrating similar findings as in IVP. In the radiographic evaluation of RPF, MRI can also be helpful, because the mass has characteristic T1- and T2-weighted images. If a kidney is suspected to be nonfunctioning, a radioisotope renogram needs to be considered to determine differential renal function because it may affect surgical planning. Representative biopsies of the mass need to be obtained percutaneously or at the time of open or laparoscopic ureterolysis to rule out malignancy and allow one to proceed with treatment for RPF.

Figure 38–33. Typical CT findings of retroperitoneal fibrosis. The study demonstrates the presence of a homogeneous mass obliterating the outline of the great vessels at the lower lumbar area. Note the placement of a stent in the right ureter.

Management

Initial Management

The initial management of RPF depends on the patient's clinical status. Patients with hydronephrosis and uremia should be emergently decompressed by either percutaneous nephrostomy or indwelling ureteral stents. The advantages to placing ureteral stents include the opportunity to perform retrograde pyelograms to evaluate the anatomy and the convenience of internal drainage. Interestingly, ureteral stent placement is usually not difficult to perform in the setting of ureteral obstruction due to RPF. In a critically ill patient with electrolyte abnormalities and little or no urine output, nephrostomy tube placement can be performed at the bedside with local anesthesia. **After renal decompression, the patient needs to be monitored closely for postobstructive diuresis, renal function status, and appropriate replacement of fluids and electrolytes.**

After the initial management, an attempt to search for the etiology of RPF should be made. Methysergide or any other potentially inciting drug, if identified, should be discontinued. Although most patients with malignant RPF have a prior history of malignancy, a thorough search for occult malignancy with careful application of imaging studies is necessary. Biopsy to rule out malignancy, performed percutaneously or at the time of ureterolysis to provide long-term relief of obstruction, needs to be considered. However, some believe that in patients with classic radiographic features on MRI or CT, no lymphadenopathy, and no history of prior malignancy, a biopsy is not essential before medical therapy.

Medical Management

Once the diagnosis of idiopathic RPF is made, the most common primary medical management has been corticosteroid therapy. Although there has been no large clinical series because the disease entity is uncommon, there are approximately 140 cases of idiopathic RPF treated with corticosteroids that resulted in about an 80% clinical response in the medical literature, including having a decrease in size of the mass and improvement in ureteral obstruction or inferior vena cava compression (Kearney et al, 1976; Baker et al, 1987; Adam et al, 1998; Higgins et al, 1998, van Bommel, 2002). The characteristic clinical response to corticosteroid therapy includes resolution of pain and constitutional symptoms within days after treatment, a rapid fall of erythrocyte sedimentation rate, and diuresis. Dose and duration of corticosteroid therapy varied considerably in the literature, but most therapies were of 6 months or greater in duration. Chronic corticosteroid therapy up to 2 years has been shown to provide significant improvement in clinical symptoms and regression of retroperitoneal mass in one recent report involving 12

patients (Kardar et al, 2002). Although corticosteroids do not reverse the established fibrosis, further inflammatory reaction and fibrosis with their associated symptomatology and sequelae may be minimized. Therefore, it appears that patients who have the evidence of active inflammation—manifested by increased erythrocyte sedimentation rate, leukocytosis, or active inflammation on a biopsy—are more likely to respond to corticosteroid therapy.

In addition to corticosteroids, several other immunosuppressive agents have been described to provide benefit in idiopathic RPF in isolated case reports, including azathioprine, cyclophosphamide, cyclosporine, and mycophenolate mofetil (Wagenknecht and Hardy, 1981; McDougall and MacDonell, 1991; Grotz et al, 1998; Marzano et al, 2001). Medroxyprogesterone acetate, progesterone, and particularly tamoxifen, a nonsteroidal antiestrogen, have been found to be beneficial in idiopathic RPF in several case reports (Clark et al, 1991; Benson and Baum, 1993; Al-Musawi et al, 1998; Dedeoglu et al, 2000; Puce et al 2000). The exact mechanisms of action of these medications are unclear, but they are believed to inhibit fibroblastic proliferation leading to clinical response.

Surgical Management: Open Ureterolysis

A ureterolysis may be performed open surgically or laparoscopically, although open surgery has been considered as the standard (Lindell and Lehtonen, 1988; Elashry et al, 1996). It is performed with concomitant biopsy of the mass in patients with an unclear diagnosis as the definitive initial treatment or in those who fail medical therapy. **When open surgery is performed, a midline, transperitoneal abdominal incision is made to allow access to both ureters.** Placement of ureteral catheters or stents before the abdominal incision is advisable to facilitate identification and dissection of the ureters. **Although hydronephrosis may be unilateral on preoperative assessment, the process is generally bilateral, requiring bilateral ureterolysis.** After medial mobilization of the ascending and descending colon, deep biopsies of the mass should be obtained for frozen and permanent section to rule out malignancy. Dissection should begin at the distal, nondilated ureteral segment to avoid injury to the thin, dilated proximal segment. A right-angle clamp can be placed between the ureter and the retroperitoneal mass along the course of the ureter, and the fibrotic tissue is then incised above the clamp. This is repeated throughout the length of the entrapped ureter, using both blunt and sharp dissection techniques to free the affected ureter from its fibrous bed. The ureteral wall may become quite thin at times after the dissection. An inadvertent ureterotomy should be closed with absorbable suture. Ureteral excision with ureteroureterostomy is usually unnecessary.

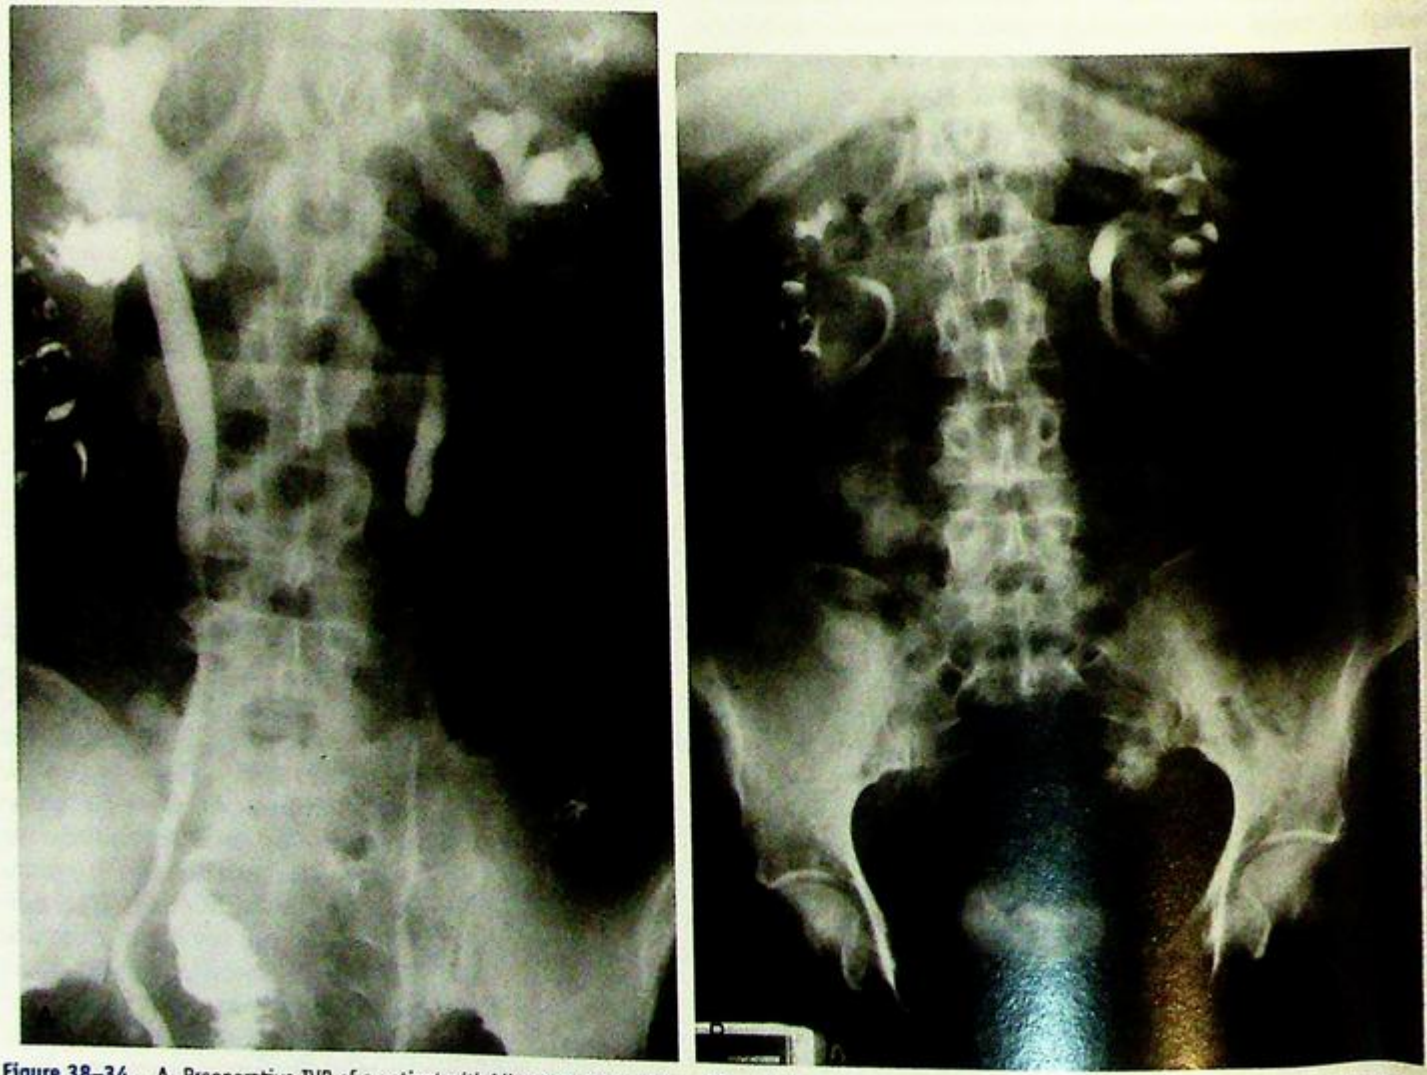

Figure 38–34. A, Preoperative IVP of a patient with idiopathic retroperitoneal fibrosis shows bilateral hydroneph[illegible] with medial deviation of the ureters. B, Postoperative IVP of the same patient after surgical ureterolysis with intraperitoneal omental wrapping.

After bilateral ureterolysis, the ureters should be repositioned and protected from further fibrous entrapment. Several surgical options are available. One option is to retract the ureters laterally and secure the overlying peritoneum medially to the psoas muscle to maintain the ureters in this location. Another option is to close the peritoneum behind the ureters so that the ureters may be displaced anteriorly into the peritoneal cavity (Tresidder et al, 1972). It is important not to obstruct the ureter in the closure of the peritoneum at the ureteral hiatus. In a report on a group of patients with idiopathic RPF undergoing intraperitoneal placement of the ureters or lateral retroperitoneal placement of the ureters, no difference in the radiologic or clinical outcome was found (Barbalias and Liatsikos,1999). In the setting of extensive RPF, a more definitive approach is to surround the ureters with omentum and reposition them within the peritoneal cavity (Carini et al, 1982). To perform the omental wrap, the omentum is first mobilized from its attachment to the transverse colon, followed by its division along its midline with ligation of the small omental vessels up to the gastric attachment. The short gastric vessels are then divided and ligated at the level of the stomach wall, after which the two halves of the omentum can be retracted laterally based on the right and left gastroepiploic arteries. The entire length of the ureter can be surrounded by omental tissue, which is tacked in place with absorbable sutures (Fig. 38–34). The omentum provides protection of the ureter against recurrent extrinsic compression and vascularity to a potentially ischemic ureter. Corticosteroid therapy may be used postoperatively in an attempt to prevent recurrent upper tract and venous compression. If no ureterotomy occurs during ureterolysis, the previously placed stents may be removed shortly after surgery.

If ureterolysis is impossible to perform due to extensive periureteral fibrosis, renal autotransplantation may be performed if the ipsilateral renal unit demonstrates satisfactory function (Penalver et al, 2001). If no significant renal function can be recovered after an adequate time period of decompression in the presence of the satisfactory contralateral renal function, nephrectomy may be considered.

Surgical Management: Laparoscopic Ureterolysis

The first laparoscopic ureterolysis was reported by Kavoussi and Clayman in 1992. Subsequent success with such technique was confirmed by others (Puppo et al, 1994). In a more recent report, Kavoussi and colleagues described their experience with laparoscopic ureterolysis in 13 patients, including bilateral procedure in 7 and unilateral procedure in 6 (Fugita et al, 2002). Preoperative stent placement was performed in all cases before laparoscopy. For each ureter, the laparoscopic procedure was performed using a transperitoneal four-port approach. After incision of the posterior peritoneum and mobilization of the colon, the affected ureter was dissected free from the retroperitoneal fibrotic tissue. Multiple frozen-section biopsies of the periureteral tissue were obtained to rule out malignancy. The edge of the posterior peritoneum was reapproximated to the side wall underneath the ureter to intraperitonealize the ureter. Laparoscopic ureterolysis was completed successfully in 11 (85%) of cases, with 2 (15%) open conversions due to iliac vein injury (in 1 patient) and marked fibrosis (in 1 patient). Mean operative time was 381 minutes for bilateral procedures and 192 minutes for unilateral procedures. Mean use of parenteral analgesics was 59 mg of morphine sulfate equivalent. Mean hospital stay was 4 days. Postoperative complications occurred in 4 (30%) patients, including epididymitis, umbilical port erythema, prolonged ileus, and urinary retention. Pathology showed fibrous tissue with lymphocytes, plasma cells, macrophages, and fibroblast proliferation in all cases. At a mean follow-up of 30 months, upper tract imaging such as intravenous urography or renal scan showed lack of obstruction in 92% (12) of the patients.

KEY POINTS: RETROPERITONEAL FIBROSIS

- Retroperitoneal fibrotic mass generally centers around the distal aorta at L4-L5 and wraps around the ureters, leading to hydronephrosis via extrinsic compression on the ureters or interference with ureteral peristalsis. In most cases, the disease is idiopathic. Drugs such as methysergide and other ergot alkaloids are most commonly associated with RPF.
- RPF symptoms and signs are usually nonspecific. Laboratory evaluation may show an elevated erythrocyte sedimentation rate, moderate leukocytosis, anemia, and variable renal insufficiency associated with electrolyte abnormalities.
- Initial management of RPF in the presence of hydronephrosis and uremia includes emergent decompression by percutaneous nephrostomy or indwelling ureteral stents. After decompression, the patient needs to be monitored closely for postobstructive diuresis.
- The most common primary medical management of idiopathic RPF has been corticosteroid therapy.
- In surgical bilateral ureterolysis, the ureters need to be protected by intraperitonealization or omental wrapping. Both open and laparoscopic techniques may be applied successfully. If ureterolysis is impossible to perform, renal autotransplantation may be performed.

39 Renal and Ureteral Trauma

JACK W. McANINCH, MD • RICHARD A. SANTUCCI, MD

RENAL INJURIES

URETERAL INJURIES

Traumatic injury is a leading national and international health problem. In the United States, 1 of every 14 deaths—over 150,000 per year—results from trauma (Baker et al, 1992). Indeed, in young people, trauma results in more deaths between ages 1 and 37 years than any other cause. Violence alone claims 50,000 lives annually, and more than 2.2 million in the United States suffer injuries from assaults each year. With the development of trauma care systems and centers, death rates from major injuries have declined significantly over the past 20 years (Kivioj et al, 1990).

The initial evaluation and resuscitation of the injured patient are done by the emergency room physician and the trauma surgeon, but it is important that the involved urologist understand the mechanism of injury, its extent, the methods used in the initial resuscitation process, and their success rates. Individuals who survive the immediate impact of the initial trauma can often be resuscitated in the field. Immediate transport to a trauma center where complete evaluation and care can be provided is essential.

The first hour of care after a major injury is extremely important and requires rapid assessment of the injuries and resuscitation based on priorities established by the American College of Surgeons' Acute Trauma Life Support Program. The mnemonic "ABCDE" defines these priorities in order of importance: A, airway with cervical spine protection; B, breathing; C, circulation and control of external bleeding; D, disability or neurologic status; E, exposure (undress) and environment (temperature control) (American College of Surgeons Committee on Trauma, 1997).

The best care provided to a polytrauma patient comes from a well-organized team of specialists, most often led by a surgeon experienced in trauma care. As approximately 10% of injuries involve the genitourinary tract—with the kidney being the most commonly injured organ—the urologist is a valued team member because of the experienced care he or she can provide for these special types of injuries.

RENAL INJURIES

Presentation

Of all injuries to the genitourinary system, injuries to the kidney from external trauma are the most common. It is essential to obtain as many details of the injury as possible; for example, depending on whether the cause is blunt or penetrating trauma, the approach to evaluation and management is quite different.

Blunt renal injuries most often come from motor vehicle accidents, falls from heights, and assaults. Perhaps the most important information to obtain in the history of the injury is the extent of deceleration involved. Rapid deceleration can cause vascular damage to the renal vessels, resulting in renal artery thrombosis, renal vein disruption, or renal pedicle avulsion. In high-velocity-impact trauma, multiple-organ injury is likely to be associated.

Penetrating renal injuries most often come from gunshot and stab wounds. The gunshot to the upper abdomen or lower chest should alert the physician to renal injury; of all patients sustaining renal trauma in a large reported series, renal gunshot wounds occurred in approximately 4.0% (McAninch et al, 1993). **Important factors in assessing a gunshot wound initially are weapon characteristics and bullet ballistics.** Bullet velocity has the greatest effect on soft tissue damage, as noted in the equation:

$$KE = \frac{\text{mass} \times V^2}{2 \times G}$$

where KE = kinetic energy, V = velocity, and G = gravity.

Whether the preceding equation reflects tissue damage precisely is controversial; however, high-velocity weapons clearly cause extensive soft tissue damage (Santucci and Chang, 2004). The greater the bullet velocity, the larger the temporary cavity created, indicating the extent of soft tissue stretch and destruction (Hutton and Rich, 1996). Handguns generally are considered low-velocity weapons (<2000 ft/sec), with numerous types of weapons in between.

Stab wounds usually result from assaults or self-inflicted injuries. The upper abdomen, flank, and lower chest are entry sites commonly resulting in renal injury. Should the weapon be recovered, its dimensions should be inspected carefully because the length and width give valuable information on its penetrating and destructive characteristics.

Physical examination must be complete and should detail all body systems. If the patient is conscious, history can be taken during the examination. In the case of polytrauma, rapid resuscitation should be under way. Immobilization of the cervical spine is necessary in blunt trauma until radiography confirms that it is intact. The abdomen, chest, and back must be examined; fractures of the lower ribs and upper lumbar and lower thoracic vertebrae are associated with renal injuries. Gunshot wounds can be misleading. Often small entrance wounds do not reveal the massive destruction within

the body. Exit wounds are frequently much larger, but a bullet seldom takes a direct path from entrance to exit. Soft tissue and bone can alter the bullet's course; should the bullet fragment, secondary missiles are created, often resulting in multiple exit sites. When radiographs are taken of the chest and abdomen, it is useful to place a small metallic object such as a paper clip at entrance and exit sites to define these locations on the films.

Hematuria

Hematuria is the best indicator of traumatic urinary system injury. The presence of microscopic (>5 red blood cells/high-power field [RBCs/HPF] or positive dipstick finding) or gross hematuria is characteristic. **However, the degree of hematuria and the severity of the renal injury do not correlate consistently**: in up to 36% of renal vascular injuries from blunt trauma, hematuria is absent (Cass, 1989). Also, gross hematuria has been observed with renal contusions, although it is more likely to be associated with a significant renal parenchymal injury. Microscopic hematuria may be present in a wide range of significant renal injuries, including vascular and parenchymal lacerations. In patients with blunt trauma, if shock (systolic blood pressure <90 mm Hg) is noted with microscopic hematuria, the incidence of significant renal injuries increases (Nicolaisen et al, 1985; Mee et al, 1989; Miller and McAninch, 1995). In addition, hematuria has been used as a predictor of intra-abdominal organ injury after blunt trauma (Knudson et al, 1992).

We use the first aliquot of urine obtained either by catheterization or by voiding to determine the presence of hematuria. Later urine samples are often diluted by diuresis from resuscitation fluids, resulting in an underestimation or absence of hematuria.

Visible blood of any degree in the urine is regarded as gross hematuria. Microscopic hematuria can be detected by dipstick analysis or microanalysis. The dipstick method is rapid and has a sensitivity and specificity for detection of microhematuria of more than 97%, even though a poor correlation with actual urinalysis was noted in a study by Chandhoke and McAninch (1988).

Classification

Numerous classifications of renal injuries exist, but the most widely used and accepted classification (Table 39–1; Fig. 39–1) was developed by the American Association for the Surgery of Trauma's Organ Injury Scaling Committee (Moore et al, 1989). The increasing use of contrast-enhanced computed tomography (CT) has provided anatomic detail that facilitates very accurate grading of renal injuries (Bretan et al, 1986). In contrast, excretory urography (intravenous pyelography [IVP]) is less sensitive and much less specific.

Grading scales of all injuries have ambiguities, and the grading of renal injuries is no exception. Grades I through III can be clearly established with appropriate studies, but grades IV and V have areas of overlap; for example, vascular and parenchymal injuries can be present in both. In grade IV injuries to the parenchyma, the scale notes that a laceration extends through the parenchyma and into the collecting system. Vascular injury in grade IV refers to main renal artery thrombosis with contained hemorrhage, implying an intimal flap dissection from blunt trauma, and to main renal vein injury with contained hemorrhage. In addition, segmental renal artery or vein injury is included in grade IV.

Grade V parenchymal injuries are referred to as "shattered kidney," suggesting multiple grade IV–type lacerations, but some authors have used grade V classification to report more than one laceration of any parenchymal depth. Grade V injuries also include renal pedicle avulsion.

Even with these minor variations in reporting, the classification system has established a common scale by which injuries can be identified at disparate centers according to the extent of damage, and it has worked well (Santucci et al, 2001).

Table 39–1. American Association for the Surgery of Trauma Organ Injury Severity Scale for the Kidney*

Grade†	*Type*	*Description*
I	Contusion	Microscopic or gross hematuria, urologic studies normal
	Hematoma	Subcapsular, nonexpanding without parenchymal laceration
II	Hematoma	Nonexpanding perirenal hematoma confined to renal retroperitoneum
	Laceration	<1 cm parenchymal depth of renal cortex without urinary extravasation
III	Laceration	>1 cm parenchymal depth of renal cortex without collecting system rupture or urinary extravasation
IV	Laceration	Parenchymal laceration extending through renal cortex, medulla, and collecting system
	Vascular	Main renal artery or vein injury with contained hemorrhage
V	Laceration	Completely shattered kidney
	Vascular	Avulsion of renal hilum, devascularizing the kidney

*Data drawn from Moore EE, Shackford SR, Pachter HL, et al: Organ injury scaling: Spleen, liver, and kidney. J Trauma 1989;29:1664-1666.
†Advance one grade for bilateral injuries up to grade III.

Staging

Staging of renal injuries refers to the use of appropriate imaging studies to define the extent of injury. Combining these findings with information gleaned at history and physical examination provides maximal guidance for management decisions.

Indications for Renal Imaging

As already stated, hematuria is the best indicator of renal injury, and most authors accept 5 RBCs/HPF as a significant level. However, when this was used in the past as the sole indication for renal imaging, IVP and other studies found a low incidence of renal abnormalities. This prompted an extensive study, based at San Francisco General Hospital, evaluating indications for radiographic imaging in a prospective manner. This study has been ongoing for more than 25 years and at least three reports have updated the findings (Nicolaisen et al, 1985; Mee et al, 1989; Miller and McAninch, 1995). Figure 39–2 provides the results of the study for adult blunt renal trauma.

Based on information from this study, **all blunt trauma patients with gross hematuria and patients with microscopic hematuria and shock (systolic blood pressure**

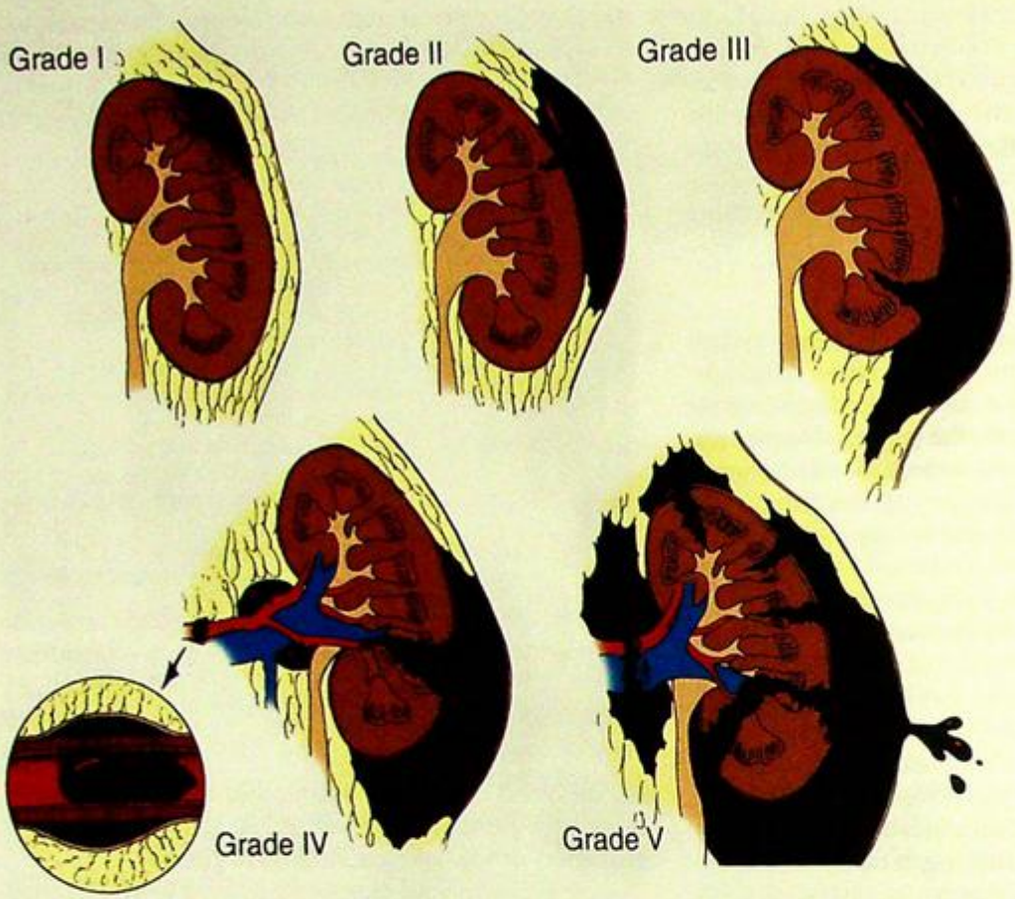

Figure 39–1. Classification of renal injuries by grade (based on the organ injury scale of the American Association for the Surgery of Trauma [based on Moore et al, 1989]).

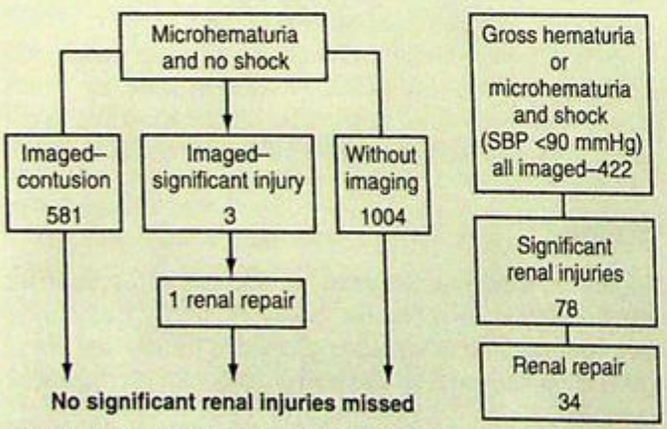

Figure 39–2. Algorithm demonstrating the results of our study on radiographic assessment of renal injuries. In adults with blunt trauma, imaging studies may be performed selectively. SBP, systolic blood pressure. (From Miller KS, McAninch JW: Radiographic assessment of renal trauma. Our 15-year experience. J Urol 1995;154:352-355.)

< 90 mm Hg any time during evaluation and resuscitation) should undergo renal imaging, usually CT with intravenous contrast.

Patients with microscopic hematuria without shock can be observed clinically without imaging studies. As noted by Miller and McAninch (1995), such patients rarely have a significant injury (<0.0016%). However, should one suspect any possible renal injury on the basis of history or examination, imaging should be performed; for example, patients sustaining blunt trauma from rapid deceleration (i.e., head-on or high-speed motor vehicle accidents or falls from great heights) are at risk for vascular injury, which can occur in the absence of microscopic hematuria.

Penetrating injuries with any degree of hematuria should be imaged. In a report by Carroll and McAninch (1985), 27 of 50 patients with penetrating renal trauma had microscopic hematuria. Three of these had 0 to 3 RBCs/HPF and one of the three had a renal pedicle injury. The presence of shock, the degree of hematuria, the location of the entry wound, and the type of injury do not permit reliable discrimination among categories.

Pediatric patients (younger than 18 years) sustaining blunt renal trauma must be carefully evaluated for hematuria. Brown and colleagues (1998a) noted that children are at greater risk for renal trauma than adults after blunt abdominal injury. Morey and associates (1996) reported no significant renal injuries in 185 children when less than 50 RBCs/HPF were noted on microscopic examination of the urine. Children have a high catecholamine output after trauma, which maintains blood pressure until approximately 50% of blood volume has been lost. Therefore, shock is not a useful criterion in children to determine whether imaging studies should be performed. For pediatric patients, liberal use of studies should be considered (Buckley and McAninch, 2004).

Imaging Studies

The preferred imaging study for renal trauma is contrast-enhanced CT (Bretan et al, 1986; Federle et al, 1987). Highly sensitive and specific, CT provides the most definitive staging

information: parenchymal lacerations are clearly defined; extravasation of contrast-enhanced urine can easily be detected (Fig. 39–3); associated injuries to the bowel, pancreas, liver, spleen, and other organs can be identified; and the degree of retroperitoneal bleeding can be assessed by the size and dimensions of the retroperitoneal hematoma. Lack of uptake of contrast material in the parenchyma suggests arterial injury.

Currently, spiral CT is being used in many centers to evaluate renal injuries (Brown et al, 1998b). Although the rapidity of the study—2 to 3 minutes—is advantageous for demonstrating arterial and venous injuries, it is a major disadvantage in renal parenchymal injuries: contrast material has not had time to be excreted into the parenchyma and collecting system adequately; and parenchymal lacerations and urinary extravasation cannot be detected reliably. Repeated scanning of the kidneys 10 minutes after injection of contrast material demonstrates parenchymal and most collecting system injuries with great accuracy.

Findings on CT that suggest major injury are (1) medial hematoma, suggesting vascular injury; (2) medial urinary extravasation, suggesting renal pelvis or ureteropelvic junction avulsion injury; and (3) lack of contrast enhancement of the parenchyma, suggesting arterial injury.

One major limitation of CT is the inability to define a renal venous injury adequately. With normal arterial perfusion, the parenchyma appears normal and the collecting system may contain contrast material. A medial hematoma accompanying the preceding findings strongly suggests a venous injury.

Excretory urography has been used for years to evaluate urinary system injuries, but it has largely been replaced by CT. The exception is "single-shot" intraoperative IVP. The indications are uncommon, but when the surgeon encounters an unexpected retroperitoneal hematoma surrounding a kidney during abdominal exploration, the study can provide essential information. The technique is key to gaining important information and minimizing the time involved: only *a single film* is taken 10 minutes after intravenous injection (IV push) of 2 mL/kg of contrast material. If findings are not normal or near normal, the kidney should be explored to complete the staging of the injury and reconstruct any abnormality found.

Figure 39–3. Computed tomographic scan of a right renal stab wound (grade IV), demonstrating extensive urinary extravasation and large retroperitoneal hematoma.

Morey and coworkers (1999) have reported their experience with single-shot intraoperative IVP for the immediate management of renal injuries; in 50 patients, the film quality was adequate to avoid renal exploration in 32%. This report supports the value of this intraoperative imaging technique when done properly.

Arteriography is largely used to define arterial injuries suspected on CT or to localize arterial bleeding that can be controlled by embolization.

Sonography is being used with greater frequency in the immediate evaluation of injuries. It confirms the presence of two kidneys and can easily define any retroperitoneal hematoma. The study cannot clearly delineate parenchymal lacerations or vascular or collecting system injuries and cannot accurately detect urinary extravasation in the acute injury. With the advent of power Doppler, perhaps in the future more functional information will be obtainable in the acute injury phase.

Nonoperative Management

Significant injuries (grades II to V) are found in only 5.4% of renal trauma cases (Miller and McAninch, 1995). A hemodynamically stable patient with an injury well staged by CT can usually be managed without renal exploration; indeed, 98% of blunt renal injuries can be managed nonoperatively. Grade IV and V injuries more often require surgical exploration, but even these high-grade injuries can be managed without renal operation if carefully staged and selected (Fig. 39–4) (Santucci and McAninch, 2000; Santucci et al, 2004).

Penetrating trauma from gunshot or stab wounds to the kidney can be managed nonoperatively if carefully staged with CT. In our experience, 55% of renal stab wounds and 24% of gunshot wounds were appropriately managed nonoperatively in carefully selected patients with well-staged injuries (McAninch et al, 1991).

Patients with high-grade injuries (grades III to V) selected for nonoperative management should be observed closely with serial hematocrit readings and abdominal CT scans. Should bleeding persist or delayed bleeding occur, angiographic studies with embolization of bleeding vessels often suffice and obviate surgical intervention.

Endovascular stents have been used with reported success during angiography in patients with renal artery thrombosis occurring from intimal flaps (Goodman et al, 1998). Longer term follow-up and more cases are needed to determine whether this will be a successful management approach.

Isolated Renal Injuries

Approximately 80% to 90% of renal injuries have major associated organ injury that can affect the choice of renal injury management. The isolated renal injury, without significant associated injuries, occurs more commonly from blunt trauma and in most circumstances can be managed nonoperatively. The exception is major grade V vascular pedicle avulsion injuries.

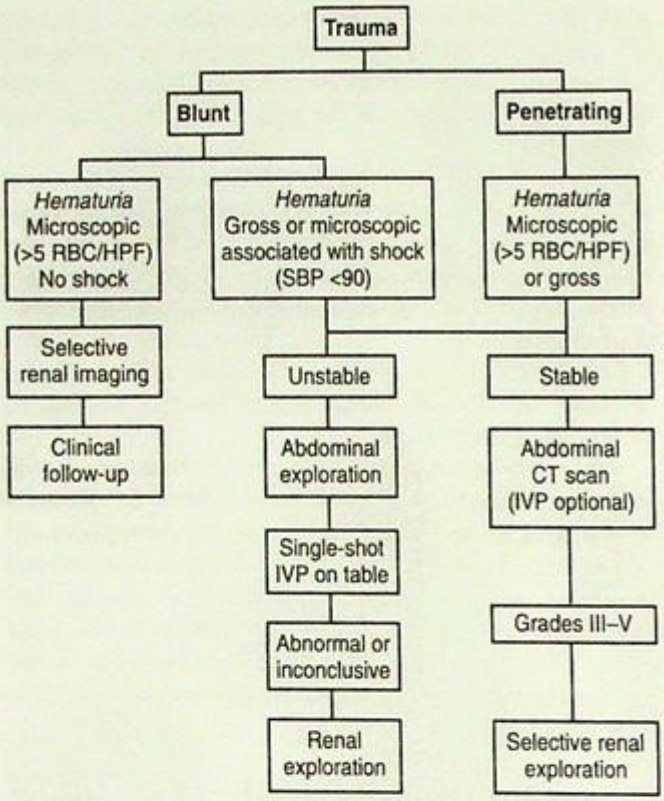

Figure 39–4. Flow chart for adult renal injuries to serve as a guide for decision-making. CT, computed tomography; IVP, intravenous pyelography; RBC/HPF, red blood cells per high-power field; SBP, systolic blood pressure.

Isolated renal injuries with parenchymal lacerations and even segmental arterial injury can have active bleeding well controlled by angiographic embolization. Interventional radiology skills and techniques allow selective embolization of even the smallest parenchymal vessels with maximal preservation of functioning parenchyma. However, one must recognize that renal vessels are end-arteries, and any selective vessel embolization results in tissue death peripheral to the embolized site.

Patients with grade IV parenchymal lacerations who have well-contained hematomas can be observed expectantly. They should be closely monitored for bleeding, with vital signs, serial hematocrit readings, and pulse rates. If urinary extravasation is present, serial renal CT scanning should be instituted. If significant urinary extravasation persists beyond 48 hours, placement of an internal ureteral stent for drainage often prevents prolongation of the extravasation and decreases the chance of perirenal urinoma formation.

If nonoperative management is selected for a patient with gross hematuria whose injury has been well staged with appropriate imaging, hospital admission and bed rest are required. Once the gross hematuria clears, ambulation is allowed; should gross hematuria recur, bed rest is reinstated. Ambulation without any sequelae allows hospital discharge with close clinical follow-up.

Operative Management

Indications for renal exploration after trauma can be separated into absolute and relative (McAninch et al, 1991). **Absolute indications include evidence of persistent renal bleeding, expanding perirenal hematoma, and pulsatile perirenal hematoma** (see Fig. 39–4). **Relative indications include urinary extravasation, nonviable tissue, delayed diagnosis of arterial injury, segmental arterial injury, and incomplete staging.**

Urinary extravasation alone from a grade IV parenchymal laceration or forniceal rupture can be managed nonoperatively with an expectation of spontaneous resolution in 87.1% of patients (Matthews et al, 1997). Should nonviable tissue constitute more than 20% in association with a parenchymal laceration or urinary extravasation or both, the potential for complications greatly increases and the choice of nonoperative management can be questioned (Husmann and Morris, 1990). Very often a combination of relative indications necessitates renal exploration (McAninch et al, 1991).

Segmental renal artery injury with an associated renal laceration results in a substantial amount of nonviable tissue (usually >20%), and such injuries usually resolve more quickly with surgical reconstruction and tissue removal. This approach often avoids the high complication rate noted when this group is observed without renal exploration (Husmann et al, 1993).

Incomplete staging is an important concern when determining whether renal exploration is needed. When the patient's critical condition necessitates surgical intervention before appropriate imaging studies and renal injury is obvious (manifested by perirenal hematoma or hematuria), single-shot intraoperative IVP should be done (see earlier). If findings are not normal, renal exploration provides the opportunity to complete the staging process and reconstruct a significant injury. Our experience in exploring over 200 renal units suggests that this approach is safe, without renal loss, and provides the opportunity to reconstruct high-grade injuries and prevent complications in the postoperative period.

Renal Exploration

Surgical exploration of the acutely injured kidney is best done by a transabdominal approach, which allows complete inspection of intra-abdominal organs and bowel. In some reported series of penetrating injuries, associated organ injury has been noted to be as high as 94% (McAninch et al, 1993). Injuries to the great vessels, liver, spleen, pancreas, and bowel can be identified and stabilized if necessary before renal exploration.

The surgical approach to renal exploration is shown in Figure 39–5 (McAninch and Carroll, 1989). The renal vessels are isolated before exploration to provide the immediate capability to occlude them if massive bleeding should ensue when Gerota's fascia is opened (Scott and Selzman, 1966). The transverse colon is lifted superiorly onto the chest, and the small bowel is lifted superiorly and to the right. This exposes the midretroperitoneum. An incision is made over the aorta in the retroperitoneum just superior to the inferior mesenteric artery. The incision is extended superiorly to the ligament of Treitz. Exposure of the anterior surface of the aorta is accomplished and followed superiorly to the left renal vein, which crosses the aorta anteriorly. With a vessel loop controlling the vein, the anatomic relationships of the right and left renal arteries as they leave the aorta provide the ability to isolate and secure these structures with vessel loops. The right renal vein can be secured through the incision; if this proves difficult,

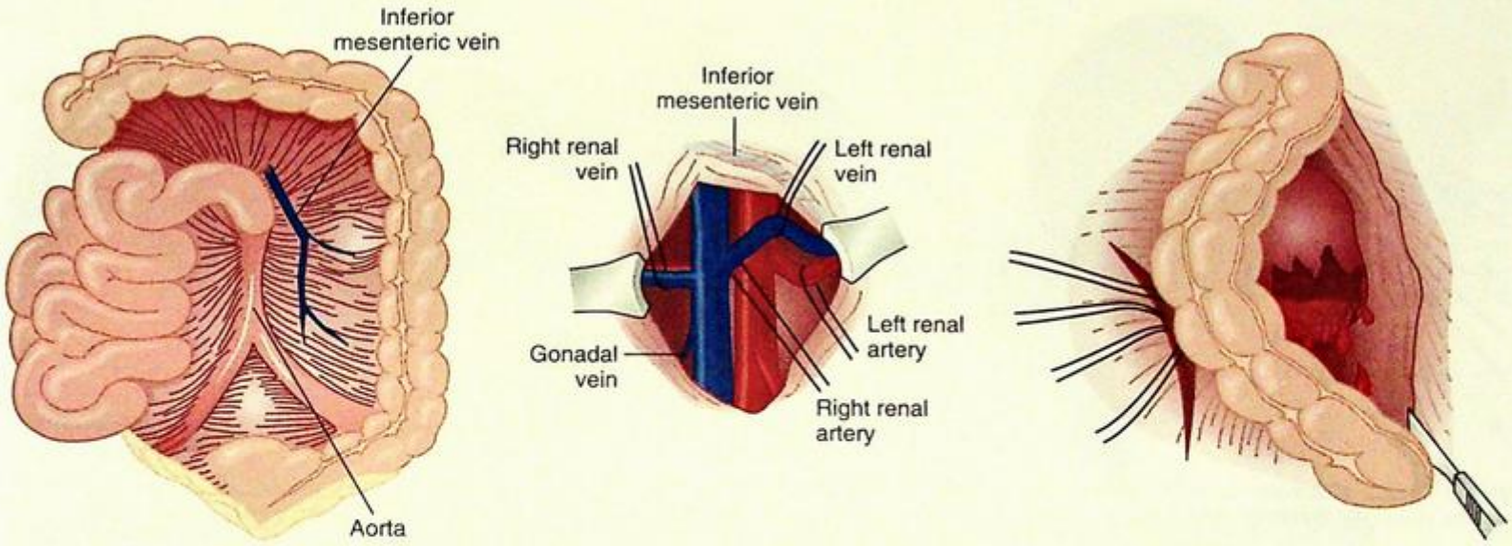

Figure 39–5. The surgical approach to the renal vessels and kidney: **A,** retroperitoneal incision over the aorta medial to the inferior mesenteric vein; **B,** anatomic relationships of the renal vessels; **C,** retroperitoneal incision lateral to the colon, exposing the kidney.

reflecting the second portion of the duodenum provides excellent exposure to the vein.

Large hematomas may extend over the aorta and obscure the landmarks for the planned initial retroperitoneal incision. In such instances, the inferior mesenteric vein can be used as an anatomic guide for an appropriate incision. By making the retroperitoneal incision just medial to the inferior mesenteric vein and dissecting through the hematoma, the anterior surface of the aorta can be identified and followed superiorly to the crossing left renal vein.

The kidney is exposed by incising the peritoneum lateral to the colon, followed by mobilization off Gerota's fascia. This maneuver often requires release of the splenic (left) or hepatic (right) attachments of the colon. Gerota's fascia is then opened and the kidney with injury is completely dissected from the surrounding hematoma. Should troublesome bleeding develop, the previously isolated vessels can be temporarily occluded with a vascular clamp or a vessel loop tourniquet.

Is Early Vessel Isolation Necessary? Renal bleeding is a major cause of nephrectomy in renal trauma. **Obtaining early vascular control before opening Gerota's fascia can decrease renal loss:** in a comparative series, the total nephrectomy rate was reduced from 56% to 18% (McAninch and Carroll, 1982). Carroll and coauthors (1989), evaluating the use of early vascular control, reported the need to occlude the vessels in 12% of renal explorations. In a series of 133 renal units in which early vessel isolation and control before opening Gerota's fascia was achieved in all, McAninch and associates (1991) reported a renal salvage rate of 88.7%.

The need for early vascular control has been questioned. Corriere and colleagues (1991) reported a series of renal units in which vascular control was obtained only if needed after opening Gerota's fascia. In this group, the total nephrectomy rate was 37.1%. Atala and coworkers (1991) reported a similar group of patients with a total nephrectomy rate of 36.2%. On the whole, the currently available data support an improved renal salvage rate with early vascular control.

Renal Reconstruction

The principles of renal reconstruction after trauma include complete renal exposure, débridement of nonviable tissue, hemostasis by individual suture ligation of bleeding vessels, watertight closure of the collecting system, and coverage or approximation of the parenchymal defect (Fig. 39–6).

Renorrhaphy denotes repair of a parenchymal laceration. The technique, illustrated in Figure 39–7, involves complete exposure of the kidney, débridement of nonviable tissue, hemostasis obtained with absorbable 4-0 chromic sutures on bleeding vessels (the addition of hemostatic agents may also be helpful), closure of the collecting system, and approximation of the margins of the laceration (3-0 absorbable suture) with the use of renal capsule and absorbable gelatin (Gelfoam) bolster.

When polar injuries cannot be reconstructed, a partial nephrectomy should be done and all nonviable tissue removed, hemostasis obtained, and the collecting system closed. The open parenchyma should then be covered when possible by a pedicle flap of omentum (see Fig. 39–6). With its rich vascular and lymphatic supply, omentum promotes wound healing and decreases the risk of delayed bleeding and urinary extravasation. Should it not be available, the use of absorbable mesh, peritoneal graft, or retroperitoneal fat has been successful.

In a high percentage of major renal injuries, intra-abdominal structures are also injured, the liver and spleen being the most common. Injuries to the colon, pancreas, and stomach also occur frequently, and in previous years total nephrectomy was suggested because of the high complication rate with attempted renal salvage. However, in our hands renal repair in these injuries has been successful with minimal complications (Rosen and McAninch, 1994; Wessells and McAninch, 1996). Drains should be used liberally in these repairs.

Renovascular Injuries. Vascular repair requires occlusion of the involved vessel with vascular clamps. The perforated main renal vessels injured by penetrating trauma can be repaired with 5-0 nonabsorbable vascular suture (Fig. 39–8). Main

Figure 39–9. **A,** Movement of the kidney from blunt trauma (deceleration injury) causes stretch on the renal artery, resulting in rupture of the arterial intima and formation of a thrombus. **B,** Computed tomography of a left kidney with renal artery thrombosis, demonstrating lack of contrast material perfusion to the kidney. **C,** Arteriography demonstrating complete occlusion of the left renal artery secondary to thrombus formation.

renal artery thrombosis from blunt trauma occurs secondary to deceleration injuries. The mobility of the kidney results in stretch on the renal artery, which in turn causes the arterial intima, low in elastic fibers, to disrupt; the consequent thrombus occludes the vessel, rendering the kidney ischemic (Fig. 39–9). Prompt diagnosis by CT or angiography should lead to immediate renal exploration in the appropriate candidate in an attempt to salvage the kidney.

Case reports of successful renal revascularization through the use of endovascular stents during angiography offer a new and perhaps promising approach to the problem of blunt trauma renal artery thrombosis caused by the intimal flap (Inoue et al, 2004). The great disadvantage of this approach has been the inability to effect anticoagulation, as this patient typically has bleeding from other organ injury. Attempts at surgical repair of renal artery thrombosis by a variety of techniques have largely failed.

With delayed diagnosis (>8 hours), the kidney typically cannot be salvaged (Cass, 1989). With a 15-year experience, Haas and coworkers (1998) have reported that surgical revascularization was seldom successful in renal artery thrombosis and at least 43% of their patients with repairs developed hypertension. Hypertension was also common in those observed nonoperatively. When repair is attempted in renal artery thrombosis, the area of injury (noted by a visible contusion on the vessel) should be excised and a replacement graft done, preferably with hypogastric or splenic artery. Many patients with renal vascular injury are critically injured, with numerous associated organ injuries; time constraints thus limit attempts at vascular repair and a nephrectomy must be done.

Segmental renal arterial injuries result in ischemic infarction to a segment of the kidney. These should be observed nonoperatively when diagnosed unless associated with a parenchymal laceration. Should the laceration with infarction be greater than 20% of the parenchyma, careful consideration should be given to surgical correction.

Injuries to the main renal vein require repair with fine vascular suture (5-0) (see Fig. 39–8). Partial occlusion of the vein is ideal for repair, but in some instances total occlusion with vascular clamps is necessary; if so, temporary occlusion of the renal artery is necessary.

Segmental venous injuries are best managed by ligation of the vessel. This can be done because of the collateral venous circulation of the kidney.

Damage Control

Coburn (2002) has noted the benefit of damage control to improve renal salvage. The wound and area around the injured kidney are packed with laparotomy pads to control bleeding with a planned return in 24 hours to explore and evaluate the extent of injury. This approach is commonly used by trauma surgeons in patients with extensive injuries and has long been used by general surgeons. It may well be useful in managing complex renal injuries to avoid total nephrectomy.

Indications for Nephrectomy

The ability to reconstruct an injured kidney depends on numerous factors. The unstable patient, with low body temperature and poor coagulation, cannot risk an attempt at renal repair if a normal contralateral kidney is present. As noted earlier, damage control (packing the wound to control bleeding and attempting to correct metabolic and coagulation abnormalities) with a plan to return for corrective surgery within 24 hours provides an option in management. Total nephrectomy would be indicated immediately in extensive renal injuries when the patient's life would be threatened by attempted renal repair. When Nash and colleagues (1995) examined the reasons for nephrectomy in patients with renal injuries, 77% required removal because of the extent of parenchymal, vascular, or combined injury and the remaining 23% required nephrectomy in otherwise reconstructable kidneys because of hemodynamic instability.

Complications

Persistent urinary extravasation can result in urinoma, perinephric infection, and renal loss. These patients are initially administered systemic antibiotics and carefully observed with appropriate antibiotics. In a high percentage, the extravasation resolves spontaneously (Matthews et al, 1997). Should it persist, placement of an internal ureteral stent often corrects the problem. A nonoperative approach with careful observation usually results in a functional renal unit.

Delayed renal bleeding can potentially occur several weeks after injury but usually occurs within 21 days. The initial management is bed rest and hydration. Should the bleeding persist, angiography can often localize the bleeding vessel and embolization can often gain control.

Perinephric abscess rarely occurs after renal injury, but persistent urinary extravasation and urinoma are the typical precursors. Percutaneous drainage offers a good initial method of management, followed by surgical drainage if necessary.

Hypertension is seldom noted in the early postinjury period (Monstrey et al, 1989), but postinjury blood pressure measurements are not obtained consistently, as patients often do not return for follow-up evaluation. The basic mechanisms for arterial hypertension as a complication of trauma are (1) renal vascular injury, leading to stenosis or occlusion of the main renal artery or one of its branches; (2) compression of the renal parenchyma with extravasated blood or urine; and (3) post-trauma arteriovenous fistula. In these instances, the renin-angiotensin axis is stimulated by partial renal ischemia, resulting in hypertension (Goldblatt et al, 1934; Crosgrove et al, 1973).

URETERAL INJURIES

Etiology

External Trauma

Ureteral injuries (Table 39–2) after external violence are rare, occurring in less than 4% of cases of penetrating trauma and less than 1% of cases of blunt trauma. During wartime in the past century, 3% to 15% of urologic injuries have involved the ureter, with an average of 5% over reports from World War II up to modern conflicts (Busch et al, 1967; Selikowitz, 1977; Marekovic et al, 1997). In the nonmilitary setting, a similar incidence of ureteral injuries is caused by civilian gunshot injuries. **These patients often have significant associated injuries and a devastating degree of mortality that approaches one third** (Medina et al, 1998). Associated visceral injury is common, predominantly small (39% to 65%) and large (28% to 33%) bowel perforation (Presti et al, 1989; Campbell et al, 1992; Medina et al, 1998). A significant percentage (10% to 28%) (Presti et al, 1989; Medina et al, 1998) of patients with ureteral injuries also have associated renal injuries. A smaller percentage (5%) have associated bladder injuries (Medina et al, 1998).

Table 39–2. **American Association for the Surgery of Trauma Organ Injury Severity Scale for the Ureter***

Grade†	Type	Description
I	Hematoma	Contusion or hematoma without devascularization
II	Laceration	<50% transection
III	Laceration	≥50% transection
IV	Laceration	Complete transection with <2 cm devascularization
V	Laceration	Avulsion with >2 cm devascularization

†Advance one grade for bilateral up to grade III.

The mechanism by which bullets injure the ureter is thought to be similar to the mechanism by which they injure analogous structures such as blood vessels, that is, not only by direct transection but by disruption of the delicate intramural blood supply and subsequent necrosis. In experimental models, such microvascular damage has been found as far away as 2 cm from the point of transection (Amato et al, 1970). This finding provides experimental support for the technique of débriding the ureter back to a bleeding edge after bullet injury to remove tissue that may have invisible microvascular damage. Some authors have even advocated injection of intravenous fluorescein and examination of the ureter by Wood's lamp to ensure viability (Gill and McRoberts, 1992); however, we have not found published evidence to support this technique.

Whereas penetrating trauma imparts a large degree of energy over a small area (as in the course of a bullet), **blunt trauma patients with ureteral injuries are subject to extreme force applied over the entire body. The great degree of energy imparted to the victim is associated with such uncommon injuries as fractured lumbar processes** (Evans and Smith, 1976) **and thoracolumbar spinal dislocation** (Campbell et al, 1992). The presence of these injuries in the blunt trauma patient should always increase the level of suspicion for ureteral injury.

Penetrating trauma victims with any degree of hematuria or a wound pattern that suggests the possibility of genitourinary injury should be imaged. Blunt trauma patients with gross hematuria or microhematuria plus hypotension, a history of significant deceleration, or significant associated injuries should be imaged (Mee and McAninch, 1989). A

history of rapid deceleration was found in 100% of patients with ureteropelvic junction (UPJ) injury in one small series (Boone et al, 1993).

The rare entity of UPJ disruption consequent to blunt trauma is often missed because the patients do not always exhibit hematuria, and the injury is difficult to palpate during intraoperative manual examination (Boone et al, 1993). Because of this, we recommend abdominal CT with contrast and delayed images whenever possible (Mulligan et al, 1998) or, if time does not permit, an intraoperative "one-shot" pyelogram (2 mL/kg intravenous contrast material given 10 minutes before flat plate abdomen radiograph). Typically, UPJ disruption is associated with an unusual pattern of either medial contrast extravasation (Kenney et al, 1987) (Fig. 39–10) or a "circumrenal" contrast extravasation (Kawashima et al, 1997).

Surgical Injury

Ureteral injuries can occur after a multitude of surgical procedures but largely result from surgeries in the pelvis (such as hysterectomy) and retroperitoneum (such as major vascular replacement). One report, which reviewed 13 previously published studies, concluded that **hysterectomy was responsible for the majority (54%) of surgical ureteral injuries. Next most common was colorectal surgery (14%), followed by pelvic surgery such as ovarian tumor removal and transabdominal urethropexy (8%), followed lastly by abdominal vascular surgery (6%)** (St Lezin and Stoller, 1991). One series reported that repeat cesarean section can also result in a large number of ureteral injuries, in this case up to 23% of the reported ureteral injuries at one hospital (Ghali et al, 1999). The total incidence of ureteral injury after gynecologic surgery is reported to be between 0.5% and 1.5%, and after abdominoperineal colon resection it ranges from 0.3% to 5.7% (St Lezin and Stoller, 1991). Open urologic procedures, because they often occur in proximity to the ureters, were also responsible for a significant number (21%) of reported ureteral injuries in one series (Selzman and Spirnak, 1996).

Figure 39–10. Computed tomography showing right medial extravasation of contrast material in a patient with a renal pelvis laceration.

Intraoperative ureteral manipulation resulting in subsequent hydronephrosis is common after aortoiliac and aortofemoral bypass surgery (12% to 20%), but the course is benign in most (St Lezin and Stoller, 1991). Symptomatic ureteral stenosis, usually delayed in presentation by months, occurs in only 1% to 2% of these patients (St Lezin and Stoller, 1991; Adams et al, 1992). This is in contrast to the experience of patients who suffer ureteral injury during pelvic surgery such as sigmoidectomy or hysterectomy: without treatment, most of these patients are immediately symptomatic, suffer lasting complications, or require reconstructive surgery or nephrectomy (St Lezin and Stoller, 1991).

In patients undergoing intra-abdominal vascular surgery, risk factors for surgical injury of the ureter include reoperation, placement of a vascular graft anterior to the ureter (Adams et al, 1992), and large dilated arterial aneurysms that cause retroperitoneal inflammation that can involve the ureter. The majority (up to 85%) of surgical injuries to the ureter after vascular procedures are not recognized immediately (Adams et al, 1992). When symptoms of ureteral injury are present, they include flank pain (36% to 90%), fever, ileus, abdominal distention, and urinary fistula (St Lezin and Stoller, 1991; Adams et al, 1992).

Since the inception of laparoscopic surgery in the 1960s, ureteral injuries have resulted during these procedures, although they were not widely reported until the early 1970s (Grainger et al, 1990). At first, laparoscopy was developed and perfected only for gynecologic indications, but the explosion of laparoscopy into other surgical specialties has meant that the incidence of ureteral injury after minimally invasive surgery has likewise skyrocketed. At one center, the incidence of ureteral injuries from laparoscopy went from 0% of all reported ureteral injuries in the early 1980s to 25% of all the reported ureteral injuries only 5 years later (Assimos et al, 1994). Currently, the reported rate of ureteral injury during laparoscopic surgery varies between 0.5% (experienced surgeons) and 14% (inexperienced surgeons) after laparoscopic hysterectomy cases, for example (Harkki-Siren et al, 1999; Cosson et al, 2001).

A large percentage of ureteral injuries after gynecologic laparoscopy occur during electrosurgical or laser-assisted lysis of endometriosis (Grainger et al, 1990). There are probably three reasons for this: (1) endometrioma can involve the ureter either extrinsically or intrinsically; (2) long-standing endometriosis can cause intraperitoneal adhesion, making ureteral visualization difficult (Ribeiro et al, 1999); and (3) the disease can deviate the ureters medially away from their normal anatomic position (Nackley and Yeko, 2000). A significant number of ureteral injuries also occur during tubal ligation, even when bipolar cautery is used (Grainger et al, 1990). The incidence of ureteral injury after laparoscopic hysterectomy severe enough to cause ureteral obstruction was 3.4% in a series of 118 patients (Ribeiro et al, 1999); however, in larger series with much higher numbers of patients and presumably more experienced surgeons, the rate was a more reasonable 1% (Harkki-Siren et al, 1999).

In contradistinction to open operation, where at least one third of ureteral injuries are recognized immediately (Rodriguez and Payne, 2001), **fewer injuries to the ureter are immediately identified after laparoscopy** (Grainger et al, 1990). **Therefore, during laparoscopy, a high index of suspi-**

cion for ureteral injury is required. Postoperatively, patients must be monitored for fever, peritonitis, and leukocytosis (Grainger et al, 1990), which herald the potential for missed ureteral injury. A smaller number of patients with missed ureteral injury present with hematuria or a pelvic mass representing urinoma (Grainger et al, 1990).

Avoidance of ureteral injury is predicated on intimate knowledge of its location, especially its relation to the uterine and ovarian arteries, if those structures are going to be ligated, as in a hysterectomy (Fig. 39–11). Visualization of the ureter in the area of the ureterosacral ligaments is thought to be especially difficult, and special care must be taken in this area (Grainger et al, 1990). It is axiomatic that ureteral injury is more likely in cases of uncontrolled bleeding, and adequate intraoperative hemostasis and surgical exposure should further decrease these injuries, even in high-risk cases. Intraoperative hydration or diuretic administration may enhance ureteral visualization and potentially further decrease the risk of injury. Preoperative ureteral stenting can be used to ease identification of the ureter in high-risk cases; however, published data in the gynecologic and colectomy population show that, although it may increase intraoperative *recognition* of ureteral injury, it may not actually decrease ureteral injuries (Leff et al, 1982; Bothwell et al, 1994; Kuno et al, 1998). Ureteral stents are not without complications: the rate of anuria after ureteral stent removal has been reported between 1% and 5% (Leff et al, 1982; Sheikh and Khubchandani, 1990; Kyzer and Gordon, 1994), and the rate of iatrogenic ureteral injury during stent placement 1% (Bothwell et al, 1994). One study showed that stents may even increase rather than reduce the chance of intraoperative injury (Dowling et al, 1986). Ureteral stents cannot be placed on one side in 13% of cases, and total failure to place either catheter can occur in 2% (Bothwell et al, 1994) Fiberoptic catheters have been used with good effect (Ben-Hur and Phipps, 2000), although rare complications of ureteral edema and obstruction have been reported after their use (Chahin et al, 2002). Finally, some authors recommend injection of 5 to 10 mL of intravenous indigo carmine dye followed by cystoscopy to ensure patency of the ureters after laparoscopic hysterectomy. When this technique was used in 118 patients undergoing laparoscopic hysterectomy, 4 of 4 cases of ureteral occlusion were identified immediately (mostly caused by suture ligation) and repaired immediately without complications (Ribeiro et al, 1999).

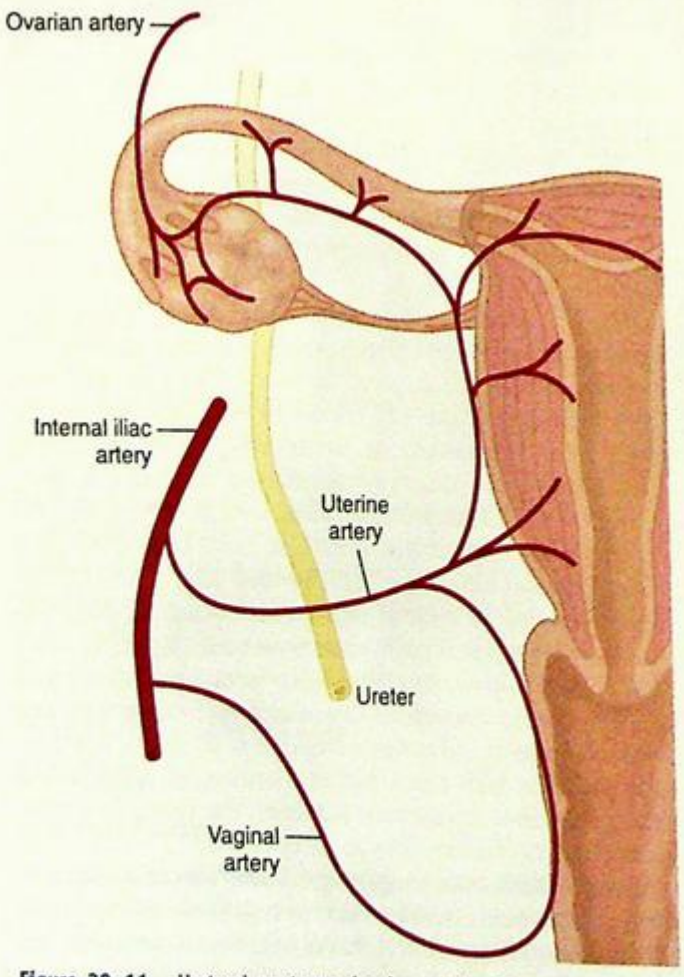

Figure 39–11. Ureteral anatomy showing relationship to fallopian tube and uterine artery.

Ureteroscopic Injury

Ever since Kaufman first reported ureteral injury after rigid ureteroscopy in 1984, countless ureteral injuries have resulted from this common procedure. For example, Huffman (1989) reported an explosion of ureteral injuries after ureteroscopy became widely used in the late 1980s. Improvements in equipment and operator experience subsequently decreased the rate of ureteral perforation to a stable average of 7% in the 1990s (range 0% to 28%) (Huffman, 1989). More recent expert series have a perforation rate of 1% to 5% (Schuster et al, 2001), of which 0.2% require open surgery (Butler et al, 2004). One factor cited as a cause of ureteral injury during ureteroscopy was persistence of stone basket attempts after recognition of ureteral tear. Current recommendations are to stop the procedure and place a ureteral stent when ureteral perforations are identified (Chang and Marshall, 1987). The wide use of the holmium:yttrium-aluminum-garnet (Ho:YAG) laser to fragment larger stones before basket manipulation is attempted should further decrease the potential for this complication (Bagley et al, 2004). It is also recommended to perform ureteroscopy alongside or over a wire placed up into the renal pelvis (Chang and Marshall, 1987; Flam et al, 1988), although some experts no longer use a safety wire during routine flexible ureteroscopy (Bratslavsky and Moran, 2004). This wire facilitates not only safe ureteroscopy but also placement of a ureteral stent later in the case if necessary. **Factors associated with higher complication rates during ureteroscopy were longer surgery times, treatment of renal calculi, surgeon inexperience, and previous irradiation** (Huffman, 1989; Schuster et al, 2001). During stone fragmentation attempts, electrohydraulic lithotripsy is associated with the highest risk of ureteral injury, followed by the neodymium:YAG (Nd:YAG) laser and finally by the Ho:YAG laser (Johnson and Pearle, 2004). Factors that are thought to protect against ureteral injury are smaller ureteroscopes (Flam et al, 1988; Huffman, 1989) and flexible ureteroscopes (Huffman, 1989).

Diagnosis

Gunshot and Stab Wounds

Incidence of Hematuria. ...cause many (25% to 45%) cases of ureteral injury after ... ...nce do not demonstrate even

microscopic hematuria (Presti et al, 1989; Campbell et al, 1992; Brandes et al, 1994; Palmer et al, 1999), a high index of suspicion is required in cases of potential ureteral injury after penetrating trauma. Attention to the course of the bullet or knife and wide use of imaging may decrease the rate of delayed appreciation of these wounds.

Intraoperative Recognition. In an analysis of five previously published reports concerning ureteral injury from external violence, Armenakas (1999) noted that 93% of injuries were recognized promptly, including 57% that were identified intraoperatively. We and others (Brandes et al, 1994; Medina et al, 1998) make every attempt to diagnose these injuries during exploratory laparotomy, which is required in 80% to 100% of cases involving the population of patients most at risk for ureteral injury (Pitts and Peterson, 1981; Palmer et al, 1983; Campbell et al, 1992). Intraoperative detection requires a high degree of suspicion, but there is evidence that specific vigilance for ureteral injuries may decrease the incidence of missed injuries (McGinty and Mendez, 1977). The trajectory of the knife or missile must be carefully examined during laparotomy and ureteral exploration undertaken in all cases of potential injury. Liberal use of preoperative diagnostic tools (urinalysis, IVP, CT), even if imperfect, is helpful.

Vigilance for delayed presentation of ureteral injuries also allows detection of injuries missed on presentation. Fever, leukocytosis, and local peritoneal irritation are the most common signs and symptoms of missed ureteral injury and should always prompt CT examination. In contrast to acute injuries, "missed" injuries that are discovered more than 48 hours after injury are best delineated with retrograde ureterography.

Methylene Blue. If a ureter or renal pelvis injury is suspected intraoperatively, 1 to 2 mL of methylene blue dye can be injected into the renal pelvis with a 27-gauge needle to confirm the diagnosis. Care must be taken not to inject excessive dye as it can spill and stain local tissues, making determination of the source of leak impossible.

Imaging Studies

Excretory Urography. Ureteral injuries after external violence, unlike renal injuries, are difficult to detect with the usual array of diagnostic tools: preoperative urinalysis, CT scan, and intraoperative one-shot IVP. IVP is often unhelpful, proving nondiagnostic 33% to 100% of the time (Palmer et al, 1983; Presti et al, 1989; Campbell et al, 1992; Brandes et al, 1994; Azimuddin et al, 1998); however, in the absence of a better test, we still recommend intraoperative one-shot pyelography together with intraoperative inspection to detect ureteral injuries. When IVP abnormalities *are* found, obvious contrast extravasation can sometimes be seen (Fig. 39–12). However, IVP findings are often subtle and nonspecific, for example, delayed function, ureteral dilation, and ureteral deviation. Insensitivity of these usual diagnostic tools is one of the reasons why delay of detection occurs in a surprising 8% to 20% of cases (Presti et al, 1989; Brandes et al, 1994; Palmer et al, 1999).

Computed Tomography. CT is used increasingly in the evaluation of the trauma patient and, although it appears promising in detecting ureteral injuries (Kawashima et al, 2001), there are few published data to assess its accuracy to date (Kenney et al, 1987; Townsend and DeFalco, 1995).

Figure 39–12. Excretory urography demonstrating extravasation in the upper right ureter consequent to stab wound. Note lack of contrast *(arrow)* in the ureter below the site of injury, indicating complete ureteral transection.

Reports of the utility of CT in ureteral trauma are still limited to small numbers of cases.

Ureteral injuries can be difficult to diagnose on CT. If the urinary extravasation from the ureteral injury is contained by Gerota's fascia, the extent of medial leakage can be very small, obscuring the diagnosis (Kenney et al, 1987). It is also known that ureteral injuries often manifest with absence of contrast in the ureter on delayed images. This underscores the absolute necessity of tracing both ureters throughout their entire course on CT scans obtained to evaluate urogenital injuries (Townsend and DeFalco, 1995). In addition, because modern helical CT scanners can obtain images before intravenous contrast dye is excreted in the urine, delayed images must be obtained (5 to 20 minutes after contrast injection) to allow contrast material to extravasate from the injured collecting system, renal pelvis, or ureter (Brown et al, 1998; Mulligan et al, 1998; Kawashima et al, 2001). Because ureteral injuries are often detected late, periureteral urinoma seen on delayed CT scans may be diagnostic (Gayer et al, 2002).

In reported series, all patients with significant ureteropelvic laceration, for instance, had either medial extravasation of

contrast material or nonopacification of the ipsilateral ureter on CT (Kenney et al, 1987; Kawashima et al, 2001). Such findings should always raise suspicion for ureteral injury.

Retrograde Ureterography. Retrograde ureterograms are used in some centers as a primary diagnostic technique to detect acute ureteral injuries (Campbell et al, 1992); however, we tend to use noninvasive methods such as one-shot IVP and CT scan or to make the diagnosis intraoperatively when feasible. Retrograde ureterography is used, however, to delineate the extent of ureteral injury seen on CT scan or IVP if further clinical information is needed. Retrograde ureterography is most commonly used to diagnose missed ureteral injuries, as it allows the simultaneous placement of a ureteral stent if possible.

Antegrade Ureterography. Anterograde ureterography is seldom used in our practice. In cases in which ureteral injury is discovered, we most often plan retrograde ureterography and stent placement or open repair. If retrograde stent placement is not possible (usually secondary to a large gap in the two ends of the transected ureter), we use anterograde ureterography and stent placement at the time of percutaneous nephrostomy placement (Toporoff et al, 1992).

Management (Fig. 39–13)

External Trauma

Contusion

Ureteroureterostomy. Ureteral contusions, although the most "minor" of ureteral injuries, often heal with stricture or breakdown later if microvascular injury results in ureteral necrosis. **Severe or large areas of contusion should be treated with excision of the damaged area and ureteroureterostomy.**

Following certain general principles of ureteral surgery increases the success rate of this delicate surgery. Repair of the ureter must be meticulous (Fig. 39–14). Ureteral blood supply is tenuous, and a sequela of imperfect repair can be urine leakage that can result in the patient's debility, nephrectomy, and in rare cases even death. Principles of management of the injured ureter are as follows:

1. Mobilize the injured ureter carefully, sparing the adventitia widely, so as not to devascularize the ureter.
2. Débride the ureter liberally until edges bleed, especially in high-velocity gunshot wounds.
3. Repair ureters with spatulated, tension-free, stented (Palmer et al, 1983), watertight anastomosis; use optical magnification and retroperitoneal drainage afterward.
4. Consider omental interposition to isolate the repair when possible.

Ureteroureterostomy, or so-called end-to-end repair, is used in injuries to the upper two thirds of the ureter. It is required commonly, up to 32% of the time in large series (Presti et al, 1989; Elliott and McAninch, 2003), and has a reported success rate as high as 90% (Carlton et al, 1971). Complications after ureteroureterostomy, usually urine leakage, occur 10% to 24% of the time (Bright and Peters, 1977a; Pitts and Peterson, 1981; Presti et al, 1989; Campbell et al, 1992; Velmahos et al, 1996; Medina et al, 1998). Other acute complications include abscess and fistula. Chronic complications, usually comprising ureteral stenosis, are less common, involving approximately 5% (Palmer et al, 1999) to 12% (Velmahos et al, 1996) of patients. Interestingly, some authors report prolonged leakage of urine from the drain in patients with ureteral injury after external violence who underwent repair but otherwise did well. Steers and colleagues (1985) reported that most of their patients had persistent drainage (averaging 12 days) from the retroperitoneal Penrose drain after repair. This has not been our experience, but this observation might prompt watchful waiting in such patients who leak persistently after repair.

Management of dehiscence by percutaneous nephrostomy placement and ureteral catheter placement for at least 6 weeks has been reported in small studies, with a surprisingly good success rate (83% [Toporoff et al, 1992] to 88% [Lang, 1984]). Other authors have recommended stenting for a longer period, up to 8 weeks (Steers et al, 1985).

Rarely, acute nephrectomy is required to treat ureteral injury after external violence. Reasons for nephrectomy include associated severe visceral injuries (although damage control without nephrectomy is probably preferable acutely) or severe associated injury to the ipsilateral kidney when renal repair is not possible (McGinty and Mendez, 1977; Gill and McRoberts, 1992). Delayed nephrectomy may be required, because of poor renal function (which can sometimes be seen after delayed recognition of an obstructing ureteral injury), severe panureteral injury when ileal ureter or other reconstruction is impossible, or persistent ureteral fistula (especially vascular fistula) despite previous intervention (Ghali et al, 1999).

Internal Stenting. Minor ureteral contusions can be treated with stent placement. Caution must be exercised, however, as minor-appearing ureteral contusions may stricture later or break down secondary to unappreciated microvascular damage to the ureter. When in doubt, the injured portion of the ureter should be débrided and ureteroureterostomy used to repair the injury.

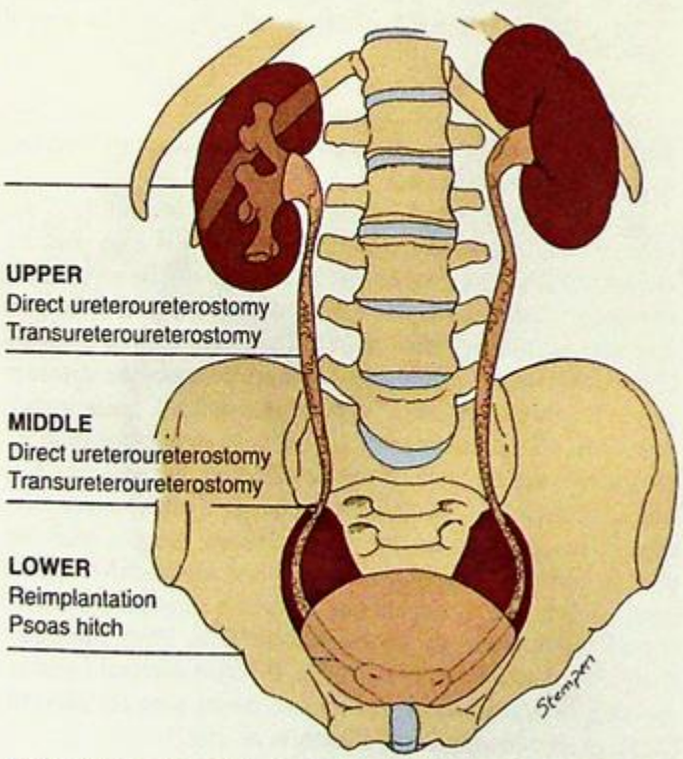

Figure 39–13. Suggested management options for ureteral injuries at different levels.

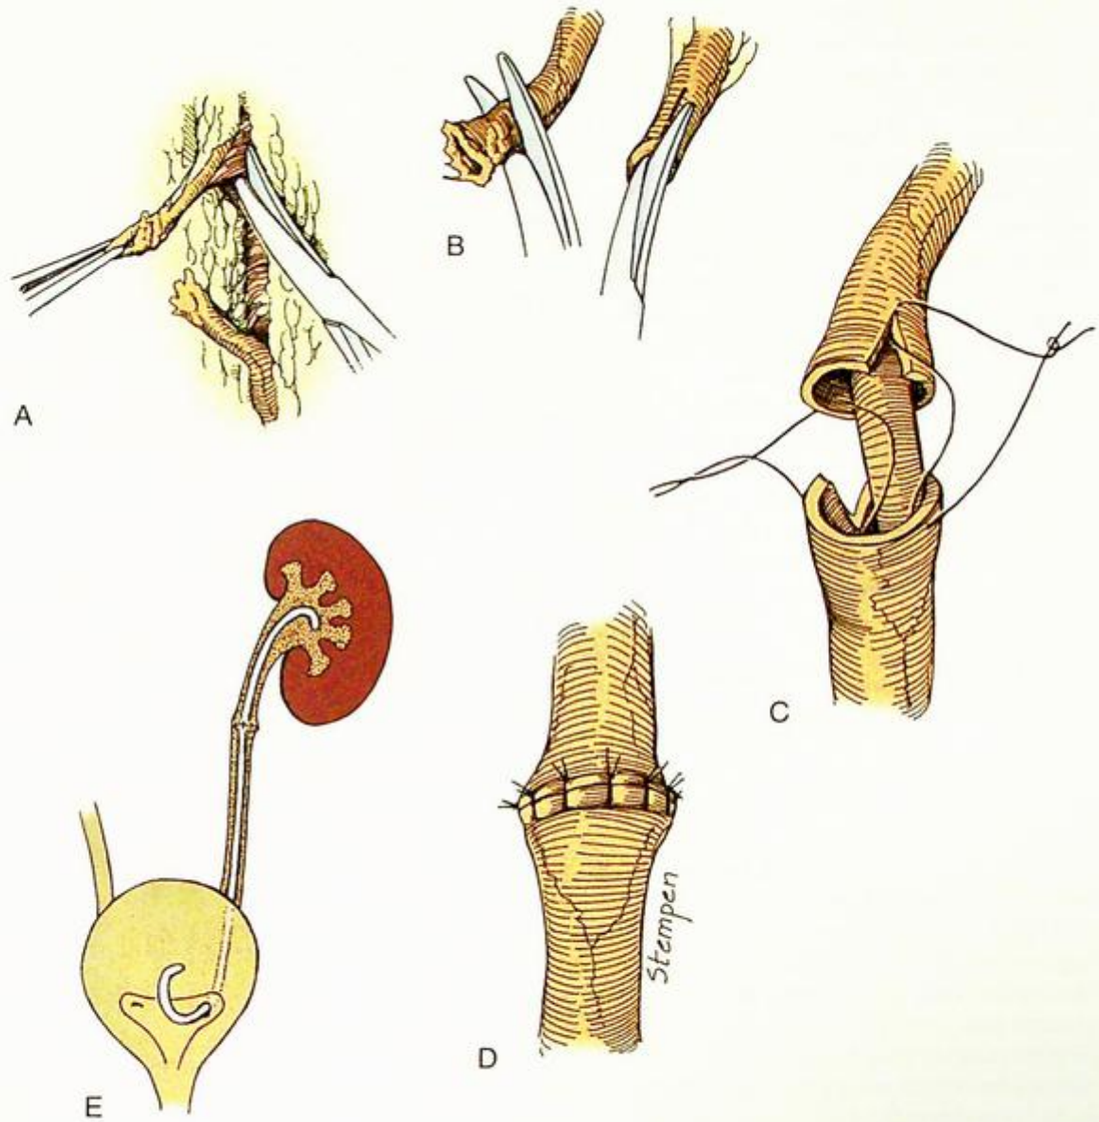

Figure 39–14. Technique of ureteroureterostomy after traumatic disruption: **A,** injury site definition by ureteral mobilization; **B,** débridement of margins and spatulation; **C,** stent placement; **D,** approximation with 5-0 absorbable suture; **E,** final result.

Upper Ureteral Injuries

Ureteroureterostomy. Ureteral avulsion from the renal pelvis, or very proximal ureteral injury, can be managed by reimplantation of the ureter directly into the renal pelvis. The principles of repair include spatulation, lack of tension, stenting, postoperative drainage, and a watertight anastomosis with fine nonreactive absorbable suture. Although the majority of these injuries are treated by open surgery (especially when not discovered immediately), laparoscopic repair of ureteral injuries is increasingly common in the literature (Tulikangas et al, 2001). Laparoscopic pyeloplasty in the absence of trauma is now quite common (Eden et al, 2004), and this procedure might mature into laparoscopic repair of traumatic UPJ avulsion in the future. Rarely, ureterocalycostomy, in which the ureteral stump is sewn end to side into an exposed renal calyx, can also be used where there is profound damage to the renal pelvis and UPJ (Matlaga et al, 2005).

Autotransplantation. Autotransplantation of the kidney has been used after profound ureteral loss or after multiple attempts at ureteral repair have failed. Renal units are sometimes lost after autotransplantation, occurring in 2 of 24 (8%) kidneys in one series (Bodie et al, 1986). The nephrectomy portion of the autotransplantation has been performed with laparoscopic techniques (Fabrizio et al, 2000; Meng et al, 2003).

Bowel Interposition. Delayed ureteral repairs, especially when a very long segment of ureter is destroyed, can also be performed by creation of a ureteral conduit out of ileum, much in the same way that an ileal conduit is constructed to drain the urine after cystectomy. Success rates for ileal replacement of the ureter have been reported to be 81% (Boxer et al, 1979; Verduyckt et al, 2002) to 100% (Bonfig et al, 2004; Matlaga et al, 2003). Some have used the Monti procedure, in which short segments of small or large bowel are formed into a long thin tube successfully in ureteral reconstruction (Ubrig et al, 2001; Ali-el-Dein and Ghoneim, 2003). The use of appendix has also been reported (Jang et al, 2002). Although most practitioners create a wide-open, refluxing, ileal replacement of the ureter, it appears that significant clinical reflux is not a problem (Waldner et al, 1999). Ileal interposition is not suggested for acute repair of ureteral injury but rather would be used in delayed or staged repairs.

Midureteral Injuries

Ureteroureterostomy: Transureteroureterostomy. A rarely used (Presti et al, 1989) but often (90% to 97%) successful (Rainwater et al, 1991; Sugarbaker et al, 2003) technique in adults is transureteroureterostomy. (Pediatric series show a lower success rate of 70% [Mure et al, 2000].) This form of repair involves bringing the injured ureter across the midline and anastomosing it end to side into the uninjured ureter and is most often performed as a secondary or delayed procedure. It might also be mandated in some cases of middle or distal ureteral injury, where ureteroureterostomy or bladder flap/hitch repair is impossible (usually because of severe bladder scarring, a congenitally small bladder, or a very long segment of missing ureter). However, transureteroureterostomy leaves the patient and urologist with some vexing problems postoperatively. The injured ureter becomes difficult to intubate or image with ureteroscopy through the bladder—ureteral access needs to be provided by a nephrostomy placed on the injured side. Some authors feel this operation is contraindicated in patients with a history of urothelial cancer or calculi, although this information is seldom available to the operating trauma surgeon. Caution is mandated in performing this procedure as it involves surgery on the uninjured, contralateral ureter with the theoretical risk of converting unilateral ureteral injury into (iatrogenic) bilateral ureteral injury. Instead of transureteroureterostomy, we have preferred either ileal ureter or ureteroureterostomy with renal mobilization if necessary.

Lower Ureteral Injuries

Ureteroneocystostomy. Ureteroneocystostomy is used to repair distal ureteral injuries that occur so close to the bladder that the bladder does not need to be brought up to the ureteral stump with a psoas hitch or Boari procedure. Principles of ureteroneocystostomy include creation of a submucosal tunnel for a nonrefluxing ureteral repair, usually a tunnel that is at least three times longer than the ureter is wide. A new ureteral orifice is constructed with the use of interrupted 6-0 monofilament absorbable sutures in a watertight and nonobstructing fashion. The repair should be stented postoperatively.

In some cases, a refluxing nontunneled anastomosis can be considered if ureteral length is insufficient for tunneling or if tunneling is thought by the surgeon to increase the risk of ureteral stenosis. Refluxing uretero-neobladder (Minervini et al, 2005) and uretero–ileal loop (Wiesner and Thuroff, 2004) anastomoses show no increase in complications related to urine reflux, although these populations of patients are different from the average trauma population and reports do not address whether ureteral implantation into the native bladder is equally safe. Further study is needed to resolve this issue.

Psoas Bladder Hitch. The psoas hitch procedure is a mainstay in the treatment of injuries to the lower third of the ureter and has a high success rate, from 95% to 100% (Middleton, 1980; Riedmiller et al, 1984; Ahn and Loughlin, 2001). It is preferred to ureteroureterostomy in this area because the tenuous independent blood supply might not survive transection.

Boari Flap. Injuries to the lower two thirds of the ureter with long ureteral defects (too long to be bridged by bringing the bladder up in the psoas hitch procedure) can be managed with a Boari flap or a transureteroureterostomy. In this case, a pedicle of bladder is swung cephalad and tabularized to bridge the gap to the injured ureter. The procedure is time consuming, however, and some have questioned its usefulness in the acute setting. The procedure is not commonly performed, but authors report a high success rate (Benson et al, 1990). Laparoscopic Boari flap has been described by one center of laparoscopic excellence (Fugita et al, 2001).

Partial Transection. Primary repair of a partial transection is used in the majority of ureteral injuries, up to 58% of the time in one large series (Presti et al, 1989). It must be limited to low-velocity gunshot wounds or stab wounds. Principles of primary repair involve spatulated, watertight closure under optical magnification, with interrupted or running 5-0 or 6-0 absorbable monofilament such as Maxon (polyglyconate) or Dexon (polyglycolic acid). The ureteral injury is closed by converting a longitudinal laceration into a transverse one so as not to narrow the ureteral lumen (Heineke-Mikulicz procedure). An internal stent and retroperitoneal drain are placed.

Damage Control. In cases of ureteral injury after external violence, it is sometimes necessary to treat the injured ureter by deferring definitive treatment until later. This is usually because the patient is too unstable to tolerate the operative time required to complete the repair (Cass, 1983). Some have suggested that in cases of severe hemorrhagic shock, uncontrollable intraoperative bleeding, or severe colon injury (especially those requiring colectomy), ureteral repair should be avoided in favor of nephrectomy or staged repair (Velmahos et al, 1996).

There are four options for damage control in ureteral injuries: (1) do nothing, but plan a reoperation when the patient is more stable, usually within 24 hours; (2) place a ureteral stent and do nothing else; (3) exteriorize the ureter; or (4) tie off the ureter and plan percutaneous nephrostomy (Hirshberg et al, 1994). In most cases of planned staged repair, we tie off the damaged ureter, using long silk ties to aid the dissection of the ureteral stump during the second-stage repair. The kidney is then drained percutaneously. We advocate percutaneous placement of a nephrostomy tube, either by the surgeon just postoperatively or later by interventional radiology specialists. We have found that intraoperative open nephrostomy placement can be too time consuming in these unstable patients. Other authors have advocated placing an 8 French feeding tube into the ureter and exteriorizing it until definitive repair can be completed (Gill and McRoberts, 1992).

Surgical Injury

Ligation. Ligation of the ureter should be treated by removal of the ligature and observation of the ureter for viability. If viability is in question, ureteroureterostomy or ureteral reimplantation should be performed (Assimos et al, 1994). Placement of a ureteral stent, either by opening the bladder or by immediate cystoscopic placement, is highly advised.

Transection

Immediate Recognition. Ureteral injuries that occur during vascular graft surgery are a special case. Intraoperative management of these injuries is debated and can uncommonly include nephrectomy, if the patient has an adequately

functioning contralateral kidney, versus primary ureteroureterostomy with isolation of the repair with omentum (Adams et al, 1992). Nephrectomy in cases of ureteral injury is controversial and should be considered only in limited situations, usually involving prosthetic graft surgery. The argument for nephrectomy is that, although it is a radical solution, it avoids the potential for postoperative urine leakage around an aortic or iliac vascular graft, which can be potentially fatal (Schapira et al, 1981). Nephrectomy must be performed with caution, however, as the mortality rate from renal failure in routine aortic aneurysmectomy is 3% and climbs to 12% in patients with a ruptured aneurysm (Schapira et al, 1981). The argument for repair also cites the risk of postoperative renal insufficiency after nephrectomy in this population. Although an accurate assessment of the complication rate after repair of ureteral injuries that occur during vascular surgery is not available, the risk of breakdown of ureteral repair after other surgeries has been reported to be 8% (Ghali et al, 1999) to 40% (Spirnak et al, 1989). In one small reported series, breakdown resulted in nephrectomy in two of two patients (Spirnak et al, 1989). We recommend careful repair of the ureteral injury, reserving nephrectomy for patients who develop urine leakage postoperatively.

Immediately discovered injuries after nonaortic surgery are largely treated in the same way delineated previously for ureteral injury after external violence. Most lacerations can be treated with ureteroureterostomy, although additional maneuvers such as omental wrapping of the repair or placement of an ipsilateral nephrostomy tube have been advocated to decrease the potential for urine leakage or breakdown of the repair (Adams et al, 1992). Although not yet commonly done, laparoscopic (Nezhat and Nezhat, 1992) and ureteroscopic (Tsai et al, 2000) ureteroureterostomies for operative ureteral injuries have been reported.

Delayed Recognition. Intraoperative recognition of ureteral injuries occurs in approximately 34% of patients undergoing open operation (Ghali et al, 1999) and sometimes in none of those undergoing laparoscopy (Grainger et al, 1990). Delayed diagnosis of ureteral injury is most often (66% [Ghali et al, 1999] to 76% [Grainger et al, 1990]) achieved by CT pyelography, IVP, or retrograde ureterography (Grainger et al, 1990). Patients present with a variety of signs and symptoms: anuria (5 of 35 patients, most with bilateral injury), urogenital fistula (4 of 35 patients), persistent pain or fever (3 of 35 patients), urinary leakage from the wound (3 of 35 patients), hydronephrosis (1 of 35 patients), and hematuria (1 of 35 patients) (Ghali et al, 1999). Some authors have cited a triad of fever, leukocytosis, and generalized peritoneal signs as being most diagnostic for missed ureteral injury (Medina et al, 1998). Repair of these delayed-recognition injuries is controversial. Some advocate immediate attempt at placement of a double-J ureteral stent (Bright and Peters, 1977b), but this is possible in only 20% (Ghali et al, 1999; Oh et al, 2000) to 50% (Cormio et al, 1993). When stent placement is possible, some authors have reported an ultimate success rate as high as 73% without the need for open surgery (Dowling et al, 1986). Usually, failure to place a stent is due to complete obstruction of the ureter or to too long a gap (Cormio et al, 1993). Some authors have suggested that stenting be avoided in patients who have had multiple pelvic operations, radiation therapy, or significant previous ureteral surgery, as they suffer high rates of failure (Chang and Marshall, 1987). The time required for stenting has never been studied in a randomized, prospective, double-blind fashion, but some authors recommend at least 6 weeks (Selzman and Spirnak, 1996). Some authors had a 100% success rate in treating late ureteral complications with a ureteral stent for 3 months (Cormio et al, 1993). Other authors reported much less satisfactory results with stenting: in a series of ureteral injuries after laparoscopy that were recognized late (3 to 33 days after surgery), all ultimately required open repair (Oh et al, 2000).

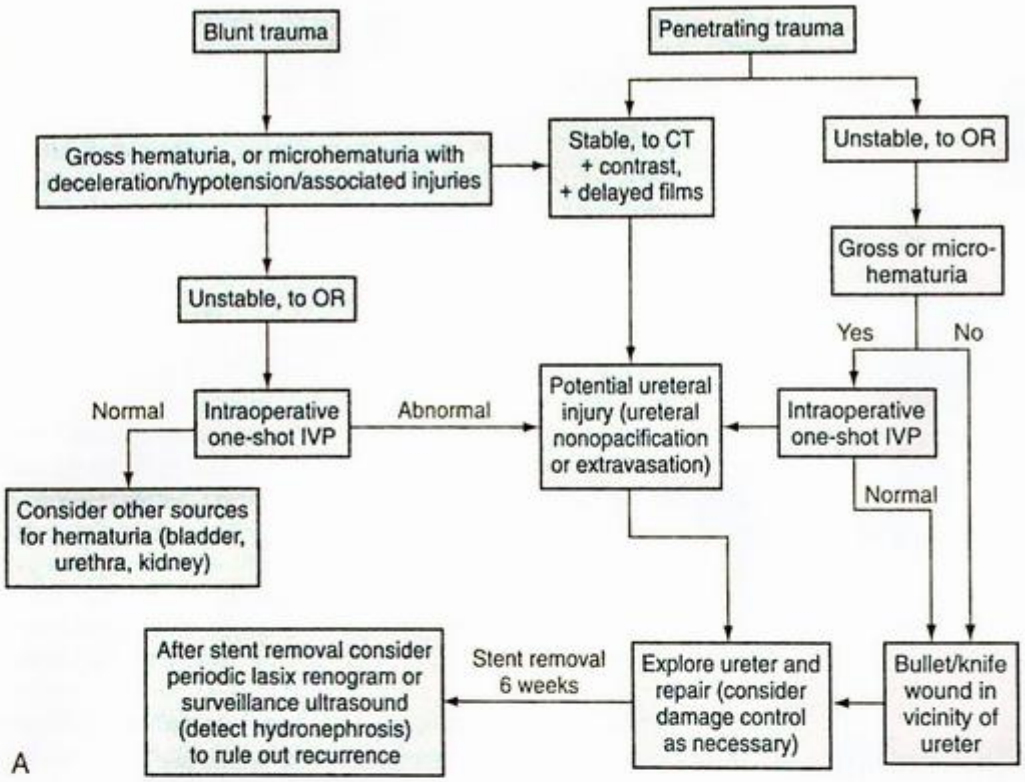
Although some suggest stent placement as the first line of therapy for ureteral injuries with delayed recognition, others recommend that these injuries be repaired in an open fashion as soon as possible. These authors cite low complication rates, which can be as low as in repair of injuries that are recognized immediately (Witters et al, 1986; Ghali et al, 1999). However, delayed diagnosis of ureteral injury itself increases the complication rate of the repair significantly (Selzman and Spirnak, 1996), from 10% to 40% in one series (Campbell et al, 1992), and some have advocated late repair (6 weeks) to allow maximal resolution of perioperative inflammation (Cangiano and deKernion, 1988).

We attempt retrograde placement of a ureteral stent in most cases of delayed recognition of ureteral injury. If stent placement is achieved, open repair is required only in patients with persistent leakage or ureteral stricture (Dowling et al, 1986; Cormio et al, 1993). In cases in which we cannot place a retrograde ureteral stent, we usually place a nephrostomy tube and make a gentle attempt at anterograde stenting of the injury. If this fails, we place a nephrostomy tube and wait 7 to 14 days to reattempt anterograde ureteral stenting. Ureteral balloon catheters, which stop urine from traveling down the ureter, may be required if simple stenting does not eliminate associated urine leakage or urinoma. If the ureter ultimately cannot be stented, we believe the safest approach is to allow at least 6 weeks for complete healing of the wounds, then attempt open repair. Some have reported the requirement for even longer ureteral drainage in some specialized cases, such as in the presence of ureteroenteric fistula (Bright and Peters, 1977b). We recognize that some experts in the field repair these injuries whenever they are discovered, with seemingly good results (Bright and Peters, 1977b; Flynn et al, 1979; Blandy et al, 1991; Oh et al, 2000).

Some authors have advocated treating postinjury ureteral stenosis endoscopically with either balloon dilation (Richter et al, 2000) or laser incision (Singal et al, 1997; Patel and Newman, 2004). Others have used endoluminal stents for ureteral obstruction after injury with good results in very limited numbers of patients (Yohannes et al, 2001). We personally have had poor results after endoscopic dilation and incision techniques in the long, devascularized, postinjury or postoperative ureteral strictures that seem to dominate our practice, although we often try them in short strictures before open repair is contemplated. Metal endoluminal stents must be considered experimental until large series validate their use.

Ureteroscopy Injury

Avulsion. Ureteral avulsion during ureteroscopy is treated in the same manner as ureteral injuries after open or laparoscopic surgery, as detailed in the previous section.



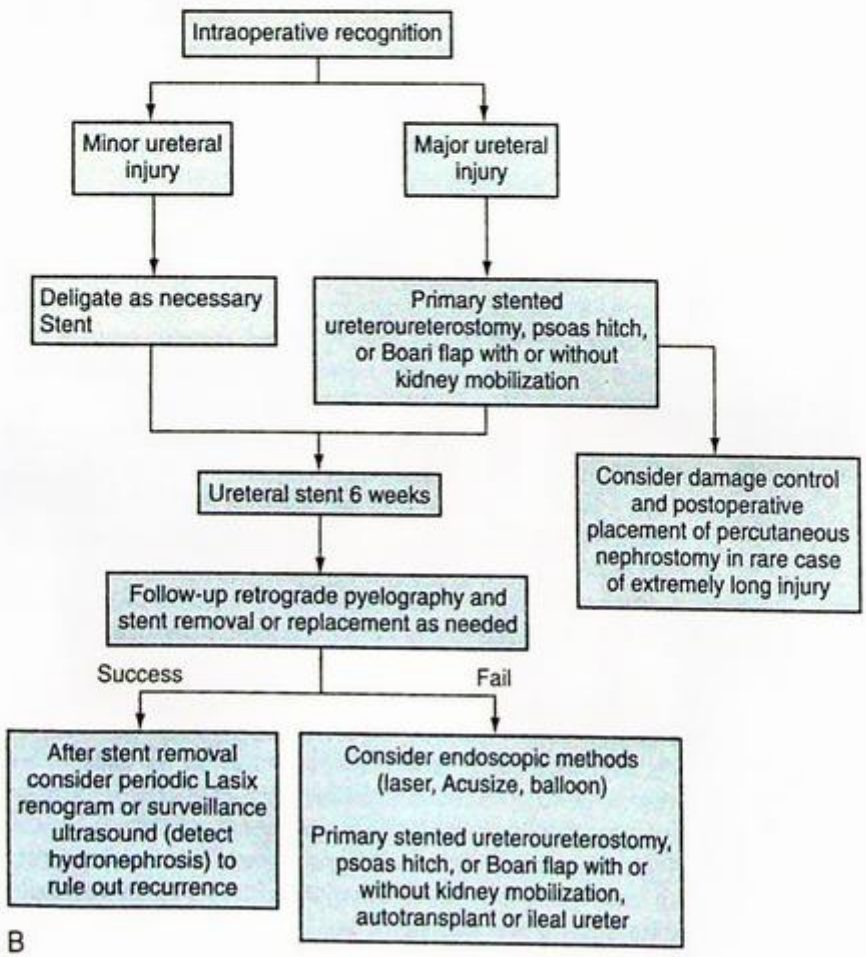


Figure 39–15. Algorithms for the diagnosis and treatment of ureteral injuries: **A**, from external violence; **B**, discovered intraoperatively.

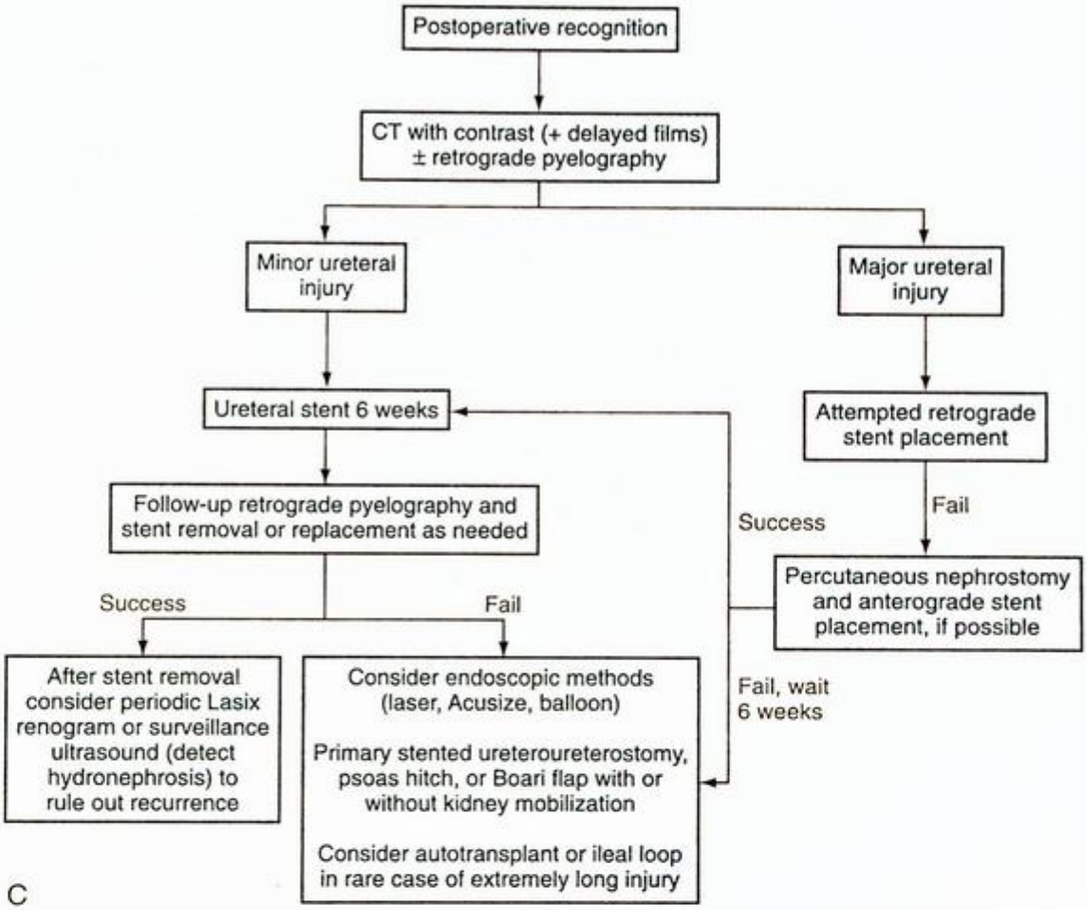

Figure 39–15, cont'd C, discovered postoperatively. CT, computed tomography; IVP, intravenous pyelography; OR, operating room.

Perforation. Ureteral perforation can be treated by ureteral stenting, usually with no subsequent complications (Flam et al, 1988; Huffman, 1989). The safest approach is to avoid injury by performing ureteroscopy over a ureteral guide wire. The next safest approach is to use a second ureteral "safety wire" that is always in place during ureteroscopy and facilitates ureteral stent placement in the presence of problems. We recognize that some expert centers do not use a ureteral guide wire during ureteroscopy and that some no longer use a safety wire (Bratslavsky and Moran, 2004), but we believe that a safety wire is most prudent for the majority of practitioners. (Fig. 39–15).

KEY POINTS: URETERAL TRAUMA

Ureteral injuries must be carefully searched for, or they will be missed.

- Intraoperatively, surgically expose and inspect the ureter when necessary:

After penetrating injury, use CT scan and intraoperative one-shot IVP liberally.

After penetrating injury, determine the course of the knife or bullet tract to ensure that the ureter is not at risk.

- If delayed recognition is suspected, use retrograde pyelography aggressively.

Successful repair of ureteral injuries, whether from external violence or surgical misadventure, is predicated on the use of well-vascularized tissue.

- Ureteral viability must be ensured by interval removal of nonviable segment before ureteroureterostomy.
- Tenuously viable distal ureter is bypassed by sewing the bladder to the uninjured proximal ureteral stump.
- Upper ureteral injuries can be removed and the ureter reimplanted into the renal pelvis after renal mobilization.

Avoidance of iatrogenic ureteral injury is of utmost importance.

- Safe ureteroscopy practices should be followed, including limiting ureteroscopy times, use of safety wires, and use of guide wires.
- Periureteral surgery should be undertaken with constant knowledge of its course.

SUMMARY

Kidney transplantation is the pioneer discipline in solid organ transplantation, and the relationship between transplant surgeon and nephrologist has served as a model for multidisciplinary team care.

Each renal transplantation operation is a study of pelvic anatomy, each deceased donor nephrectomy is a study of intraperitoneal and retroperitoneal anatomy, and each living donor nephrectomy is a surgical procedure on a kidney, procedures that are decreasing in frequency because of the development of nonoperative methods of treating renal stones and obstruction. Nowhere in urology must the principles of urinary tract reconstruction and infection control be more rigorously applied than in the immunosuppressed kidney transplant recipient. Understanding the molecular mechanisms of antigen-lymphocyte interactions in transplantation should provide insights into other disease processes such as cancer and infection. Renal preservation principles are often applied to parenchyma-sparing renal operations and to complex renovascular reconstruction procedures. As more renal transplantations are performed, more of these patients are likely to present to the practicing urologist for evaluation and preparation of the urinary tract for transplantation and for the care of urologic problems after transplantation, which may or may not be related to the transplantation surgery or to the consequences of immunosuppression.

END-STAGE RENAL DISEASE

Incidence and Prevalence

The estimated number of patients starting renal replacement therapy each year for end-stage renal disease (ESRD) in the United States is about 335 per million population (U.S. Renal Data System [USRDS], 2004). The median age of these new ESRD patients is 65 years. Both the prevalence and the incidence of ESRD are more common in elderly than in young patients, in men than in women, and in African Americans, Hispanics, and Native Americans than in whites. Diabetes mellitus is the most frequent cause of ESRD, followed in order by hypertension and glomerulonephritis. Diabetes is especially common among Native Americans, and hypertension is disproportionately high among African Americans. The incidence of ESRD is greater than that for any urologic malignancy except prostate cancer, and more patients die annually of ESRD than from any urologic malignancy (USRDS, 2004: Hoyert et al, 2005; Jemal et al, 2005).

Treatment Options

The purposes of renal replacement therapy are to prolong and to maintain the quality of life. **The treatment or treatments that are chosen for an individual patient are those that will allow the longest extension of useful life.** Renal replacement therapy is now considered to be a right in the United States and most other developed countries. Permanent renal failure in adults is commonly defined as an irreversible glomerular filtration rate of less than 10 mL/min or a serum creatinine level of greater than 8 mg/dL (United Network for Organ Sharing [UNOS], 1994). Patients with symptomatic uremia, especially children and diabetic adults, are considered on an individual basis as meeting criteria for permanent renal failure. A reasonable goal for ESRD treatment programs is the transplantation of all patients in whom the risk is equal to or less than that of remaining on maintenance dialysis. Renal

transplantation is the preferred method of therapy for most patients with ESRD because it is more cost effective and allows a return to a more normal lifestyle than maintenance dialysis does. A recent quality of life year (QALY) cost analysis strongly favored transplantation over dialysis (Mendeloff et al, 2004). The number of patients listed for kidney transplantation continues to expand disproportionately to the number of kidney transplantations performed annually. There are currently more than 60,000 patients waiting for deceased donor kidney transplants, and with about 9500 deceased donor kidney transplants performed annually, there are nearly seven times as many ESRD patients waiting as there will be deceased donor kidneys available in the coming year. Despite this obvious disparity, the number of deceased donor kidney transplants has increased only 22% over the past 10 years, and this is mostly due to the use of expanded criteria kidney transplants (Organ Procurement and Transplant Network [OPTN], 2005). The inadequate supply of deceased donor kidneys is one of the factors that has influenced the increase in the number of living donor kidney transplants by 120% in the past decade. The increase in living renal donation has been further facilitated by the widespread adoption of minimally invasive donor nephrectomy techniques, the increased use of living, biologically unrelated renal donors, and the development of protocols for transplantation across alloantibody barriers, including ABO blood group incompatibility. Xenotransplantation and tissue engineering are fields of research for the continuing problem of inadequate supply of transplantable organs.

In-center hemodialysis is the predominant form of therapy for adults with ESRD. In the United States, it accounts for more than one half of all treated ESRD patients (USRDS, 2004). Transplantation, however, is the predominant mode of care for patients younger than 20 years. About 10% of ESRD patients are treated with chronic peritoneal dialysis. A desire for self-care, a long distance from a hemodialysis unit, difficulties with hemodialysis therapy, serious cardiac disease, diabetes mellitus, and small stature are characteristics of patients especially suited for peritoneal dialysis. Unsuitable characteristics of patients for chronic peritoneal dialysis are considered to be obesity, hernias, poor hygiene, inflammatory bowel disease, and obliterated peritoneal space (Nicholson and White, 2001).

The advantages of living related donor renal transplantation compared with deceased donor renal transplantation are better probabilities of graft survivals, less recipient morbidity, specific planning of the operation to allow preemptive transplantation or limitation of the waiting time on dialysis, and partial alleviation of the insufficient supply of deceased donor kidneys. **The timing of preemptive renal transplantation must be such that the patient does not have months to years of usable function in the failing native kidneys.** Objections to transplantation before dialysis are that the procedure removes the experience of dialysis so that the advantages of transplantation are not appreciated and that of concern that a preemptive deceased donor kidney transplantation means that a patient has been unfairly advantaged over patients already on dialysis, some of whom have been waiting a long time for a kidney graft.

When compared with adults with ESRD, children are more likely to receive chronic peritoneal dialysis and they are more likely to undergo renal transplantation (USRDS, 2004). There is a relatively greater availability of parental kidney donors, and children receive preferential points when they are listed for deceased kidney transplantation. **Special problems in children with ESRD include growth failure, poor nutrition, and psychiatric problems.** They often suffer from a cycle of depression, anxiety, and loss of self-esteem, and these problems can result in family stress and divorce (National Institutes of Health [NIH] Consensus Development Conference, 1993). The development of recombinant growth hormone has made possible the treatment of short stature in pediatric patients with chronic renal failure and after renal transplantation (Fine, 1997). Nutritional supplementation can be done by nasogastric feeding tube or button gastrostomy.

Results of Treatment

Data from the USRDS indicate that survival after renal transplantation is significantly better than that of patients treated with dialysis (USRDS, 2004). Although this may simply mean that healthier patients are more likely to undergo a transplant, more controlled analyses have indicated a significantly reduced mortality risk for renal transplant recipients when compared with acceptable transplantation candidates waiting on dialysis (Meire-Kriesche et al, 2002). Regardless of whether the treatment modality is dialysis or transplantation, the major causes of death are, in order, heart disease, sepsis, and stroke (USRDS, 2004).

The survival of kidney grafts has steadily improved, and those for the current era are quite remarkable (Table 40–1).

HISTORY OF HUMAN RENAL TRANSPLANTATION

The history of renal transplantation illustrates the successful combination of the fields of surgery, medicine, immunology, and government. Carrel established the modern method of vascular suturing at the turn of the 20th century, and he was awarded the Nobel Prize in 1912 for his work on organ grafting (Hamilton, 2001). In 1933, the first human renal allograft was performed by Voronoy in the Ukraine (Hamilton and Reid, 1984). The recipient was a 26-year-old woman who had attempted suicide by ingesting mercuric chloride. The donor was a 66-year-old man whose kidney was removed 6 hours

Table 40–1. Kidney Transplant Survival Rates for Primary Transplants Done 1998-2002

Donor	No.	5 Year (%)	Half-Life (Yr)*

after death. Under local anesthesia, the renal vessels were anastomosed to the femoral vessels and a cutaneous ureterostomy was performed. A small amount of blood-stained urine appeared, but the patient died 48 hours after the procedure.

The first long-term success with human renal allografting, in which the patient survived for over a year, occurred in Boston in 1954, when a kidney from one twin was transplanted into the other, who had ESRD (Murray et al, 1955). In 1958, the first histocompatibility antigen was described. Radiation was used for immunosuppression in 1959, azathioprine became available for human use in 1951, and corticosteroids became part of a standard immunosuppression regimen with azathioprine in 1962 (Goodwin et al, 1963). In the same year, the first use of tissue matching to select donor-recipient pairs was done. The direct crossmatch between donor lymphocytes and recipient serum was introduced in 1966, and heterologous antilymphocyte serum was used as an immunosuppressant in human renal transplantation.

In the late 1960s, human renal preservation over 24 hours became possible with either pulsatile machine perfusion (Belzer et al, 1967) or simple cold storage after flushing with an ice-cold intracellular electrolyte solution (Collins et al, 1969). The beneficial effect of blood transfusions was described by Opelz and colleagues in 1973, and this led to immunologic conditioning with blood products for both deceased and living donor renal transplants. Donor-specific blood transfusions eventually became part of standardized pretransplantation immunologic conditioning protocols for living donor renal transplantation (Salvatierra et al, 1980). In the cyclosporine era, the beneficial effects of random blood transfusions and donor-specific blood transfusion protocols have been difficult to establish, and transfusion protocols have been associated with donor-specific sensitization and the transmission of viral illnesses. For these reasons, pretransplantation transfusion protocols are no longer routinely prescribed.

Medicare co-insurance for ESRD patients was passed into law in 1972 and instituted in 1973. This removed a significant impediment to renal transplantation in the United States. In the mid 1970s, brain-death laws were passed. This allowed organ retrieval from beating-heart deceased donors, reduced warm ischemia time, and improved the quality of deceased donor kidney grafts. The first clinical trials of cyclosporine were reported by Calne and colleagues in 1978, and this was followed 3 years later by reports of the successful use of a monoclonal antibody for the treatment of renal allograft rejection in humans (Cosimi et al, 1981). In 1984, Congress passed the National Transplant Act, which authorized a national organ-sharing system and grants for organ procurement. The University of Wisconsin (UW) solution, introduced in the late 1980s, provided one solution for the preservation of all transplantable abdominal organs, including kidneys (Belzer and Southard, 1988). Recombinant erythropoietin became available in 1989, and this significantly improved the quality of life for maintenance dialysis patients and reduced the need for blood transfusions (Carpenter, 1990). This has decreased the risk of virally transmitted infections and the risk of the development of anti-human leukocyte antigen (HLA) antibodies in potential kidney transplant recipients. Thirty-six years after the first long-term success of human-to-human kidney transplantation, Joseph E. Murray received the Nobel Prize in Medicine in 1990 for his pioneering work in renal transplantation.

Laparoscopic donor nephrectomy was introduced in 1995 to reduce disincentives for living donor nephrectomy (Schulam et al, 1996; Pradel et al, 2003).

The last decade has witnessed the development of novel immunosuppressive agents as well as approaches to graft tolerance that may allow reduction and, in some cases, complete discontinuation of chronic immunosuppressive agents (Matthews et al, 2003; Starzl et al, 2003).

SELECTION AND PREPARATION OF KIDNEY TRANSPLANT RECIPIENTS

The pretransplantation evaluation is a multidisciplinary process that is performed well in advance of the renal transplantation operation and immunosuppression. **The purposes of the evaluation are generally considered to be to diagnose the primary renal disease and its risk of recurrence in the kidney graft and to rule out active invasive infection, a high probability of operative mortality, noncompliance, active malignancy, and unsuitable conditions for technical success** (Barry, 2001; Kasiske et al, 2001).

Preliminary Screening

The process of evaluating the transplantation candidate is initiated by identifying the presence or absence of the risk factors at the top of the algorithm in Figure 40–1. Candidates with a history of substance abuse must have unannounced drug screens with negative results before continuing the process. Candidates with morbid obesity, defined as greater than 100 pounds over desirable body weight or a body mass index of greater than 35, must demonstrate weight reduction before continuing the process because of the risks associated with renal transplantation in obese patients (Glanton et al, 2003; Meier-Kriesche et al, 2003). Gastric bypass surgery may be an option to prepare dialysis-dependent morbidly obese patients for transplantation (Alexander et al, 2004). Candidates considered to be at risk for noncompliance must demonstrate contract satisfaction, for example, a hemodialysis-dependent patient may be required to maintain his or her serum phosphorus level less than or equal to 6 mg/dL, predialysis serum potassium level less than or equal to 6 mmol/L, and interdialytic weight gain less than or equal to 3 kg for 3 months. It is recommended that patients older than age 50 years or with a history of coronary artery disease, cardiac symptoms, or insulin-dependent diabetes mellitus undergo stress cardiac testing with further diagnosis and treatment of significant cardiac disease before proceeding with the rest of the algorithm (Lewis et al, 2002).

Kidney Disease Recurrence

Patients with focal segmental glomerulosclerosis, hemolytic-uremic syndrome, and primary oxalosis should be counseled about the significant probability of disease recurrence and the risk of secondary graft failure (Cameron, 1993; Jamieson, 1998; First and Peddi, 1999; Hariharan et al, 1999). Patients with a high risk of recurrent focal segmental

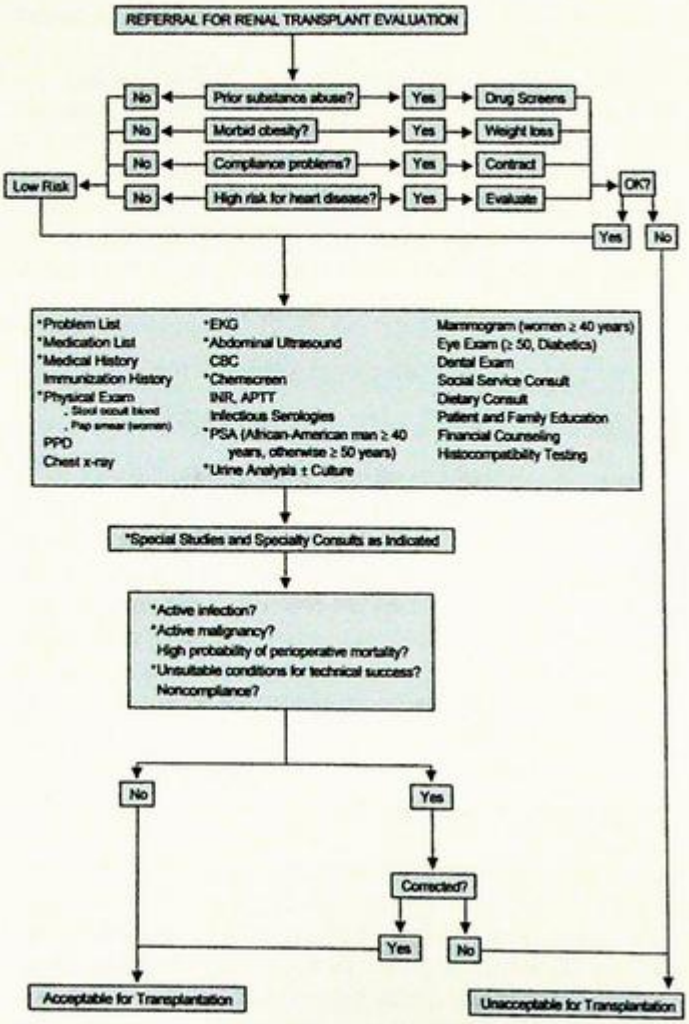

Figure 40–1. Algorithm for the evaluation of renal transplantation candidates. Circumstances may change the order in which data are obtained. APTT, activated partial thromboplastin time; CBC, complete blood cell count; EKG, electrocardiogram; INR, International Normalized Ratio; PPD, purified protein derivative (tuberculin skin test); PSA, prostate-specific antigen; PT, prothrombin time. *Asterisks* indicate items of special significance for the urologist. (From Barry JM: Current status of renal transplantation: Patient evaluations and outcomes. Urol Clin North Am 2001;28:677.)

glomerulosclerosis are those younger than 15 years of age, those who have a rapidly progressive course, and those with mesangial proliferation on biopsy of the native kidneys. If a first transplant has failed because of recurrent focal segmental glomerulosclerosis, the risk of recurrence in a second transplant approaches 80%. Hemolytic-uremic syndrome is a relatively common cause of ESRD in children, and recurrence has been associated with cyclosporine immunosuppression. Oxalosis can rapidly recur in a kidney graft, and this disease is probably best treated with combined liver and kidney transplantation to correct both the metabolic defect and the renal failure. The ESRD of renal amyloidosis, cystinosis, and Fabry's disease is potentially treatable with renal transplantation despite significant recurrence rates.

Diabetes mellitus and IgA nephropathy are examples of diseases that commonly recur in the transplanted kidney but rarely result in graft failure.

Autosomal dominant polycystic kidney disease (ADPKD), renal dysplasia, and Alport's syndrome without antiglomerular basement membrane antibodies are examples of renal diseases that do not recur in the transplanted kidney.

Infection

Infections must be detected and treated before transplantation or prevented with immunizations.

Potential sources of dental sepsis must be treated. Dialysis access sites must be clear of infection. Pulmonary infections or tuberculin skin test conversions require treatment before immunosuppression. Reasonable indications for pretransplantation cholecystectomy are considered to be symptomatic cholecystitis, multiple small gallstones, and cholelithiasis with gallbladder wall thickening. Segmental colectomy is reasonable for patients with recurrent diverticulitis because of the morbidity and mortality of bowel perforation in the immunosuppressed kidney transplant recipient (Salem et al, 2004). Diabetic foot ulcers must be healed before transplantation, and urinary tract infection should be inactive at the time of engraftment.

Serologic testing for cytomegalovirus (CMV) is important because this disease is a major cause of morbidity in immunosuppressed patients (Kaye, 1999). Patients who are seropositive for herpes simplex virus or who have a history of oral or genital herpes simplex or shingles need antiviral therapy during intense immunosuppression. Epstein-Barr virus titers are determined in children; and for the Epstein-Barr virus-seronegative child, a kidney from an Epstein-Barr virus—seronegative donor is preferred to reduce the risk of a post-transplantation lymphoproliferative disorder (Birkeland et al, 1999), the most common new malignancy in pediatric organ transplant recipients (Penn, 1998). Recipient human immune deficiency virus (HIV) infection has been considered to be a contraindication to renal transplantation, but successful outcomes have been reported in HIV-positive patients who have had low viral loads and sufficient CD4 T-cell counts (Stock et al, 2003). Chronic active hepatitis is a major cause of mortality in the late post-transplantation period. The treatment of chronic, active hepatitis B and C is evolving (Simon, 1999), and patients with active hepatitis C infection may benefit from antiviral therapy before transplantation (Mahmoud et al, 2005).

Corticosteroids enhance viral replication, and these infections should be inactive at the time of transplantation. Unless the patient is protected by antibody development after infection or prior immunizations, the following immunizations are given to transplantation candidates: hepatitis A, hepatitis B, pneumococcus, diphtheria, tetanus, pertussis, polio, varicella, measles, mumps, and rubella.

Active Malignancy

To reduce the risk of cancer recurrence, a waiting time of 2 to 5 cancer-free years from the time of the last cancer treatment is recommended for patients who have had invasive malignancies (Kasiske et al, 2001). Shorter intervals from cancer treatment to transplantation are generally accepted for patients who have had low-grade, noninvasive cancers. The application of cancer progression algorithms to recommend cancer-free intervals before transplantation may be helpful in individual cases (Secin et al, 2004). Cholecystectomy is

recommended for transplantation candidates with gallbladder polyps greater than 1 cm in diameter because of the risk of malignancy (Boulton and Adams, 1997).

High Probability of Perioperative Morbidity or Mortality

Heart disease is the predominant cause of death after renal transplantation (USRDS, 2004), and it is common for kidney transplantation candidates with a history of cardiac disease, cerebrovascular disease, or diabetes mellitus or who are older than 50 years to undergo a cardiac performance evaluation. Further testing and treatment are based on the results of a screening evaluation. Cerebrovascular disease, peptic ulcer disease, and significant pulmonary disease must be detected and treated. For example, patients with ADPKD and headaches or a family history of stroke should be screened for cerebral aneurysms. Cigarette smoking increases the risks of surgery, post-transplantation malignancy, cardiovascular disease, and renal allograft loss (Sung et al, 2001). It must be stopped before transplantation in patients who already have clinical evidence of vasculopathy or cardiopulmonary disease.

Noncompliance

Compliance issues are extremely important in the long-term management of kidney transplant recipients. Transplantation candidates with chemical dependency need to have an objectively documented drug- or alcohol-free period of at least 6 months before transplantation (Kasiske et al, 2001). Financial and psychosocial consultations are necessary to identify and correct problems that could result in noncompliance, for example, the lack of funds to pay for maintenance immunosuppressants or a mental handicap that could prevent the recipient from following a post-transplantation treatment plan.

Unsuitable Conditions for Technical Success

Evaluations of the vascular system and the urinary tract are necessary to identify problems that need to be corrected before transplantation or addressed at the time of transplantation.

Patients with symptoms and signs of lower extremity arterial disease or a history of abdominal or pelvic vascular surgery need to undergo a diagnostic evaluation to be certain that revascularization of a kidney graft is possible. Vascular screening with Doppler flow studies is recommended for the indications listed in Table 40–2. If significant arteriosclerosis or venous disease is detected, it may be necessary to perform angiography to select alternative sites, such as the aorta or splenic artery, for renal revascularization, or to plan corrective vascular surgery before renal transplantation.

Thrombosis is a significant cause of kidney transplant loss, especially in children (Singh et al, 1997). Renal transplantation patients at risk for graft thrombosis are those with previous vascular access thrombosis, previous venous thrombosis, antiphospholipid antibodies, and previous large vein renal transplant thrombosis (DeLoughery, 2004). A hypercoagulable state can occur in the nephrotic syndrome with urinary loss of the natural anticoagulants antithrombin III, protein C, and protein S. Hyperhomocysteinemia is common in ESRD, and it has been associated with thrombophilia (Levey et al, 1998). Antiphospholipid antibodies are found in 30% to 50% of patients with systemic lupus erythematosus, a systemic cause of ESRD. Patients can be evaluated with the activated protein C–resistant ratio (factor V Leiden mutation), protein C activity, protein S activity, antithrombin III activity, homocysteine level, prothrombin gene mutation, and antiphospholipid antibodies (DeLoughery, 2004; Irish, 2004). It is reasonable to screen for thrombophilia when a patient is admitted for renal transplantation, to administer low-dose heparin intraoperatively to all recipients, and to continue low-molecular-weight heparin therapy until the results of the thrombophilia panel are known. Based on the thrombophilia panel results, a decision can be made about intermediate- or long-term anticoagulation with low-molecular-weight heparin or warfarin.

The purposes of the urologic evaluation are to determine the suitability of the urinary bladder or its substitute for urinary tract reconstruction and to determine the necessity for removal of the native kidneys before or at the time of renal transplantation. The urologic evaluation includes a history for urologic disease and operations on the urinary tract; a physical examination, including the location of scars, abdominal catheters, and stomas that may interfere with transplantation; urinalysis; urine or bladder wash culturing; and ultrasonography of the abdomen and pelvis to include a postvoid bladder image, the kidneys, and the gallbladder. Further study of the urinary tract is indicated for a history of urologic abnormalities, nonglomerular hematuria, single-

Table 40–4. Indications for Pretransplant Nephrectomy

- Renal stones not cleared by minimally invasive techniques or lithotripsy
- Solid renal tumors with or without acquired renal cystic disease
- Polycystic kidneys that are symptomatic, extend below the iliac crest, have been infected, or have solid tumors
- Persistent antiglomerular basement membrane antibody levels
- Significant proteinuria not controlled with medical nephrectomy or angioablation
- Recurrent pyelonephritis
- Grade 4 or 5 hydronephrosis

organism bacteriuria, calculi, hydronephrosis, ADPKD, significant bladder residual urine, or inconclusive preliminary imaging studies (Table 40–3). The anuric patient will need to be queried about bladder function that was present before urine production ceased. In chronic peritoneal dialysis patients, ultrasound examination of the bladder may overestimate residual urine.

An ESRD patient with upper urinary tract diversion may have a bladder that is acceptable for transplantation, especially if the original reason for diversion was vesicoureteral reflux. **A defunctionalized bladder usually regains normal volume within weeks of transplantation.** It is advisable that transplantation candidates with small, contracted bladders who have had multiple lower urinary tract operations undergo bladder biopsy. If fibrosis is extensive on histologic examination and the bladder cannot be coaxed into becoming a low-pressure reservoir with bladder cycling, autoaugmentation or augmentation cystoplasty can be done before renal transplantation or afterward if satisfactory bladder function does not return within a few months (Barry, 2004). Functionalized augmentation is preferable to dry augmentation because it permits continence and bladder compliance to be documented before transplantation (Gonzales, 1997). A urothelium-lined augmentation is best because mucus does not have to be rinsed from the bladder on a regular basis. Advantages of gastrocystoplasty over enterocystoplasty are the lack of metabolic acidosis and significant mucus with the former. Disadvantages of gastrocystoplasty are the frequency-urgency syndrome due to acid from gastric mucosa and recalcitrant metabolic alkalosis. Patients with augmented bladders usually require clean intermittent catheterization after transplantation, and the patient should be trained in this technique well in advance of the transplantation procedure. **Clean intermittent self-catheterization has been used successfully in transplant recipients for more than 2 decades for patients with neuropathic bladders or transient bladder outlet obstruction** (Schneidman et al, 1984).

Cyclophosphamide is commonly used to treat immune complex glomerulonephritis, and a bladder wash for cytologic examination is recommended for patients with prior cyclophosphamide therapy because of its reported association with transitional cell carcinoma (Radis et al, 1995).

Renal transplants into intestinal conduits or continent intestinal pouches have been successful (Hatch et al, 2001; Surange et al, 2003). The pouches require frequent irrigations before transplantation to remove mucus and to maintain pouch volume.

Men with obstructing prostates whose voiding problems cannot be managed successfully with medical therapy are candidates for prostatectomy or transurethral incision of the bladder neck and prostate before or after transplantation. **Sometimes, it is possible to treat both hypertension and bladder outlet obstruction with one of the less specific α-adrenergic blocking agents, such as doxazosin or prazosin.** It is preferable to avoid surgical treatment of bladder outlet obstruction in the oligoanuric renal transplant candidate until after transplantation because of the risk of bladder neck contracture or prostatic fossa obliteration. If bladder outlet surgery is done pretransplant in the oligoanuric patient, it is advisable to place a suprapubic cystostomy at the time of bladder outlet surgery to allow the patient to instill sterile water and void daily until the operative site has healed, usually 6 weeks, or to have the patient perform daily intermittent self-catheterization, fill the bladder, and then void.

The generally accepted indications for pretransplantation nephrectomy are outlined in Table 40–4. Renal calculi can be managed by minimally invasive techniques, and severe proteinuria can be managed by renal infarction. **The incidence of renal cell carcinoma is more common in patients with acquired renal cystic disease and in transplant recipients than in the general population,** and nephrectomy is indicated for solid renal tumors (MacDougall et al, 1990). If a polycystic kidney extends below the iliac crest, it is best removed to allow room for a kidney transplant. Pretransplantation nephrectomy is usually performed 6 weeks before transplantation or active wait-listing for deceased donor renal transplantation to allow wound healing and the detection and treatment of surgical complications. It is common to perform kidney removal at the time of renal transplantation in children. It is common to do preliminary nephrectomies in adults, especially when the patient is to be listed for deceased donor renal transplantation, when recurrent pyelonephritis has been noted, or when difficult nephrectomy with possible adjacent

organ injury is anticipated. Bilateral nephrectomies for ADPKD at the time of renal transplantation have been reported (Glassman et al, 2000). We reserve this option for ADPKD patients who are undergoing living donor renal transplantation. The use of synthetic erythropoietin has reduced the effects of anemia while the patient awaits transplantation. Although laparoscopic or retroperitoneoscopic nephrectomies are becoming more commonly performed in these patients, bilateral vertical lumbotomies are quickly performed and well tolerated by patients with small kidneys undergoing nephrectomy (Freed, 1976). An open flank approach is often used when a kidney is too large to be removed by a vertical lumbotomy or a laparoscopic technique. The open abdominal approach is used when the kidneys are too large to remove with a minimally invasive technique, or when additional procedures, such as total ureterectomy, intestinal conduit removal, augmentation cystoplasty, the creation of a continent intestinal pouch, or the kidney transplantation are to be done at the same time.

Impotence is a significant problem in men with ESRD, and potency improves in a significant proportion of men after transplantation. Contributing factors to erectile dysfunction in ESRD are the accelerated arteriosclerosis associated with dialysis, hyperprolactinemia with secondary testosterone deficiency, side effects from antihypertensive drugs, and a poor self-image. **If penile prosthesis surgery is necessary before renal transplantation, a device that has no prevesical reservoir is recommended because a prevesical reservoir can interfere with urinary tract reconstruction and be mistaken for the urinary bladder until the reservoir has been accidentally incised.**

DONOR SELECTION, PREPARATION, AND SURGERY

The basic criteria for a renal donor are an absence of renal disease, an absence of active infection, and an absence of transmissible malignancy. Whether the kidney is removed from a living donor or a deceased donor, the surgical goals are to minimize warm ischemia time, to preserve renal vessels, and to preserve ureteral blood supply. In the deceased donor, it is also necessary to obtain histocompatibility specimens.

Living Donor

On the basis of the preoperative evaluation, one must be able to assure the living donor of nearly normal renal function after unilateral nephrectomy. On evaluation, if one of the potential donor's kidneys is better than the other, the better kidney is left with the donor (Murray and Harrison, 1963). It is preferable to use the right kidney from women who may become pregnant because hydronephrosis of pregnancy and pyelonephritis of pregnancy occur predominantly in that kidney (Stevens, 1933; Monga, 1998). An algorithm for the evaluation of a living renal donor is presented in Figure 40–2. Circumstances may change the order in which data are obtained. A living renal donor is considered to be unsuitable when one of the following is present: significant mental dysfunction, significant renal disease, high risk of perioperative mortality or morbidity, and significant transmissible disease. ABO incompatibility and a positive crossmatch between donor lymphocytes and recipient serum were usually considered to be contraindications to directed living renal donation, but protocols are evolving to deal with these issues (Warren et al, 2004). Serologic testing is performed for human immunodeficiency virus (HIV) and human T-lymphoproliferative virus type 1 (HTLV-1) infection, hepatitis, CMV infection, and syphilis. Some programs also screen for Epstein-Barr virus (Bia et al, 1995), especially when the recipient is a child. Diabetes mellitus is excluded in the donor by determining that the casual or random plasma glucose level is less than 200 mg/dL; the fasting plasma glucose level is less than 125 mg/dL; or after a 75-g glucose load, the 2-hour plasma glucose level is less than 200 mg/dL (Report of the Expert Committee on the Diagnosis and Classification of Diabetes Mellitus, 1997). Abdominal ultrasonography can be performed to exclude donors with significant renal abnormalities and to detect incidental intra-abdominal abnormalities. Diagnostic imaging techniques for living renal donors are compared in Table 40–5. Three-dimensional CT angiography without and with intravenous contrast material followed by

APTT, activated partial thromboplastin time; CBC, complete blood count; C & S, culture and sensitivity; EKG, electrocardiogram; GFR, glomerular filtration rate; PPD, tuberculin skin test; PSA, prostate-specific antigen; PT, prothrombin time; UA, urinalysis.

plain radiography of the abdomen has been widely accepted because it satisfactorily excludes stone disease, demonstrates renal and vascular anatomy, and defines the urinary collecting system, all with minimal donor morbidity and at reasonable expense (Tsuda et al, 1998; Pozniak and Lee, 1999).

Hyperfiltration injury has not been a significant problem for living renal donors. Endogenous creatinine clearance rapidly approaches 70% to 80% of the preoperative level, and this has been shown to be sustained for more than 10 years (Najarian et al, 1992). The development of late hypertension is nearly the same as for the general population, and the development of proteinuria is negligible (Steckler et al, 1990; Kasiske et al, 1995). The mortality of kidney donation has been estimated to be 0.02% (Matas et al, 2003), the risk of a potentially life-threatening or permanently debilitating complication has been estimated to be 0.23%, and there are isolated reports of ESRD developing in renal donors (Bia et al, 1995). **The short- and long-term risks of living donor nephrectomy are generally considered to be low enough, and the probability of successful graft outcome high enough, to make the risks acceptable for fully informed donors.**

Live donor nephrectomy can be performed either as an open or laparoscopically assisted procedure. Open live donor nephrectomy (ODN) is usually performed through a flank incision with a rib-resecting (Marchioro et al, 1964) or supracostal approach (Barry and Hodges, 1974), or by an anterior extraperitoneal incision (Jones et al, 1999). Laparoscopic donor nephrectomy (LDN) has become the preferred technique for live donor nephrectomy at most transplant centers in the United States (Ratner et al, 1999; Jacobs et al, 2004), and a retroperitoneoscopic approach for either kidney has been described (Yang et al, 2001). Regardless of the technique of living donor nephrectomy, diuresis is promoted by intravenous fluids, mannitol infusion, and loop of Henle diuretics. Overnight hydration of the living donor is unnecessary. It is common to prepare the LDN candidate with a clear liquid diet and a laxative the day before surgery.

Regardless of the technique, the upper pole of the kidney is usually mobilized early in the procedure, diuresis is confirmed by transecting the ureter and observing urine flow before interrupting renal circulation, and care is taken to preserve ureteral blood supply. A hand-assisted laparoscopic left donor nephrectomy is described in detail in Figure 40–3. General anesthesia is used. Epidural analgesia for pain management is optional. Nitrous oxide inhalation is avoided to prevent bowel distention. Intravenous fluids and mannitol are used to prevent oliguria associated with pneumoperitoneum. Right laparoscopic hand-assisted donor nephrectomy is slightly different from left donor nephrectomy. Positions of the monitor, surgical team, and patient and incision and trocar placements are the mirror images of those described for the left-sided procedure. However, the telescope is used through the right lower quadrant trocar, the left hand is placed through the hand assist device, and the upper trocar is used for working instruments operated with the surgeon's right hand. An additional 5-mm trocar is placed in the subxiphoid region through which a locking grasper can be placed for liver retraction. This grasper is used to lift the liver craniad, which is then clamped to the body wall. The remainder of the procedure is the same as for left nephrectomy, except for management of the renal vein. After clipping or stapling and dividing the renal artery, the renal vein is stapled with the Endo TA device placed through the upper trocar, across the renal vein, and flush with the inferior vena cava. The vein is incised with endoscopic scissors just beyond this staple line. Although it is not possible to obtain a small cuff of vena cava with this technique, the length of vein is usually adequate. It is unnecessary to administer and reverse heparin during ODN, but this is commonly done during laparoscopic donor nephrectomy because the renal vessels are sometimes divided between rows of vascular staples that must be removed after renal extraction and before core cooling is initiated by renal artery infusion of an ice-cold kidney preservation solution. The kidney is then taken in an ice bath into the recipient's operating room or cold-stored until the time of transplantation if that procedure is delayed. (See "Preparation of Kidney Graft.")

The reported advantages of LDN when compared with historical cases of ODN have been decreased analgesic requirement, decreased length of hospital stay, and an earlier return to work. The disadvantages have been reported to be increased operating time, donor surgeon preference for the left kidney, an increased need for special equipment, a longer warm ischemia time, and delayed graft function (Jacobs et al, 2004; Barry, 2005). Although initial renal transplant function may be somewhat slower to recover after LDN, and single center longer-term results are not significantly different from those of ODN (Goel et al, 2004; Tooher et al, 2004), registry data have indicated that 3-year kidney transplant survivals and projected half-lives of kidney transplants significantly favor the ODN flank approach over the LDN approach (Cecka, 2003). This difference in favor of ODN has been documented with the transplantation of adult kidneys into children (Troppman et al, 2005). Although LDN for right kidneys was initially associated with poorer results due to thrombosis of the shorter right renal vein, further experience with this technique has resulted in results equivalent to those reported for left LDN (Posselt et al, 2004). Emerging randomized trials of ODN versus LDN have reported equivalent renal transplant outcomes (Simforoosh et al, 2005).

Deceased Donor

The declaration of brain death is the responsibility of the potential deceased organ donor's physician.

The criteria for an ideal deceased kidney donor are normal renal function, no hypertension requiring treatment, no diabetes mellitus, no malignancy other than a primary brain tumor or treated superficial skin cancer, no generalized viral or bacterial infection, acceptable urinalysis, age between 6 and 50 years, and negative assays for syphilis, hepatitis, HIV, and human T-lymphoproliferative virus. Exceptions are made in an effort to expand the donor pool, resulting in the adoption of the "expanded criteria donor" (ECD). ECDs are defined as donors older than 60 years or donors 51 to 59 years old with any two of the following risk factors: cerebrovascular death, hypertension, and serum creatinine level greater than 1.5 mg/dL (Cecka, 2004). Blood is cultured if the donor has been hospitalized for more than 72 hours. ECD kidney transplant survival rates and those from donors younger than the age of 6 years and older than the age of 50 years are significantly inferior to those from ideal deceased donor kidney transplants (Cecka, 2003). The poorer

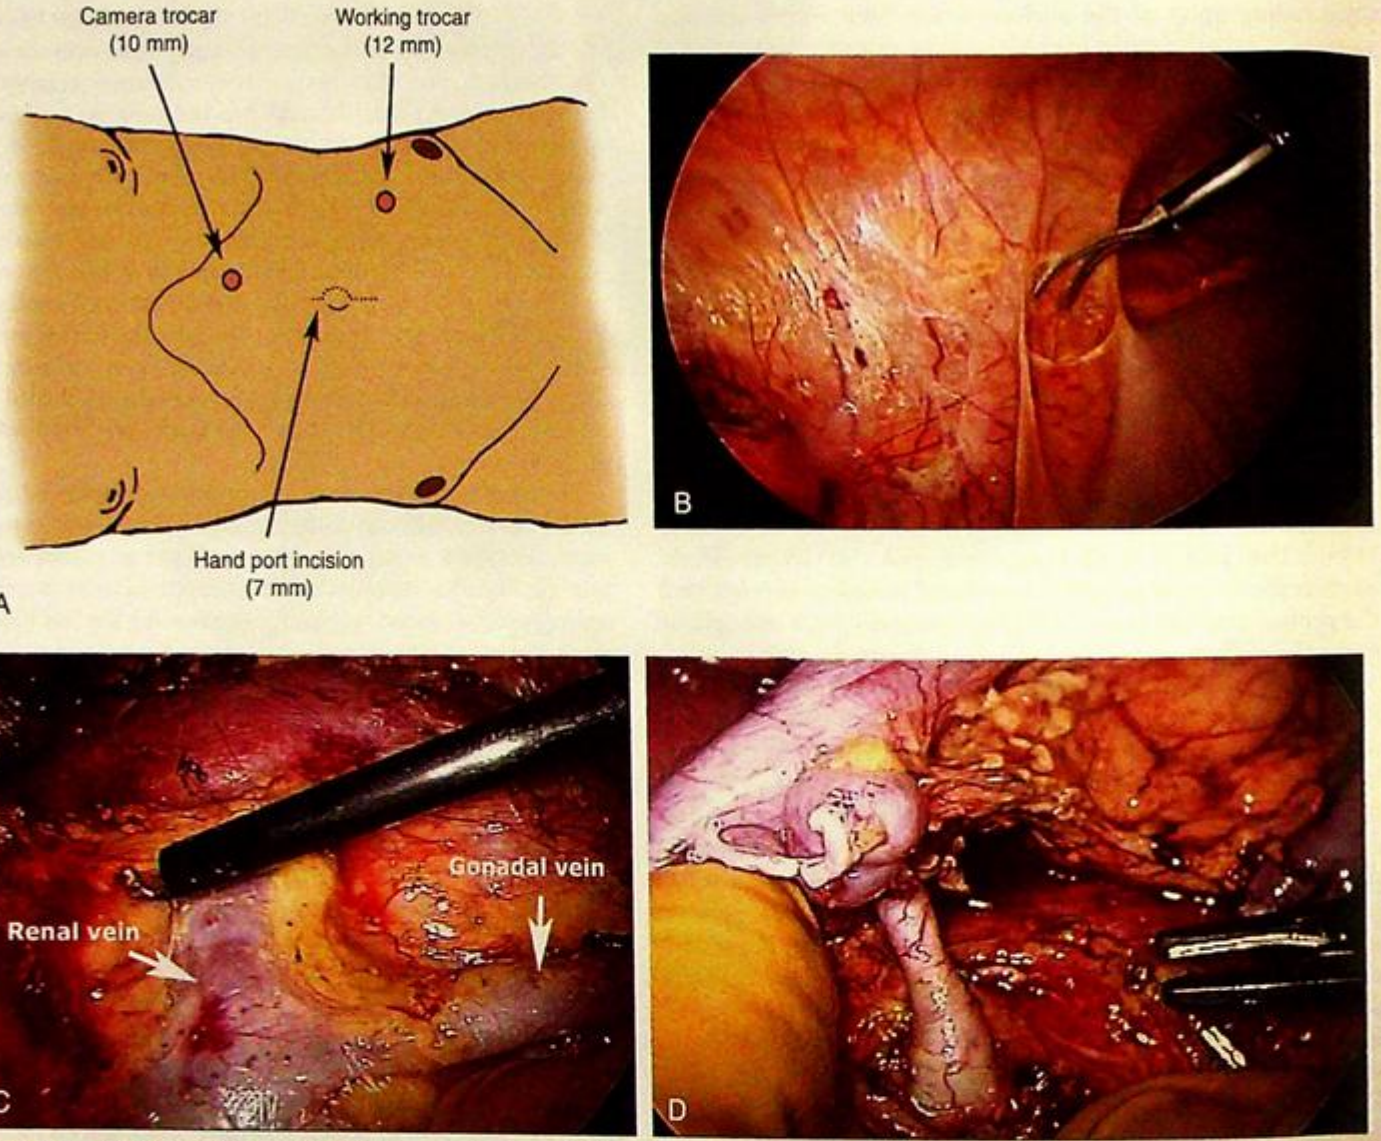

Figure 40–3. Hand assisted laparoscopic left donor nephrectomy. **A,** The patient is placed in a modified right lateral decubitus position with the left side elevated approximately 45 degrees with a large gel roll. The table is partially flexed; it is unnecessary to raise the kidney rest. The patient's left arm is placed in a sling and all extremities are padded. The patient is secured to the table with 2-inch cloth tape just below the anterior superior iliac spines. This will permit rotation of the table during the procedure. The monitors are placed on the left side of the patient, across from the surgeons. The nurse assistant generally stands opposite the surgeons on the patient's left. Following the skin preparation and draping, a 7-cm periumbilical, midline incision is made. The peritoneum is opened under direct vision. A hand assist device that will allow room on the abdomen for placement of two trocars is placed in the incision. A trocar is inserted directly through the hand assist device. The abdomen is insufflated to 15 mm Hg. A 10-mm 30-degree telescope that will be used throughout the procedure is first used through this trocar in the hand assist device. A 12-mm trocar is inserted under direct vision into the left lower quadrant (LLQ) at the lateral border of the rectus muscle. This trocar must be 12 mm to allow passage of the endoscopic stapling device. The telescope is removed from the trocar in the hand assist device and inserted into the LLQ trocar, and the trocar in the hand assist device is removed. A second trocar (10-12 mm) is placed in the subcostal area (LUQ) just lateral to the midline. Occasionally, a third trocar (5 mm) will be placed in the midaxillary line for lateral retraction. The left laparoscopic donor nephrectomy is performed with the telescope in the LUQ trocar, the left hand in the hand assist device, and the right hand using the working instruments through the LLQ trocar. **B,** The first step is the reflection of the colon and spleen from the level of the iliac vessels to above the spleen. Anteromedial traction of the left colon will keep the tissue to be divided under tension. The first layer of tissue encountered, the peritoneum, is divided with either scissors or hook electrocautery. A combination hook, suction, and irrigation device will enable the surgeon to quickly switch between sharp dissection with hook cautery and blunt dissection with the suction probe. Anterior and medial retraction of the colon with the left hand is critical for identification of the plane between the mesentery and Gerota's fascia. Once the peritoneum is incised, the colon can be reflected primarily with blunt dissection. The splenocolic ligament is left intact, and the plane of dissection is carried lateral to the spleen to allow the spleen to drop medially. Care is taken when reflecting the colon to avoid injury to the bowel or its mesentery. At this point in the procedure, the table is rotated toward the surgeon to place the patient in a more lateral decubitus position, so gravity will aid with retraction of the intestines. **C,** The next step is exposure of the gonadal and renal veins. This is generally easily done after complete reflection of the left colon. Hook electrocautery is used to clean the surface of the gonadal vein to its insertion in the renal vein. The renal vein is dissected, and its branches (gonadal, lumbar, and adrenal veins) are freed in the process. A 10-mm laparoscopic right angle dissector is useful for dissection of these branches. The branches of the renal vein are divided with either clips, vascular staples, or a feedback controlled vessel sealing bipolar device. These bipolar devices will seal and divide vessels up to 7 mm in diameter. Avoidance of clips on the branches of the renal vein will diminish the chance of an endoscopic vascular stapler misfire due to a clip in the jaws of the stapling device. **D,** After division of the lumbar vein, the renal artery is visible posterior to the renal vein. Be careful when dissecting in the renal hilum area because there are frequently more than one lumbar vein, and these lumbar veins are difficult to identify on preoperative CT scan because they do not reliably fill with contrast medium. The tissue surrounding the artery is divided with the hook electrocautery. Once the proper plane is entered immediately adjacent to the renal artery, the emancipated artery will spring free of the surrounding tissues. All of the tissue surrounding the artery and between the artery and vein must be divided. Cautery is generally sufficient.

Continued

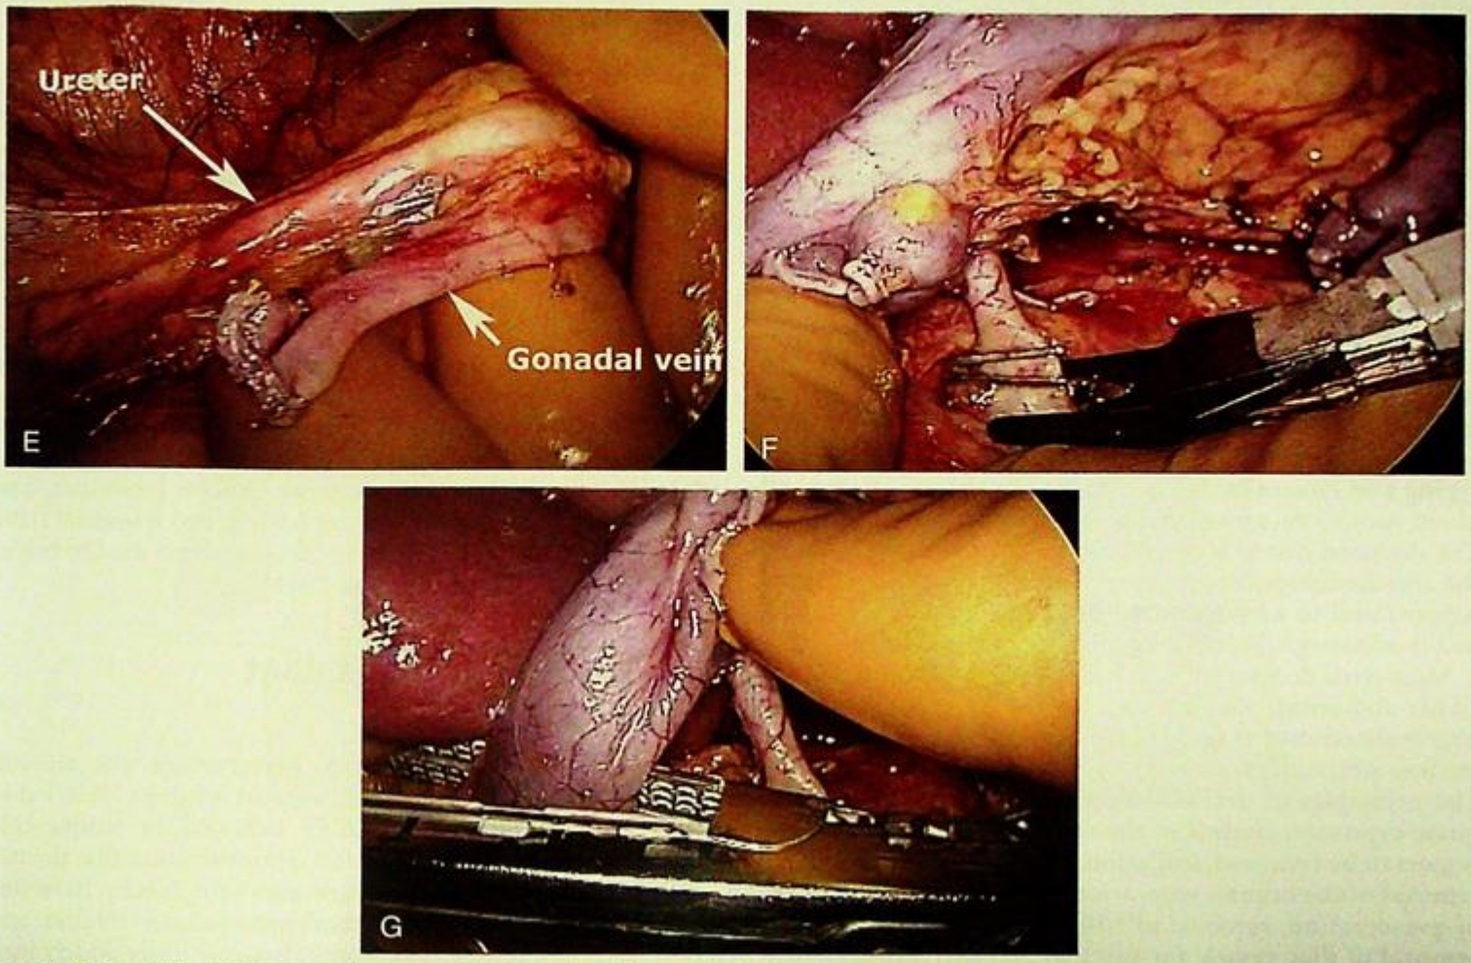

Figure 40–3, cont'd. **E,** The ureter is prepared by blunt dissection and hook electrocautery. It may be necessary to leave the gonadal vein attached to the ureter to preserve ureteral blood supply. The ureter is not divided until the kidney and renal vessels have been completely dissected to prevent rotation of the kidney and torsion of the renal vessels. The kidney is freed laterally and flipped medially to allow exposure and dissection of the posterior surfaces of the renal vessels. The division of the renal vessels is rehearsed with the surgical team to ensure that all instruments are present and working and that the order of their use is familiar to all. Exposure of the renal vessels is greatly facilitated by retraction of the kidney with the intraperitoneal hand. **F,** The artery is ligated with three long titanium clips or with a vascular load (2.0- to 2.5-mm staples) of the endoscopic stapler. Either the Endo GIA or Endo TA stapling devices are used (U.S. Surgical, Norwalk, CT). The Endo TA stapling device only places three rows of staples and allows inspection of the staple line before division of the vessel with the endoscopic scissors. The lack of distal staples will gain 3 to 4 mm in vessel length. Roticulating staplers are preferred. **G,** The vein is stapled and divided as described for the artery. The kidney is immediately delivered from the periumbilical incision, placed on slush, and flushed with ice-cold preservation solution. The renal fossa, staple lines, and clips on vessels are inspected for bleeding, the colon is returned to its normal position, and the wounds are closed.

graft survivals for kidneys from the very young are due to small anatomic parts and the risk of technical problems. There are, however, reports of successful kidney transplants from small deceased donors that were transplanted either as single units or en bloc with donor aorta and inferior vena cava (Hudnall et al, 1989; Bretan et al, 1997). The transplantation of both kidneys from a deceased donor with abnormal renal function or abnormal biopsy findings has also been used with success as an option to expand the donor pool, but the long-term function of such kidneys is inferior (Light, 1999; Wolters et al, 2005). Table 40–6 shows biopsy guidelines that some have found useful for the selection of transplantable kidneys from ECDs.

The initial goals of resuscitation of the brain-dead deceased donor are systolic blood pressure of 90 mm Hg or mean arterial pressure of 60 mm Hg and urinary output exceeding 0.5 mL/kg/hr. Monitoring of central venous pressure, capillary wedge pressure, or pulmonary artery pressure is helpful for managing fluid administration (Soifer and Gelb,

1989; Boyd et al, 1991). Serum electrolyte levels are checked every 2 to 4 hours. If the resuscitation goals cannot be met by fluid challenge and the central venous pressure is greater than 15 cm H_2O, dopamine or dobutamine at less than 10 μg/kg/min can be infused without causing renal vasospasm.

If bradycardia does not respond to atropine, dopamine, or low-dose epinephrine, a temporary pacemaker can be inserted. If intravascular volume expansion and vasopressors are unsuccessful in promoting a diuresis, furosemide, 1 mg/kg, with or without mannitol, 0.5 to 1 g/kg, can be infused. If diabetes insipidus causes an unmanageable diuresis, aqueous vasopressin can be infused to reduce urinary output. Because hypothermia can cause cardiac irritability and coagulopathy, the head can be wrapped, intravenous fluids can be warmed, and the body can be placed on a warming blanket. Tissue typing and crossmatching can be performed on a peripheral blood sample or groin lymph nodes before organ retrieval. The deceased donor is maintained in the operating room by the anesthesiology team to ensure ventilation and circulatory support and to administer drugs such as diuretics, heparin, and α-adrenergic blocking agents.

Most renal donors are now multiple organ donors, and the classic abdominal midline and cruciate incisions have been largely abandoned in favor of the total midline approach with median sternotomy, even when kidneys alone are retrieved. **The principles of deceased donor organ retrieval are adequate exposure, control of the vessels above and below the organs to be removed, initiation of preservation in situ, the removal of the organs, separation of the organs, completion of preservation, removal of histocompatibility specimens, removal of iliac vessels for vascular reconstruction of pancreas and liver grafts, and organ packaging.** The technical aspects of an en bloc method are illustrated in Figure 40–4 (Nakazato et al, 1992; Barry, 1996). Some retrieval teams prefer to do much more dissection in situ before organ removal. When that occurs, the kidneys are the last transplantable organs to be removed. To avoid renal warming in this situation, it is important to maintain surface cooling of the kidneys by surrounding them with ice slush during liver and pancreas recovery.

KIDNEY PRESERVATION

Cellular Injury

Warm ischemic injury is due to failure of oxidative phosphorylation and cell death due to adenosine triphosphate (ATP) depletion (Belzer and Southard, 1988). ATP is required for the cellular sodium-potassium pump to maintain a high intracellular concentration of potassium and a low internal concentration of sodium. **When the sodium-potassium pump is impaired, sodium chloride and water passively diffuse into the cells, resulting in cellular swelling and the "no-reflow" phenomenon after renal revascularization.** Cellular potassium and magnesium are lost, calcium is gained, anaerobic glycolysis and acidosis occur, and lysosomal enzymes are activated. This results in cell death. During reperfusion, hypoxanthine, a product of ATP degradation, is oxidized to xanthine with the formation of free radical scavengers that cause further cell damage.

Principles of Simple Cold Storage of Kidneys

Cellular energy requirements are significantly reduced by hypothermia. This is done by surface cooling, hypothermic pulsatile perfusion, or flushing with an ice-cold solution followed by cold storage. Making the flush solution slightly hyperosmolar with impermeant solutes such as mannitol, lactobionate, raffinose, or hydroxyethyl starch helps prevent endothelial cell swelling and the "no-reflow" phenomenon. When the sodium-potassium pump is impaired, there is passive transfer of ions across the cell membrane; and if the electrolyte composition of the flush solution is nearly the same as that inside the cell, electrolyte balance will be maintained. ATP-$MgCl_2$ infusions have been evaluated as an energy source. Calcium channel blockers, xanthine oxidase inhibitors, free-radical scavengers, vasoprotective agents, and lysosome stabilizers such as methylprednisolone have all been used to reduce ischemic injury (Marshall et al, 2001).

Clinical Kidney Transplant Preservation

The basic methods of kidney preservation are pulsatile machine perfusion with a protein-based solution (Belzer et al, 1967) and hypothermic flushing followed by simple cold storage (Collins et al, 1969). After demonstration that the two methods provided equivalent results with ideally harvested dog kidneys after 48 hours of preservation (Halasz and Collins, 1976), simple cold storage became more widely used for human kidney preservation. Machine perfusion has provided reliable human kidney preservation for up to 72 hours (Feduska et al, 1978), and it may be the preferred method of preserving kidneys from non–heart-beating deceased donors. There are reports of successfully extending the preservation time for 48 to 95 hours with cold storage alone or in combination with machine perfusion (Haberal et al, 1984). A review of 33,278 first deceased donor kidney transplants demonstrated no significant differences in graft survivals up to 5 years for kidneys that were preserved by pulsatile machine perfusion or simple cold storage, but the rate of delayed graft function was significantly lower for the pumped kidneys (Cecka, 2002).

The commonly used UW solution (Belzer and Southard, 1988) minimizes cellular swelling with the impermeant solutes lactobionate, raffinose, and hydroxyethyl starch. Phosphate is used for its hydrogen ion buffering qualities, adenosine is for ATP synthesis during reperfusion, glutathione is a free-radical scavenger, allopurinol inhibits xanthine oxidase and the generation of free radicals, and magnesium and dexamethasone are membrane-stabilizing agents. A major advantage of this preservation solution has been its utility as a universal preservation solution for all intra-abdominal organs. A prospectively randomized study of 695 deceased kidney grafts preserved with either UW solution or Euro-Collins solution showed that the UW solution resulted in a significantly more rapid reduction in the postoperative serum creatinine level, a significantly lower postoperative dialysis rate, and a 6% higher 1-year graft survival compared with kidneys preserved by Euro-Collins solution (Ploeg et al, 1992).

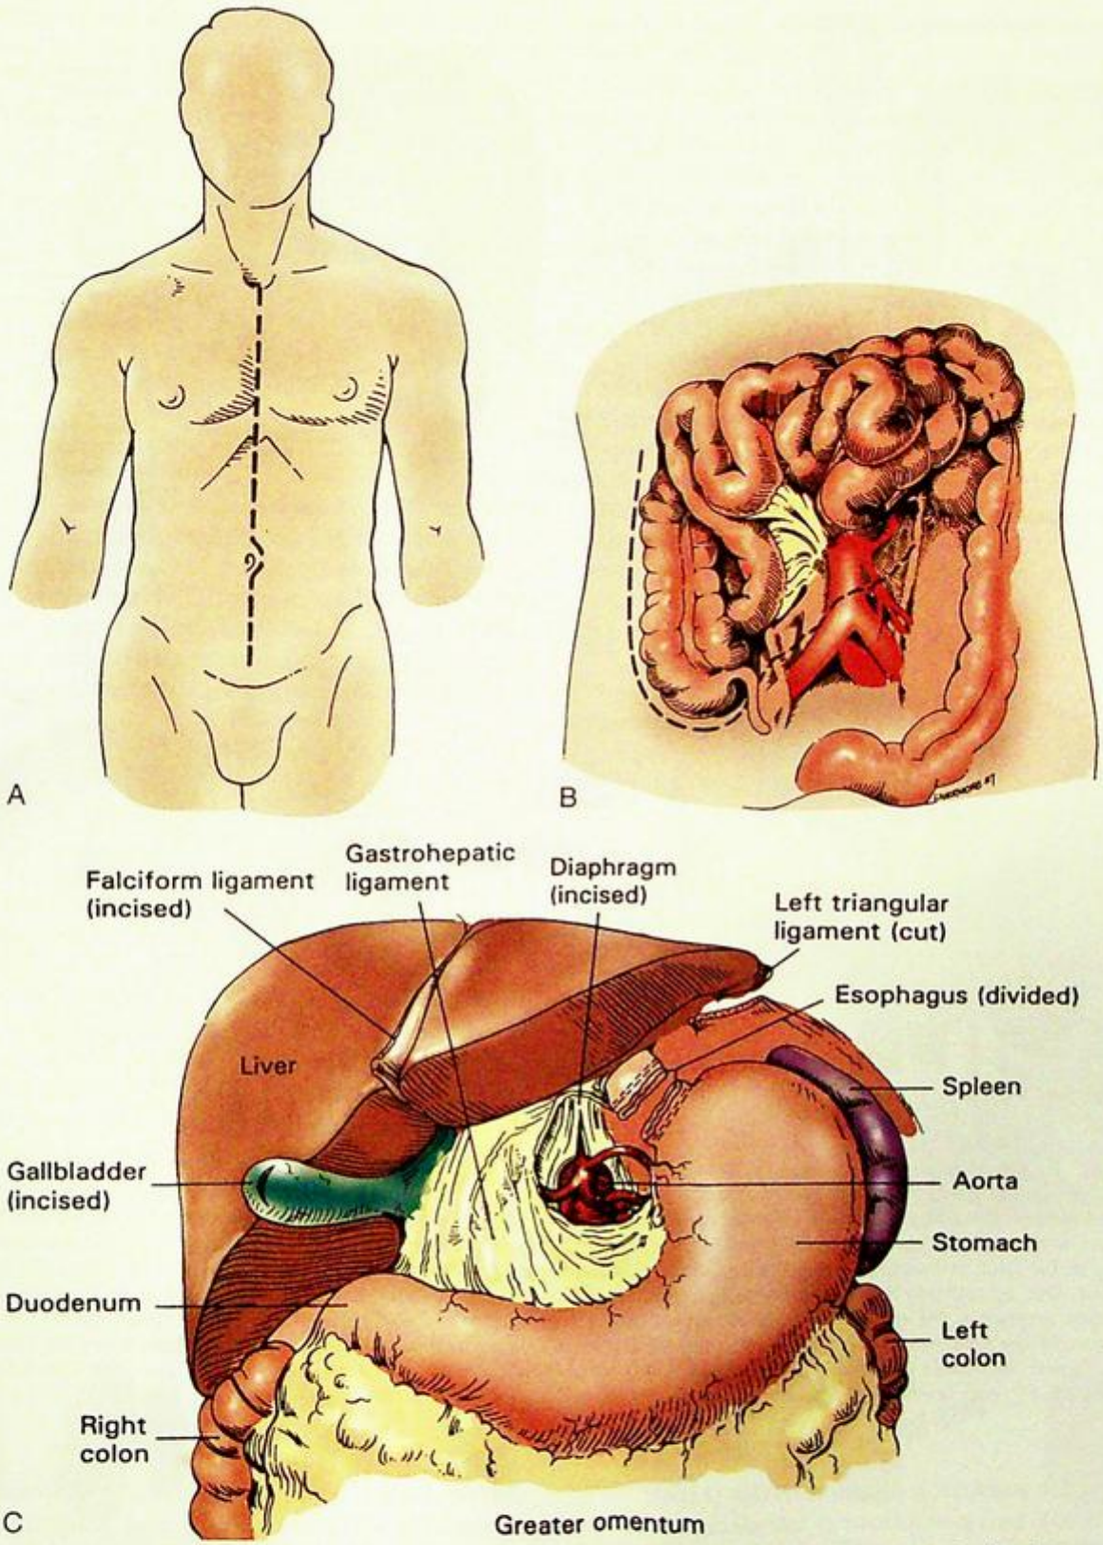

Figure 40–4. **A,** A total midline incision with splitting of sternum and diaphragm exposes all transplantable organs in the chest and abdomen. It also provides excellent exposure when retrieving only abdominal organs. **B,** The retroperitoneum is exposed as for a retroperitoneal lymphadenectomy. **C,** For multiple abdominal organ retrieval, the aorta is controlled above the celiac axis. The inferior vena cava (IVC) is controlled above the liver *(not shown)*.

Continued

An analysis of the Collaborative Transplant Study database for first deceased kidney transplants performed over a 10-year period revealed that kidney graft survival rates were significantly better for kidneys preserved with UW solution compared with Euro-Collins solution (Opelz and Wujciak, 1996).

The detrimental effects of the events surrounding deceased kidney retrieval and the detrimental effects of preservation injury are shown by the 12% better 5-year graft survival for 5897 living biologically unrelated donor kidney transplants compared with 34,208 primary deceased kidney transplants (Cecka, 2004).

Expansion of the deceased kidney donor pool by the use of non–heart-beating donors has resulted in renewed interest in pulsatile machine perfusion because it allows

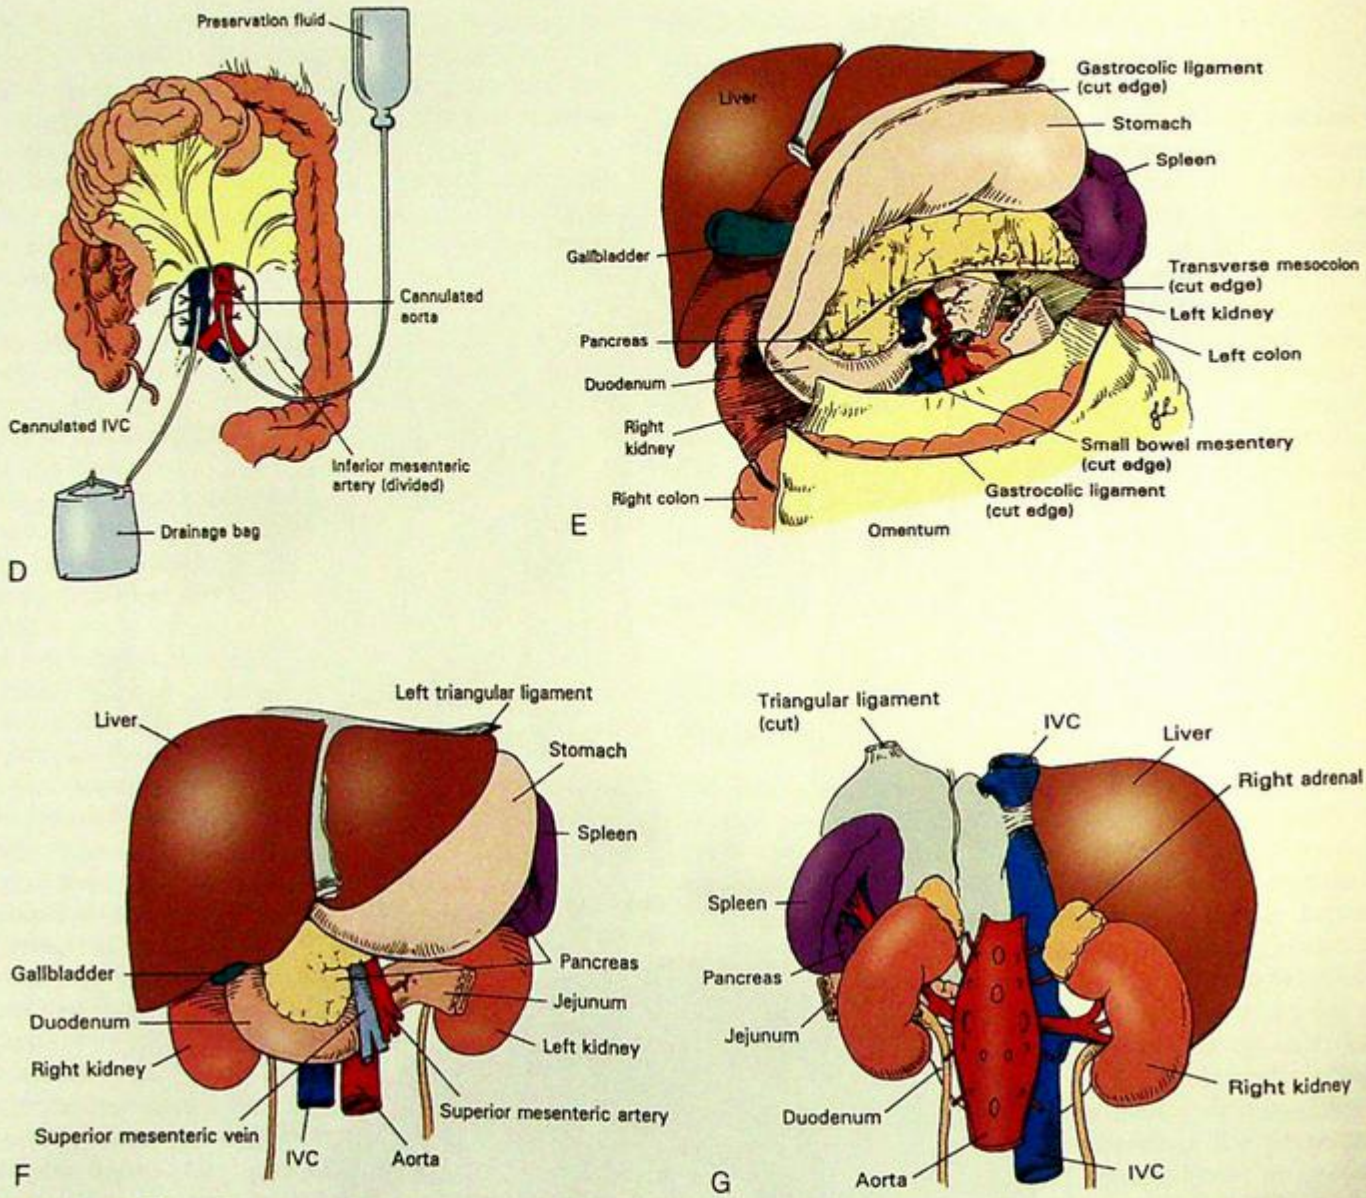

Figure 40–4, cont'd. **D,** The aorta and IVC are controlled below the renal vessels, heparin is administered to the donor, and the great vessels are cannulated. The proximal aorta is occluded, the IVC is vented into the chest or through the distal IVC cannula, and in-situ flushing with an ice-cold preservation solution is performed through the aortic cannula. **E,** The gastrocolic ligament is divided, the small bowel mesentery is divided along with the superior mesenteric artery and vein, and the small bowel is divided at the ligament of Treitz. **F,** The esophagus is divided, and, with further dissection, the en bloc specimen consisting of the liver, stomach, spleen, pancreas, both kidneys, aorta, and IVC is removed. **G,** The specimen is placed "face down" in a pan of slush and is separated, first, by splitting the aorta posteriorly between lumbar arteries to identify all renal arteries; second, by transecting the aorta between the superior mesenteric artery and the renal arteries; third, by splitting the anterior aortic wall between the renal arteries; fourth, by transecting the IVC just above the entrance of the renal veins; and fifth, by dividing the left renal vein where it enters the IVC. (**A** and **B** from Barry JM: Cadaver donor nephrectomy. In Novick AC, Streem SB, Pontes JL [eds]: Stewart's Operative Urology. Baltimore, Williams & Wilkins, 1989, pp 294-300; **C** to **G** from Barry JM: Donor nephrectomy. In Marshall FF [ed]: Textbook of Operative Urology. Philadelphia, WB Saunders, 1996, pp 235-247.)

viability testing with perfusion characteristics (Light, 1999; Matsuno et al, 2000), and glutathione-S transferase determinations (Gok et al, 2004), and it has been clearly demonstrated in the laboratory to be superior to simple cold storage for kidneys subjected to significant warm ischemia time (Halasz and Collins, 1976).

RECIPIENT SELECTION FOR DECEASED KIDNEY TRANSPLANTS

A point system has evolved in the United States for the selection of deceased kidney transplant recipients (Bryan et al, 2003). Initial screening consists of ABO blood group identity determination and negative microcytotoxicity lymphocyte crossmatches between donor and recipient. Patients whose serum reacts to a high proportion of lymphocytes on a random or selected panel have high panel reactive antibody levels, and they receive additional points because the probability of obtaining a crossmatch-negative kidney for them is decreased compared with minimally sensitized transplant candidates. The time on the waiting list, histocompatibility between the donor and the recipient, prior vital organ donation, and age younger than 18 years result in additional points. A score is developed for each of the potential recipients, and the candidates are placed in rank order by that score. The patient with the highest score is ranked first for that specific kidney. The kidney graft is then offered in turn to each of the

potential recipients by the final rank. If there is no suitable recipient on a local list, the kidney graft is offered to those on a regional list and, if necessary, the national list. There is mandatory distribution of a kidney when there are zero HLA-A, HLA-B, and HLA-DR antigens mismatched between a deceased kidney donor and an ABO blood group–compatible, not identical, recipient on the national waiting list.

Candidates for ECD kidney engraftment must agree to receive one of these kidneys before being placed on the waiting list. These kidney transplants are usually recommended for patients older than the age of 60 years, diabetic patients older than the age of 40 years, and patients who have significant dialysis access problems or who are unable to tolerate dialysis.

PREOPERATIVE ASSESSMENT

Just before kidney transplantation, the history, physical examination, and diagnostic studies of the recipient focus on a search for interval medical problems such as symptomatic cardiac disease, active infection, and the need for additional crossmatch testing because of recent blood transfusions or an out-of-date serum sample. Immunosuppression and infection prophylaxis protocols are assigned, a preliminary determination about the need for an intensive care unit bed is made, a final decision is made to perform the transplant operation, and the team queues up for the operating room. The quality of early renal function is directly correlated with cold ischemia time, and deceased donor kidney transplantation is done on an urgent basis.

PREPARATION OF KIDNEY GRAFT

A kidney graft removed from a living renal donor by an open technique requires little preparation by the kidney transplant recipient team because most of the preparation has been done in situ by the donor team. Because of the presence of significant amounts of perirenal fat, stapled vessels, and retraction of the renal vein into the renal hilum, significantly more bench work is required for kidneys removed laparoscopically. If not done by the LDN team, prompt identification of the renal artery and vein, removal of the staple lines, and rapid flushing of the kidney with ice-cold preservation solution is the initial priority, followed by the final dissection. Some programs have adopted a three-row rather than a six-row stapler for the renal vein, followed by distal transection of the vein. This avoids the need to resect the venous staple line at the back table before arterial flushing and reduces venous blood in the kidney. The disadvantage is somewhat more difficult visualization laparoscopically after transecting the renal vein because the distal end is open, permitting venous blood to obscure the operative field.

For a deceased donor kidney, the short right renal vein can be extended with a variety of techniques that use the inferior vena cava or donor external iliac vein (Fig. 40–5). Before the use of donor inferior vena cava to provide extension of the right renal vein in deceased donor kidney transplants, the left kidney was preferred because of its longer renal vein. Techniques for the management of multiple renal arteries from deceased and living donors are shown in Figure 40–6.

RECIPIENT OPERATION

The usual responsibilities of the anesthesia and the surgical teams are depicted in Table 40–7.

A prophylactic antibiotic is administered just before surgery and continued postoperatively until the results of intraopera-

J Urol 1988;140:1479; **E** from Corry RJ, Kelley SE: Technic for lengthening the right renal vein of cadaver donor kidneys. Am J Surg 1978;135:867.)

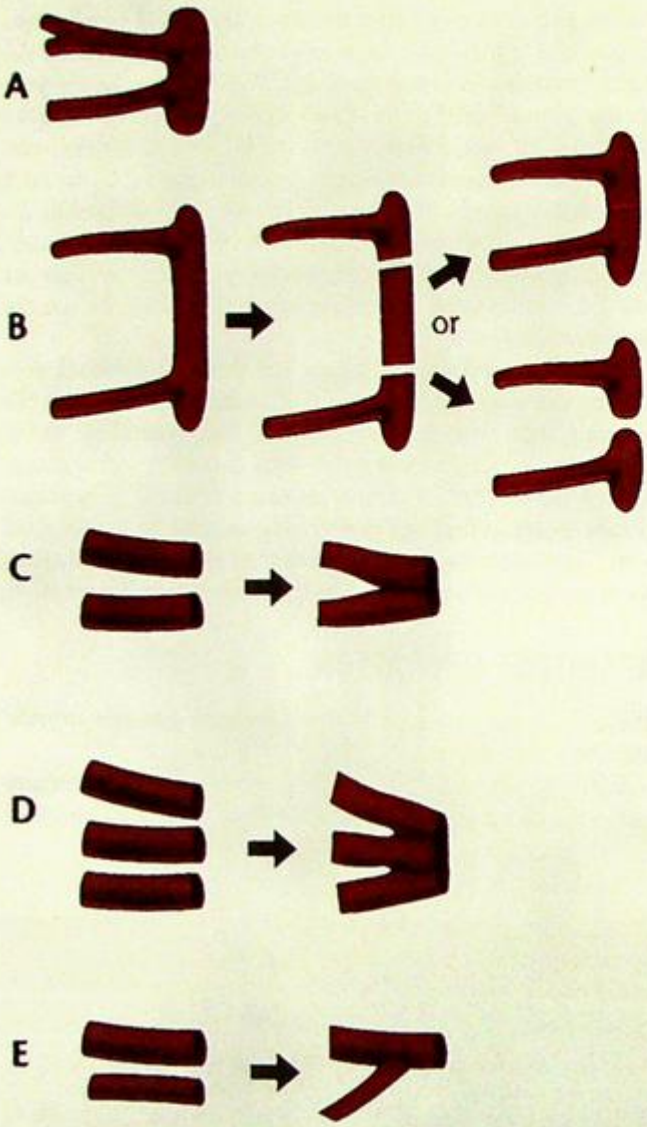

Figure 40–6. Preparation of the kidney transplant with multiple renal arteries. **A** and **B**, Use of aortic patches when the kidney is from a deceased donor. **C** and **D**, Pair of pants or three-legged pair of pants is used when an aortic patch is not available, such as when the kidney is from a living donor. **E**, Anastomosis of segmental renal artery to main renal artery. The segmental renal artery can also be anastomosed to the inferior epigastric artery using an end-to-end technique. (**A** to **E** from Barry JM: Technical aspects of renal transplantation. In Schrier RW [ed]: Atlas of Diseases of the Kidney. Philadelphia, Current Medicine, 1998, p 14.4.)

tive cultures are known. Immunosuppression is started just before or during surgery in the deceased kidney graft recipient and, in some programs, in the week before transplantation in the living donor kidney transplant recipient.

After the induction of anesthesia and the placement of a triple-lumen central venous catheter, the genitalia and skin are prepared, and a Foley catheter is placed in the bladder or bladder substitute. **It is helpful to have the catheter attached to a three-way drainage system that allows intraoperative filling and draining of the bladder, especially in a small recipient or in an individual who has a small, defunctionalized bladder.** The bladder or bladder substitute is rinsed with a broad-spectrum antibiotic solution, such as neomycin-polymyxin B, and gravity filled. The catheter tubing is clamped until it is time to do the ureteroneocystostomy. A self-retaining ring retractor attached to the operating table that has been flexed and rotated toward the surgeon allows the operation to be performed by a surgeon and one assistant (Fig. 40–7). To prevent spinal injury, patients with significant back disease, such as ankylosing spondylitis, should be placed in a comfortable, padded position before anesthetic induction and table flexion should be avoided. Antibiotic irrigation is used liberally during the procedure. Central venous pressure is maintained between 5 and 15 cm H_2O with intravenous fluids. If fluid administration alone cannot maintain the mean arterial pressure at greater than 60 mm Hg and the systolic blood pressure greater than 90 mm Hg, respectively, a dopamine or dobutamine infusion is started.

In adults and children who weigh more than 20 kg, a first kidney graft is usually placed extraperitoneally in the contralateral iliac fossa by way of a rectus-preserving Gibson incision. This allows the renal pelvis and ureter to be the most medial structures in case subsequent urinary tract surgery is necessary on the kidney graft. Common exceptions to this principle are the obese recipient in whom it is easier to place a kidney graft in the right iliac fossa because of the more superficial iliac veins and the simultaneous pancreas and kidney transplant recipient in whom it is common to place the left kidney with its longer renal vein in the left iliac fossa. **If there is some doubt about whether there will be enough room in the left pelvis of a small patient for a large kidney, placement of the kidney on the right side will allow access to a wider choice of arteries and veins for vascular reconstruction.** In small children, this is accomplished by extension of the Gibson incision to the right costal margin or by a midline abdominal incision. In men, the spermatic cord is preserved and retracted medially. In women, the round ligament is divided between ligatures. The recipient's target blood vessels are dissected. When the renal vein is short, it is helpful to completely mobilize the external and common iliac veins by dividing the gluteal and internal iliac veins between ligatures or large clips. These branches can be retracted anteriorly with a loop of heavy silk. Lymphatic vessels are divided between ligatures to prevent the development of postoperative lymphocele. **The surgeon must be careful not to mistake the genitofemoral nerve, which sometimes crosses the external iliac artery, for a lymphatic vessel.**

Before temporary vascular occlusion, heparin, 30 units/kg, is commonly given intravenously to the recipient. During the vascular anastomosis, an infusion of mannitol is begun to act as a free-radical scavenger and as an osmotic diuretic. Infusion of an electrolyte solution provides intraoperative volume expansion. The addition of an albumin infusion has been found to be helpful in promoting early renal function in the deceased donor kidney transplant (Dawidson et al, 1994). It is a common practice to keep the kidney transplant cool by wrapping it in a sponge containing crushed saline ice, by dripping an ice-cold electrolyte solution on it, or by placing it in a plastic bag or glove filled with slush. The renal artery is usually anastomosed to the end of the internal iliac artery or to the side of the external iliac artery (Fig. 40–8). Other possible locations for the arterial anastomosis are dictated by the clinical situation, and they include the common iliac artery, the aorta, the splenic artery, and the native renal artery. Moderate arteriosclerosis of the internal iliac artery can be managed by endarterectomy. In the event of significant

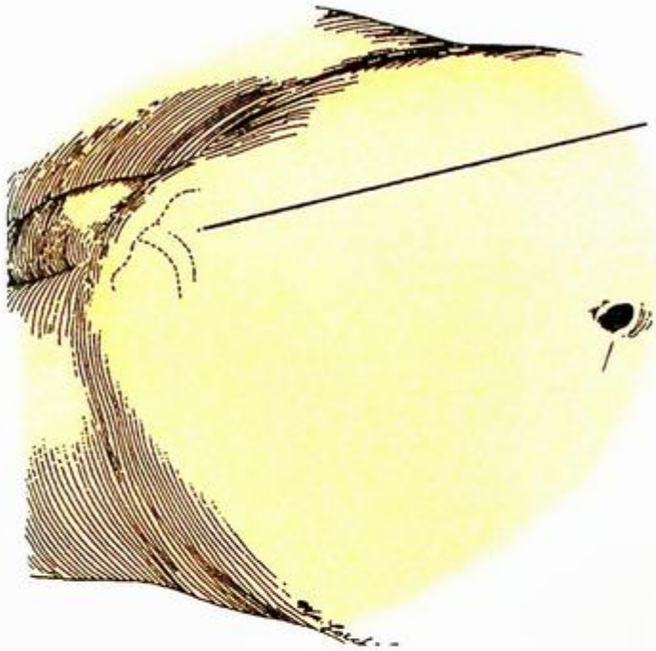

Figure 40–7. Patient position for kidney transplantation into right iliac fossa. Table flexion opens the iliac fossa and retropubic space, just as for radical cystectomy or open prostatectomy. Rotation of the table toward the surgeon, who stands on the patient's left side, assists in performance of the lateral aspects of the vascular anastomoses. (From Montie JE: Technique of radical cystectomy in the male. In Marshall FF [ed]: Textbook of Operative Urology. Philadelphia, WB Saunders, 1996, p 399.)

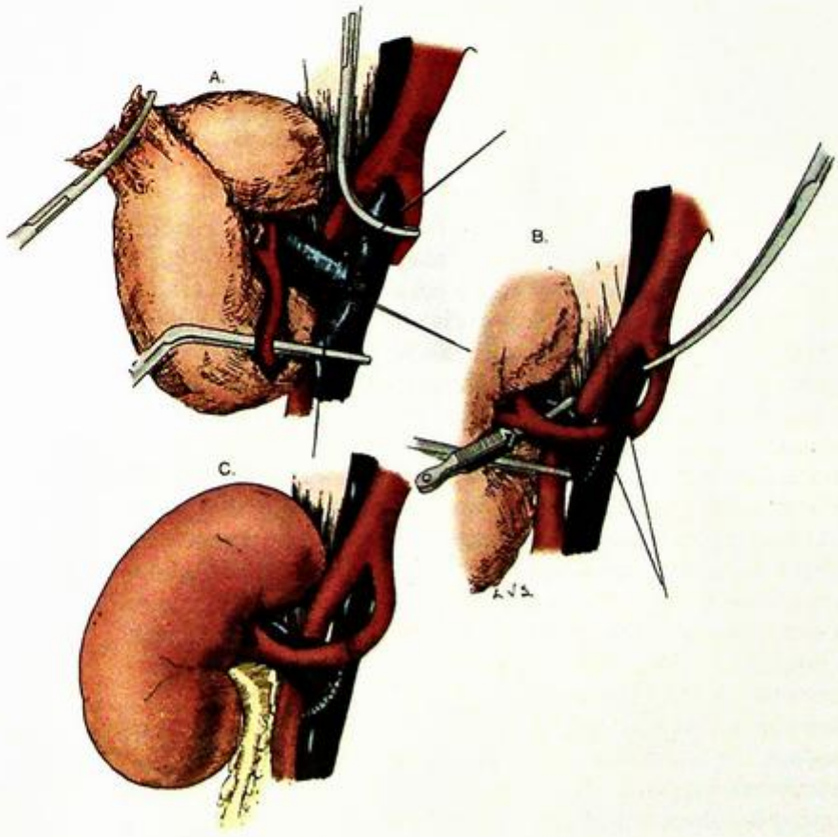

Figure 40–8. **A,** The renal vein is anastomosed to the external iliac vein, usually medial to the external iliac artery. When the recipient has a tortuous iliac artery, the venous anastomosis is best performed lateral to the bowed external iliac artery. **B,** In the absence of significant recipient arteriosclerosis, the renal artery is commonly anastomosed to the internal iliac artery with 5-0 or 6-0 monofilament, nonabsorbable sutures. Many prefer to perform the renal artery anastomosis before the venous anastomosis. If significant internal iliac arteriosclerosis is present or the contralateral renal artery has been used in a previous renal transplant in a man, the external or common iliac arteries become the target vessels for renal artery anastomosis. **C,** The completed venous and arterial anastomoses. (**A** to **C** from Salvatierra O Jr: Renal transplantation. In Glenn JF [ed]: Urologic Surgery, 4th ed. Philadelphia, JB Lippincott, 1991, pp 243-251.)

arteriosclerosis of that vessel, the renal artery is anastomosed end to side to the external iliac artery or to the common iliac artery. **A vascular punch is useful for creating a round hole in a rigid or arteriosclerotic vessel and in the common iliac artery or aorta of a child to prevent renal artery coaptation and thrombosis if hypotension occurs.**

When the pelvic vessels are unsuitable for renal revascularization, orthotopic renal transplantation with anastomosis of the renal artery to the splenic artery or native renal artery and venous reconstruction with the renal vein or inferior vena cava can be done (Gil-Vernet et al, 1989).

It is usually preferable to do the renal artery anastomosis first because it is the more critical of the two vascular anastomoses, the kidney is not tethered by the venous anastomosis, and venous occlusion can be delayed until after the renal artery anastomosis. This results in decreased iliac venous occlusion time and reduces the risk of iliofemoral venous thrombosis. In cases in which the renal vein is short and exposure is limited, it may be preferable to perform the venous anastomosis first. A man undergoing repeat renal transplantation with the prior transplant anastomosed to the contralateral internal iliac artery should not have the ipsilateral internal iliac artery used. This is to preserve blood supply to the corpora cavernosa and reduce the risk of iatrogenic impotence (Gittes and Waters, 1979). The renal vein, with or without an extension, is usually anastomosed end to side to the external iliac vein or to the junction of the external and common iliac veins. When transplanting an adult kidney into the right retroperitoneum of a small child, the renal vein often has to be shortened to prevent redundancy with anastomosis to the inferior vena cava.

Furosemide is commonly infused just before release of the vascular clamps. After renal revascularization, injection of verapamil, a calcium channel blocker, into the renal arterial circulation of the deceased donor kidney graft has been shown to protect the kidney from reperfusion injury (Dawidson et al, 1994).

Urinary tract reconstruction is usually by antireflux ureteroneocystostomy, of which there are several techniques (Politano and Leadbetter, 1958; MacKinnon et al, 1968; Konnak et al, 1975; Texter et al, 1976; Barry, 1983). **Most surgeons prefer an extravesical rather than the transvesical approach for ureteroneocystostomy because it is faster, a separate cystotomy is not required, and less ureteral length is necessary, thus ensuring a distal ureteral blood supply** (Figs. 40–9 and 40–10). Figure 40–9C demonstrates a rapid technique that can be used with or without a stent when the patient has a very small bladder or the procedure must be quickly completed. **If a prior augmentation cystoplasty had been done, the transplant surgeon will need to know the blood supply of the patch so as not to interfere with it at the time of transplantation.** Indications for ureteroureterostomy and pyeloureterostomy are short or ischemic allograft ureters, very limited bladder capacity, or the surgeon's preference. Double-pigtail ureteral stents are used when there is concern about the ureteroneocystostomy technique, or when ureteroureterostomy or pyeloureterostomy has been performed. The routine use of a ureteral stent for all cases has been shown to reduce the incidence of ureteral complications (Pleass et al, 1995; Mangus and Haag, 2004). Long-term results of renal transplantation into the valve bladder and other abnormalities of the lower urinary tract have been very satisfactory (Luke et al, 2003; Mendizabel et al, 2005).

When a patient with an intestinal conduit undergoes renal transplantation (Surange et al, 2003), the kidney graft should be placed in such a way that it does not interfere with the flat surface at the stoma site and contribute to a poor fit of the urinary appliance and subsequent urinary leakage. The technique of ureteral implantation into an intestinal pouch is the same as that for ureteroneocystostomy. The pouch is irrigated free of mucus with an antibiotic solution, and the best site for the ureteral implantation is chosen with the pouch filled. Intraoperative identification of the conduit and subsequent ureteral anastomosis can be facilitated by cannulation of the stoma with a 14-French Foley catheter and inflating the balloon with 3 to 4 mL of sterile water or staining the conduit with methylene blue. To avoid a kink in the allograft ureter, the kidney transplant can be placed upside down in the iliac fossa so that the ureter is pointing cephalad. The ureteral anastomosis is usually protected with a stent that is left in place for several weeks.

It is common practice to send swab culture specimens from the surface of the deceased donor kidney transplant and from the urinary bladder. It is unnecessary to do so from the surface of a living donor kidney unless there has been a break in sterile technique in the retrieval, perfusion, or transportation of the kidney.

When both kidneys from a deceased donor with marginal renal function are transplanted into the same recipient, one kidney can be transplanted into each iliac fossa by way of a vertical midline incision or by way of separate Gibson's incisions, or both kidneys can be placed in the right retroperitoneum, one on top of the other (Masson and Hefty, 1998). This technique can also be used for simultaneous kidney and pancreas transplantation (Fridell et al, 2004). The first transplant can be anastomosed to the inferior vena cava and common iliac artery, and the second can be anastomosed to the external iliac vein and external or internal iliac artery.

The uncomplicated renal transplantation can be closed by a variety of running or interrupted suture techniques without drains unless anticoagulation is planned. If the rectus-retracting approach has been used, it is not necessary to place any sutures in the rectus muscle; one simply closes the anterior rectus sheath after the external oblique, internal oblique, and transversus abdominis muscles and their fascial layers have been closed in the cephalad aspect of the wound. **A closed suction drain is recommended in the subcutaneous tissue of an obese patient.** A running absorbable subcuticular suture eliminates the need for subsequent suture or clip removal.

POSTOPERATIVE CARE

Fluid and Electrolyte Management

Postoperative fluid and electrolyte management are simple for patients with initial kidney graft function. Intravenous fluid of 0.45% saline in 5% dextrose is given to replace estimated insensible losses, and 0.45% saline in 0% dextrose is given at a rate equal to the previous hour's urinary output. When the urinary output is high, this regimen reduces the probability of a glucose-driven diur[illegible] **An optional method of fluid**

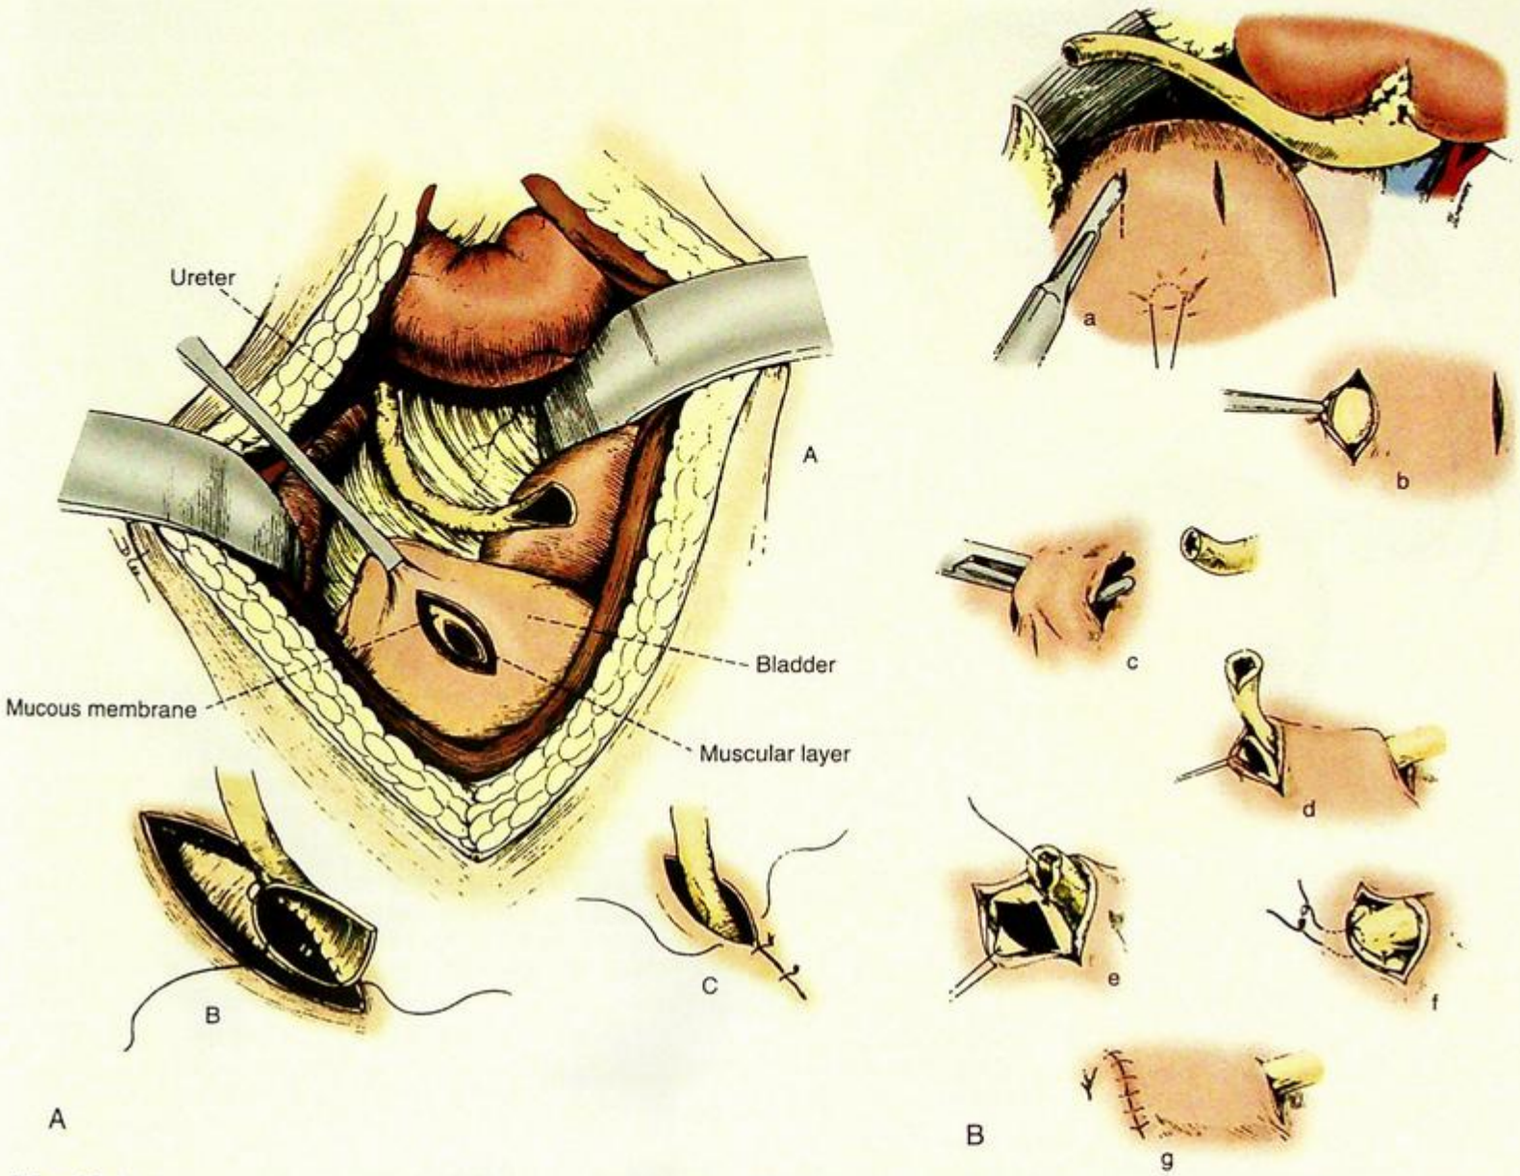

Figure 40–9. Three examples of extravesical ureteroneocystostomy. **A,** An anterolateral seromuscular incision is made down to the bulging bladder mucosa. The bladder is drained, the mucosa incised, and the ureter anastomosed to the bladder *(as shown)* with fine absorbable sutures. A distal anchoring stitch to hold the ureter to the bladder is used to prevent proximal migration in the tunnel *(not shown)*. The seromuscular layer is then loosely closed over the ureter. **B,** Steps *a* through *c* are completed with the bladder full of an antibiotic solution. The anesthesiologist unclamps the catheter before mucosal incision, and steps *d* through *g* are completed with fine absorbable sutures. *Continued*

management in the recipient of a living donor kidney transplant is a fixed rate protocol of 125 to 200 mL/hr of 0.45% normal saline in 5% dextrose with an occasional fluid bolus if hypotension ensues (Hatch et al, 1985). Serum electrolyte levels are monitored every 4 to 8 hours, and potassium is added to the intravenous solution when the serum potassium level declines to the middle of the normal range. When delayed graft function occurs, the previously described intravenous fluid is administered at a rate to maintain the central venous pressure at 10 to 15 cm H_2O for 2 to 3 hours, and furosemide is administered intravenously in an effort to induce a diuresis. The oliguric patient may require urgent treatment of hyperkalemia with administration of intravenous calcium chloride, intravenous sodium bicarbonate, insulin, and glucose, or dialysis.

If a diuresis has ensued and the next day's serum creatinine level is significantly reduced, a baseline radioisotope renogram is unnecessary. An ultrasonogram is indicated for delayed graft function, ipsilateral leg swelling, ipsilateral abdominal swelling, or a decreasing hematocrit. When oliguria occurs after renal transplantation, radioisotope renograms are commonly performed biweekly until the serum creatinine level begins to decrease without dialysis. If the radioisotope renogram deteriorates, a diagnostic renal biopsy is commonly done.

Management of Tubes and Drains

A urine culture is obtained just before catheter removal, and the patient is given a single dose of a broad-spectrum

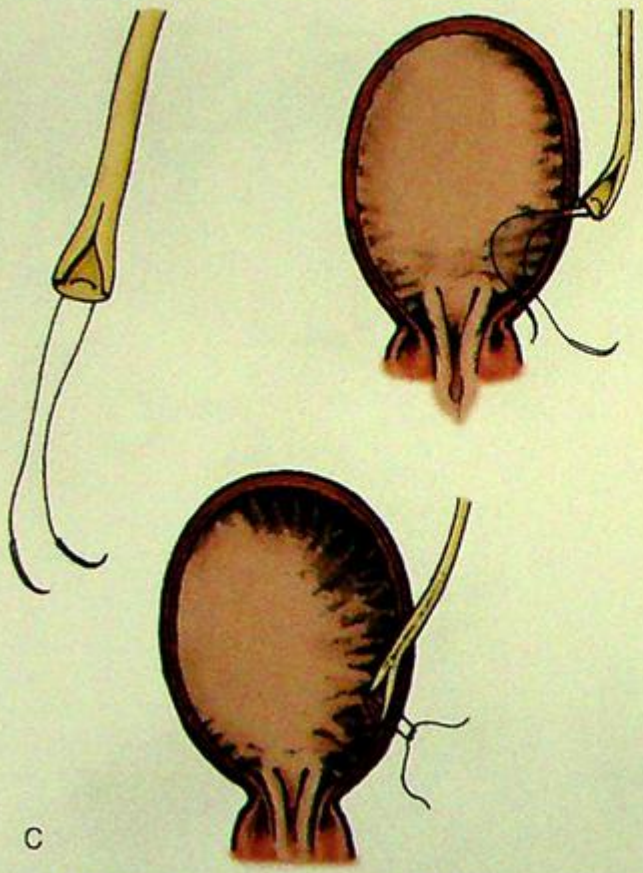

Figure 40–9, cont'd. C, Double-needle mattress suture is placed through the spatulated ureter, the ends of the suture and ureter are introduced into the bladder lumen, and the suture is tied outside the bladder wall. If the seromuscular incision is too large, it is closed over the ureter with interrupted fine absorbable sutures. (A from Konnak JW, Herwig KR, Finkbeiner A, et al: Extravesical ureteroneocystostomy in 170 renal transplant patients. J Urol 1975;113:299-301; B from Barry JM: Unstented extravesical ureteroneocystostomy in kidney transplantation. J Urol 1983;129:918-919; C reprinted from Texter JH Jr, Bokinsky G, Whitesell AL, et al: Simplified experimental ureteroneocystostomy. Urology 1976;7:21-23, with permission from Elsevier Science.)

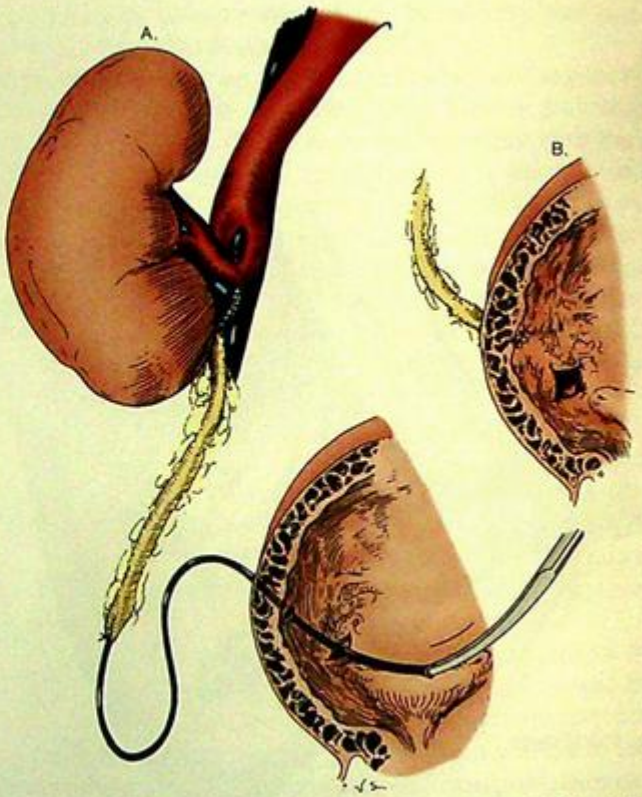

Figure 40–10. Transvesical ureteroneocystostomy. **A,** A No. 8 French catheter is passed through the submucosal tunnel and tied to the transplant ureter. **B,** The ureter is drawn through the tunnel, transected, and anastomosed to the bladder with fine absorbable sutures. The distal suture anchors the ureter to the bladder muscularis. Finally, the cystotomy is closed with one or two layers of absorbable sutures. (From Salvatierra O Jr: Renal transplantation. In Glenn JF [ed]: Urologic Surgery, 4th ed. Philadelphia, JB Lippincott, 1991, pp 243-251.)

antibiotic at that time. If the urine culture is subsequently positive, culture-specific therapy is given for 10 to 14 days. The timing of catheter removal is variable, but most catheters are removed within a week. A cystogram is optional. The closed suction drains are removed when the output is less than 50 mL/24 hr or in 3 weeks, whichever comes first. **If a ureteral stent was used to protect the urinary tract reconstruction, it is removed as an outpatient procedure 6 to 12 weeks after the operation.** If the surgeon had attached the stent to the indwelling Foley catheter, it will come out as the Foley catheter is withdrawn.

Anticoagulation

Most patients undergoing renal transplantation meet the criteria for low-dose anticoagulation to prevent deep venous thrombosis. Patients with hypercoagulable states such as systemic lupus erythematosus, factor V Leiden mutation, prothrombin gene mutation, the anticardiolipin antibody syndrome, or deficiencies of protein C, protein S, or antithrombin III usually receive daily warfarin therapy after the discontinuance of heparin therapy.

RENAL ALLOGRAFT REJECTION

Histocompatibility

The histocompatibility systems of greatest importance in renal transplantation are the ABO blood group and the major histocompatibility complex (MHC) (Denton et al, 1999; Halloran, 2004). The donor and recipient must be ABO compatible because A and B substances are present on endothelial cells, and most individuals have antibodies to the red blood cell antigens they lack. A common exception is the transplantation of ABO blood group A_2 kidneys into blood group O and B recipients, who have low anti-A2 antibody levels (Alkhunaizi et al, 1999). A rare exception is the transplantation across major ABO incompatibilities by recipient preparation with plasmapheresis to remove anti-A or anti-B antibodies, off-label use of the anti-CD 20 antibody rituximab with or without splenectomy to reduce antibody production, and intense induction immunosuppression (Takahashi et al, 2004; Warren et al, 2004).

The MHC antigens are glycoproteins on the cell membrane. They are encoded by MHC genes on the short arm of chromosome 6. Autosomal class I antigens are known as the HLA-A, HLA-B, and HLA-C antigens, and they are present on

Table 40–8. Influence of Histocompatibility on Standard Criteria Deceased Donor Kidney Transplant Survivals

HLA Antigens Mismatched	*No.*	*Half-Life (Yr)**
0	4,182	15
1-3	9,391	12
4-6	14,186	10

HLA, human leukocyte antigen.
*Half-life is projected for those kidney transplants surviving the first year.
Data from Cecka JM: The OPTN/UNOS renal transplant registry 2003. In Cecka JM, Terasaki PI (eds): Clinical Transplants 2003. Los Angeles, UCLA Immunogenetics Center, 2004, p 5.

nearly all nucleated cells. They are detected by tissue typing T lymphocytes, usually with a DNA polymerase chain reaction amplification technique. HLA-DR, HLA-DQ, and HLA-DP antigens are class II antigens present on B lymphocytes, activated T lymphocytes, monocytes, macrophages, dendritic cells, and some endothelial cells. HLA-DR antigens are detected by tissue typing B lymphocytes. Testing for HLA-DQ and HLA-DP antigens is not routinely done. Recipient circulating cytotoxic antibodies against the MHC antigens of a specific donor are detected by pretransplantation crossmatching techniques, and a positive complement-dependent T-cell lymphocytotoxicity crossmatch is considered to be a contraindication to renal transplantation when the serum used is recently obtained from the transplantation candidate. Protocols have been developed to use kidney transplants when the recipient has a positive crossmatch to the donor, and the crossmatch is rendered negative by plasmapheresis and immunoglobulin administration to permit an otherwise prohibited transplant to take place (Jordan et al, 2004).

Because of inheritance patterns of the HLA antigens, each potential kidney graft recipient is a "half-match," or haploidentical, with his or her parents and children and has a 0.25 probability of HLA identity, a 0.50 probability of haploidentity, and a 0.25 probability of a total HLA mismatch with a sibling. The influence of histocompatibility on deceased kidney transplant survival rates is demonstrated in Table 40–8. Within the past 5 years, the influence of histocompatibility matching on graft survival has decreased in the presence of more effective and less toxic immunosuppressive regimens (Halloran, 2004).

Incompatibility with MHC antigens on donor tissue stimulates the immune response (Fig. 40–11). Class II antigens on donor dendritic cells can directly stimulate recipient CD4+ helper T cells and initiate the rejection process. These MHC antigens are also processed by recipient macrophages, which present these class II alloantigens to the CD4+ helper T cells. **A second, or co-stimulatory, signal must be provided by cognate ligands on the antigen-presenting cell to fully activate CD4+ helper T cells.**

These two signals cause the CD4+ helper T cells to secrete cytokines, most importantly, the T-cell growth factor interleukin-2 (IL-2), and to express new cell surface IL-2 receptors. The cascade of events within the CD4+ helper T cell, after receiving the alloantigenic signal through the T-cell receptor and the co-stimulatory signal, is calcineurin activation; dephosphorylation of the nuclear factor of activated T cells,

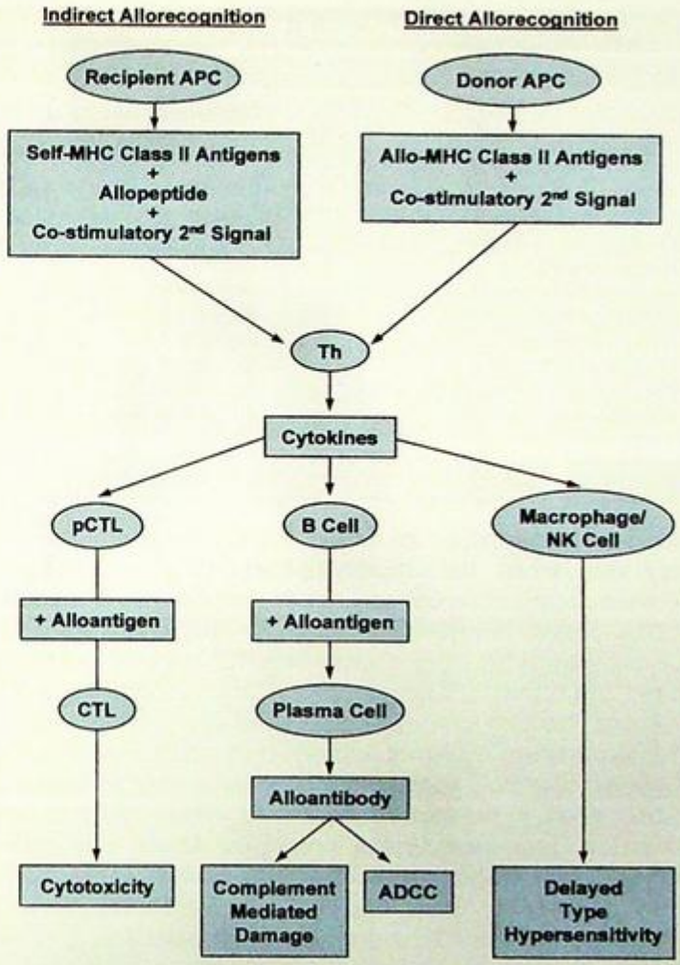

Figure 40–11. Cellular interactions in renal transplant rejection. CD4+ helper T cells (Th) are activated by antigen-presenting cells (APCs) that express incompatible major histocompatibility complex (MHC) class II antigens and provide a co-stimulatory second signal. The Th cells produce lymphokines that promote proliferation of B cells, maturation of CD8+ cytotoxic T lymphocytes (CTLs), activation of macrophages and natural killer (NK) cells, and induction of MHC class II antigens on renal cells. ADCC, antibody-dependent cell-mediated cytotoxicity; pCTL, precursor cytotoxic T cell.

enabling it to enter the nucleus and bind to the IL-2 gene promoter; and the production of IL-2.

IL-2, the third signal, stimulates the IL-2 receptor, and this induces lymphocytes to proliferate. IL-2 is necessary for the maturation of CD8+ cytotoxic T-cell precursors into cytotoxic T cells. IL-2 also stimulates antigen-activated helper T cells to release other lymphokines, such as IL-3, IL-4, IL-5, IL-6, and interferon-γ. IL-3 is a growth factor for bone marrow stem cells. IL-4, IL-5, and IL-6 enable alloantigen-activated B cells to mature into plasma cells, which produce cytotoxic antibodies against the MHC molecules of the graft. Interferon-γ activates the cytodestructive capabilities of macrophages, augments natural killer cell activity, and induces the expression of MHC class II antigens on kidney graft cells.

Classification of Rejection

Hyperacute rejection occurs immediately after renal revascularization. It is an irreversible process mediated by preformed circulating cytotoxic antibodies that develop after pregnancy,

Table 40–9. Mechanisms of Action of Immunosuppressants

Immunosuppressant	*Mechanism of Action*	*Interferes with . . .*
Glucocorticoids	Reduce transcription of cytokine genes	Intracellular signaling
Azathioprine	Inhibits purine synthesis	Lymphocyte proliferation
Mycophenolate mofetil	Inhibits purine synthesis	Lymphocyte proliferation
Sirolimus	Inhibits cell cycle progression	Lymphocyte proliferation
Tacrolimus	Inhibits calcineurin and interleukin-2 production	Intracellular signaling
Cyclosporine	Inhibits calcineurin and interleukin-2 production	Intracellular signaling
Monomurab CD3	Depletes T lymphocytes	Antigen recognition
Equine antithymocyte globulin	Depletes T lymphocytes	Antigen recognition
Rabbit antithymocyte globulin	Depletes T lymphocytes	Antigen recognition
Alemtuzumab (off label)	Depletes T and B lymphocytes	Antigen recognition and antibody production
Rituximab (off label)	Depletes B lymphocytes	Antibody production
Basiliximab	Blocks interleukin-2 receptor	Intercellular signaling
Daclizumab	Blocks interleukin-2 receptor	Intercellular signaling

blood transfusions, or an earlier failed transplantation. It is very rare when the microlymphocytotoxicity crossmatch between recipient serum and donor lymphocytes is negative.

Accelerated rejection is mediated by humoral and cellular components of the immune response. It occurs within days to weeks and often does not respond to antirejection therapy.

Acute rejection can occur any time after transplantation. **The symptoms of acute kidney transplant rejection are those of "the flu," accompanied by pain over an enlarged kidney graft, hypertension, decreased urinary output, fluid retention, increased serum creatinine levels, and radioisotope renography indicating decreased renal blood flow, glomerular filtration, and tubular function.** Acute pyelonephritis must be ruled out by urinalysis and, subsequently, negative urine culture. Needle biopsy of the kidney graft is the standard to confirm the diagnosis of acute rejection. The typical histologic findings of acute renal allograft rejection are mononuclear cellular infiltration, tubulitis, and vasculitis (Gaber et al, 1998). The Banff classification is now accepted as the standard schema for diagnosing rejection (Racusen et al, 2004).

Chronic rejection is characterized by a gradual decline in renal function associated with interstitial fibrosis, vascular changes, and minimal mononuclear cell infiltration. A positive B-cell crossmatch or a positive flow crossmatch against donor B or T cells is considered by some to be predictive of chronic rejection and poorer long-term graft survivals (Ghasemian et al, 1997; Kimball et al, 1998).

Immunosuppression

Immunosuppressive drug regimens commonly include a corticosteroid in combination with other drugs such as cyclosporine or tacrolimus (calcineurin inhibitors), azathioprine or mycophenolate mofetil (purine antagonists), and sometimes antilymphocyte antibody preparations. Triple maintenance immunosuppression with prednisone; cyclosporine or tacrolimus; and azathioprine or mycophenolate mofetil is common. Sirolimus inhibits cell cycle progression, and it is used in combination with corticosteroids or with cyclosporine or tacrolimus in combination with corticosteroids (Groth et al, 1999). The mechanisms and sites of action of clinically useful immunosuppressant medications are listed in Table 40–9 and illustrated in Figure 40–12. An example of an immunosuppression algorithm is presented in Figure 40–13. Antilymphocyte antibodies such as muromonab CD3, rabbit antithymocyte globulin, equine antithymocyte globulin, antibodies to the CD25 component of the IL-2 receptor such as daclizumab and basiliximab, or the off-label lymphocyte depleting antibody to CD52, alemtuzumab, are used by some as part of induction immunosuppressive regimens to allow the kidney graft to recover from

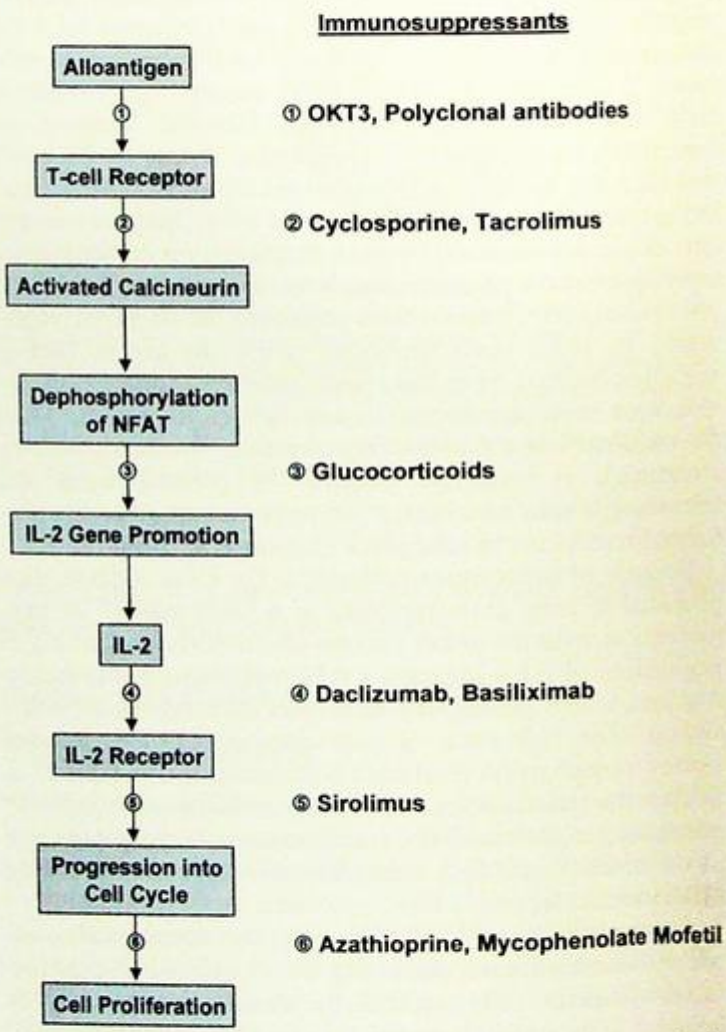

Figure 40–12. Sites of action of commonly used immunosuppressants. IL-2, interleukin-2; NFAT, nuclear factor of activated T cells.

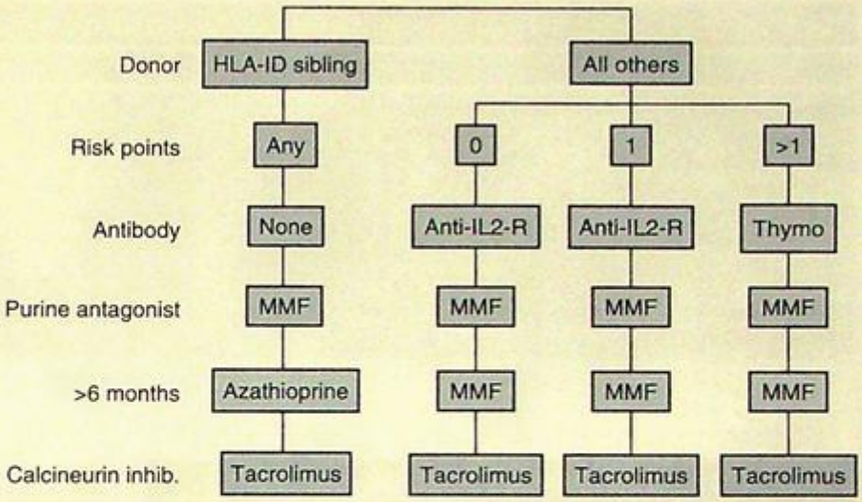

Figure 40–13. Example of kidney transplant immunosuppression protocol. This algorithm is based on donor and recipient histocompatibility, immunologic risk factors, and immunosuppressant mechanism of action. All receive corticosteroids. Assignment of immunologic risk points: 2 points each for more than 50% panel reactive antibody, positive flow crossmatch; 1 point each for prior transplant, six HLA antigens mismatched, delayed graft function, African American ethnicity, lupus nephropathy; subtract 1 point for age older than 60 years. preservation injury before the administration of the nephrotoxic calcineurin inhibitors cyclosporine or tacrolimus (Halloran, 2004).

Corticosteroid therapy is usually started at high doses and then rapidly tapered during the first few weeks after engraftment. Cyclosporine and tacrolimus have similar mechanisms of action, effectiveness, and cost, but slightly different side effect profiles, and they are not used together. Both cyclosporine and tacrolimus are metabolized mainly by the cytochrome P-450 enzyme system. Substances that inhibit that system result in increased blood or plasma levels of these drugs (Table 40–10). Diltiazem and ketoconazole have been used to reduce cyclosporine dosing and cost while maintaining blood levels and the immunosuppressive effect (Patton et al, 1994). Drugs known to induce that enzyme system usually result in increased metabolism of cyclosporine and tacrolimus and decreased whole-blood or plasma levels and immunosuppressive effects. A determination of cyclosporine or tacrolimus blood levels is helpful when toxicity or insufficient immunosuppression is suspected. Drug interactions with sirolimus are very similar to those with the calcineurin inhibitors. Higher and more frequent doses of cyclosporine and tacrolimus are usually necessary in children. Azathioprine and mycophenolate mofetil have similar mechanisms of action, but mycophenolate mofetil is more effective, more toxic, and more expensive (Matthew, 1998). Table 40–11 lists the common organ system targets for toxicity of the drugs used for maintenance immunosuppression. Some programs taper patients off one or more of the maintenance immunosuppressants after many months of stable graft function (Shapiro et al, 2003). The goals of such protocols are to decrease and possibly eliminate maintenance immunosuppression to reduce the long-term complications of malignancy, bone loss, infection, and post-transplant diabetes mellitus and to reduce the costs of transplantation. Tolerance, the achievement of long-term graft acceptance without immunosuppression, has long been a goal of transplantation.

Table 40–10. Potential Drug Interactions with Cyclosporine and Tacrolimus

Drugs That Affect Plasma or Whole Blood Concentrations		
Decrease	*Increase*	*Drugs with Nephrotoxic Synergy*
Rifampin	Diltiazem	Gentamicin
Rifabutin	Verapamil	Tobramycin
Isoniazid	Nicardipine	Vancomycin
Phenobarbital	Erythromycin	Azapropazone
Phenytoin	Clarithromycin	Amphotericin B
Carbamazepine	Ketoconazole	Cisplatin
	Fluconazole	Melphalan
	Itraconazole	Cimetidine
	Clotrimazole	Ranitidine
	Bromocriptine	Diclofenac
	Danazol	
	Cimetidine	
	Methylprednisolone	
	Metoclopramide	

Conventional treatment for acute renal allograft rejection is high-dose pulses of corticosteroids. Treatment of corticosteroid-resistant rejection is with antilymphocyte antibody preparations such as muromonab CD3, equine antithymocyte globulin, and rabbit antithymocyte globulin. In some cases, recalcitrant rejection and graft salvage can be achieved by conversion of one baseline immunosuppressive regimen to another, even in the presence of corticosteroid-resistant rejection (Jordan et al, 1997).

Commonly used regimens to prevent infections and peptic ulcer disease are listed in Table 40–12. CMV infection is a significant problem after renal transplantation, and CMV-seronegative recipients have better outcomes than CMV-seropositive recipients, provided the kidney donor is also CMV-seronegative (Cecka, 2000). Recipients of CMV-seropositive deceased donor kidneys had lower 3-year survival rates, whether or not the recipient was CMV seropositive before kidney transplantation. Prophylaxis against CMV infection is possible with ganciclovir , valganciclovir , or valacyclovir (Preiksaitis et al, 2005).

Future immunomodulation strategies in transplantation include blockade of T-cell co-stimulation, blockade of T-cell adhesion molecules, blockade of T-cell accessory molecules, peptide-mediated immunosuppression, gene therapy, and induction of tolerance (Starzl et al, 2003).

Table 40–11. Common Organ System Targets for Toxicities of Immunosuppressant Therapy

	Prednisone	*Cyclosporine*	*Tacrolimus*	*Sirolimus*	*Azathioprine*	*Mycophenolate*

Table 40–12. Postoperative Infection and Peptic Ulcer Prophylaxis

Problem	*Commonly Used Drug Prophylaxis*	*Alternate(s)*
Urinary tract infection	Trimethoprim-sulfamethoxazole × 3 months	Nitrofurantoin
Pneumocystis pneumonia	Trimethoprim-sulfamethoxazole × 3 months	Pentamidine inhalant
Oral candidiasis	Clotrimazole lozenges × 1-3 months	Nystatin troches
Vaginal candidiasis	Clotrimazole vaginal inserts × 1-3 months	Nystatin inserts
Herpes simplex virus	Acyclovir × 3 months	Gancyclovir
Primary CMV disease	Gancyclovir ± CMV immune globulin × 4 months	Valacyclovir, acyclovir
Recurrent CMV disease	Gancyclovir × 3 months or during antibody therapy	Valacyclovir, acyclovir
Peptic ulcer disease	H_2 receptor antagonist + antacid if symptomatic	

CMV, cytomegalovirus.

PROBLEMS

Early Graft Dysfunction

Early graft dysfunction can be due to infection, renal allograft rejection, urinary or vascular obstruction, cyclosporine or tacrolimus nephrotoxicity, hyperglycemia, or dehydration. The cause can usually be sorted out by following the suggestions in Tables 40–13 and 40–14. Fever is common with infection and/or rejection. Physical examination for sinusitis, dental abscess, pneumonia, cholecystitis, appendicitis, diverticulitis, and kidney graft tenderness can be quickly performed. An ultrasound examination that includes a Doppler flow study can demonstrate renal allograft enlargement, the presence or absence of hydronephrosis, and blood flow in and out of the kidney graft. In addition, it can assess the gallbladder and native kidneys for stones and obstruction. Tremor can be a clue to calcineurin inhibitor toxicity, which can be confirmed by determining the blood level of the calcineurin inhibitor. The pseudorejection of hyperglycemia can be quickly diagnosed with a bedside blood glucose determination. Dehydration can also be quickly diagnosed at the bedside and treated intravenously with a 5- to 10-mL/kg bolus of fluid.

Vascular Complications

Immediate vascular complications include kinking of the kidney graft's artery or vein, suture line stenosis, or thrombosis. Thrombosis of the kidney graft may occur because of hyperacute rejection or thrombophilia. Renal artery stenosis after renal transplantation is usually diagnosed because of hypertension that is progressively difficult to manage, with or without impaired renal function. Color Doppler sonography has a high sensitivity and specificity for detecting transplant renal artery stenosis (Radermacher et al, 2000). The causes are atheroma, faulty suture technique, clamp trauma, and immunologic mechanisms (Lacombe, 1988). The finding of a bruit over the kidney graft is unreliable because it is a common sign after renal transplantation with or without hypertension; however, the detection of a new bruit may be significant. **Surgical intervention for transplant renal artery stenosis is difficult, with a significant risk of technical failure, and percutaneous transluminal angioplasty, with or without endoluminal stent placement, has become the initial treatment of choice** (Nicita et al, 1998).

Renal allograft rupture is rare and requires immediate operation. It is usually due to acute rejection or renal vein thrombosis. If it is due to the former, rejection crisis treatment and operative repair with bolstered mattress sutures, administration of topical thrombotic agents, and the use of synthetic glue and polyglactin mesh wrap have resulted in graft salvage (Chopin et al, 1989). If it is due to renal vein thrombosis, graft salvage with thrombectomy and repair of graft rupture is rare, and allograft nephrectomy is usually necessary (Richardson et al, 1990).

Allograft Nephrectomy

The indications for allograft nephrectomy are to remove a symptomatic irreversibly rejected kidney transplant and, in the case of a chronically rejected asymptomatic graft, to withdraw immunosuppression and to prevent the development of anti-HLA antibodies that could delay or prevent a subsequent transplantation.

The usual approach is through the original incision. Within the first month after transplantation, allograft nephrectomy is a straightforward procedure, and it is usually possible to

Table 40–13. Sorting Out Early Graft Dysfunction

Cause	*Physical Finding*	*Initial Diagnostics Based on Suspicion*
Infection	Fever, chills, normal or ↓ BP, ± pulmonary findings, ± native or kidney transplant tenderness	Chest radiograph, urinalysis, smears and cultures of sputum, urine, wound drainage, and blood; ultrasonogram of abdomen and kidney graft
Rejection	± Fever, normal or ↑ BP, normal or ↑ CVP, kidney transplant tenderness	Ultrasound of kidney graft, allograft biopsy
Obstruction	Vital signs normal unless infected, ± kidney transplant tenderness	Irrigate bladder catheter, ultrasound and Doppler flow study of kidney graft
Calcineurin inhibitor toxicity	Afebrile, normal or ↑ BP, normal CVP, ± tremor	Calcineurin inhibitor blood level
Hyperglycemia	Afebrile, ↓ BP, ↓ CVP	Blood sugar
Dehydration	Afebrile, ↓ BP, ↓ CVP	IV fluid bolus

BP, blood pressure; CVP, central venous pressure; IV, intravenous.

Table 40–14. Differentiation of Calcineurin Inhibitor Toxicity from Acute Rejection

Characteristic	*Tacrolimus or Cyclosporine Toxicity*	*Acute Rejection*
Fever	No	Yes
Urinary output	Usually maintained	Decreased
Graft tenderness	No	Yes
Graft size	Stable	Increased
Serum creatinine level rise	Slow	Rapid
Cyclosporine/tacrolimus blood level	High	Normal or low
Graft biopsy	May be normal	Cellular infiltration, vasculitis, tubulitis

remove all of the transplanted tissue. After 4 to 6 weeks, a dense fibrous reaction surrounds the kidney transplant and the procedure can be a formidable one. It is usually accomplished with the subcapsular technique and knowledge of the vascular reconstruction that was done at the time of transplantation. The surgeon must be prepared to occlude the vascular pedicle with a large vascular clamp, transect the vascular pedicle distal to the clamp, and either separately ligate the renal veins and arteries or oversew the stumps of the vessels with 4-0 or 5-0 vascular suture. The renal capsule and the intravesical ureteral stump are left behind. The wound is liberally irrigated with an antibiotic solution, a suction drain is commonly placed, and the wound is closed as described under "Recipient Operation."

Perioperative antibiotic therapy is discontinued, changed, or continued on the basis of intraoperative culture results, and immunosuppression is discontinued within a few weeks. Cyclosporine or tacrolimus is withdrawn immediately; azathioprine, mycophenolate mofetil, or sirolimus is continued for 4 to 6 weeks because of residual allograft tissue, especially in the case of a subcapsular nephrectomy; and prednisone is gradually tapered and withdrawn with the following formula: 1 week of corticosteroid taper for every month of immunosuppression for a maximum of 6 weeks.

Hematuria

Hematuria immediately after transplantation is usually due to catheter trauma or urinary tract reconstruction. If it cannot be controlled with catheter irrigation, endoscopy with clot evacuation and fulguration of the bleeding site or sites in the bladder is necessary. If those treatments fail, surgical exploration is indicated.

Late hematuria can be due to medical renal disease in the kidney graft, infection, calculus, or malignancy. If hematuria persists after treatment of a documented urinary tract infection, a standard hematuria workup with microscopy for red blood cell casts or dysmorphic red blood cells should be done, followed, if necessary, by imaging of the native kidneys and kidney transplant, cystoscopy, a bladder wash for cytologic examination, and pertinent urothelial biopsies.

Fluid Collections

Most fluid collections after renal transplantation are incidental findings on baseline ultrasound examinations and require no treatment (Pollak et al, 1988). An algorithm for the evaluation and management of perigraft fluid collections is shown in Figure 40–14. When fluid collections are large or associated with dilatation of the collecting system, pain, fever, or an unexplained decline in renal function, then an ultrasonically guided aspiration can be diagnostic. If the fluid is purulent, microscopic examination of the fluid for pus cells and organisms is performed, and antibiotic treatment is initiated. In the event of infection, cyclosporine or tacrolimus therapy is usually continued; azathioprine, mycophenolate mofetil, or sirolimus therapy is discontinued; and prednisone is reduced to less than 15 mg/day. Although percutaneously placed tube drainage can be effective, open surgical drainage is often necessary for infected fluid collections. Lymph, urine, and blood can be differentiated from each other by creatinine and hematocrit determinations. Lymph has a creatinine concentration that is the same as that of serum, urine has a creatinine concentration higher than that of serum and approaching that of bladder urine, and blood has a high hematocrit level when compared with the other two fluids.

If the symptoms or the urinary tract obstruction are relieved by aspiration and there is no recurrence of the fluid, no further treatment is necessary. If blood reaccumulates, exploration and control of bleeding are usually necessary.

If an uninfected lymphocele recurs, it is usually treated by unroofing it into the peritoneal cavity by either open or laparoscopic technique (Schweitzer et al, 1972; Gill et al, 1995). **Lymphoceles that are lateral to the kidney are**

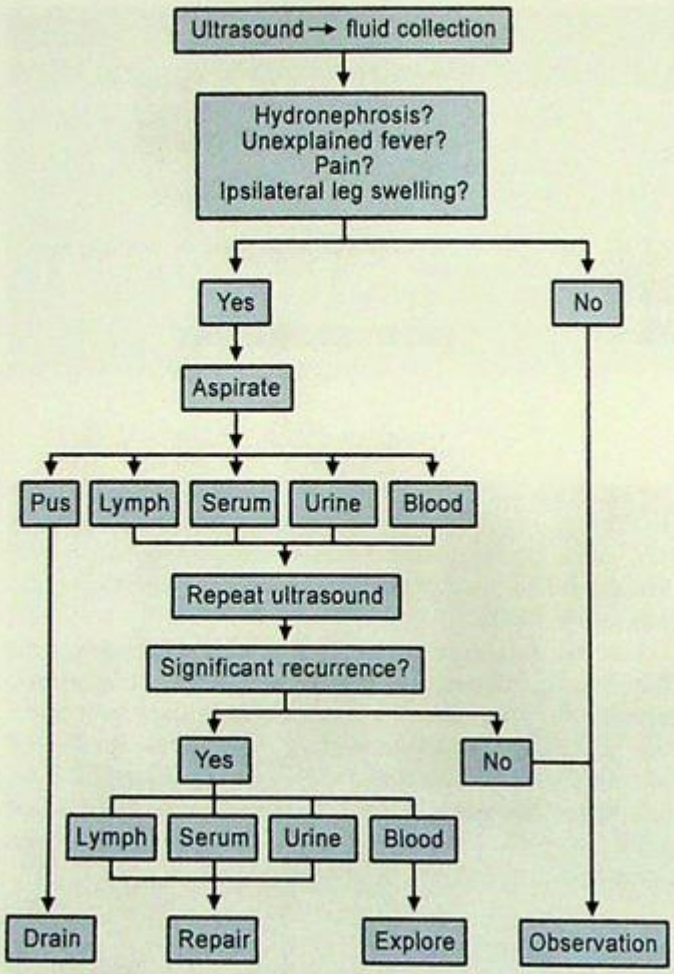

Figure 40–14. Algorithm for evaluation and treatment of perigraft fluid collection. (Modified from Barry JM: Renal transplantation. In Krane RJ, Siroky MB, Fitzpatrick JM [eds]: Clinical Urology. Philadelphia, JB Lippincott, 1994, p 325.)

difficult to access laparoscopically (Gruessner et al, 1995). Success has been reported with percutaneous sclerosis (Rivera et al, 1996). If the lymphocele is infected, open drainage is often necessary.

Urinary extravasation often requires open surgical repair. A retrograde or CT cystogram will document leakage at the cystotomy or ureteroneocystostomy site. If a retrograde cystogram does not show extravasation, contrast CT may suggest, and percutaneous antegrade pyelography will confirm, a site of extravasation from the ureter or renal pelvis. Excretory urography may also be used but is often impractical in this setting because of inadequate renal function. Some urinary leaks at the ureteroneocystostomy site may be managed simply by bladder catheter drainage, with or without percutaneous nephrostomy, by percutaneous or retrograde passage of a double-J ureteral stent, or by the performance of another ureteroneocystostomy. If open repair is necessary, retrograde pyelography and the passage of a ureteral catheter into the native ureter at the time of repair will facilitate the identification of that structure if it is needed for ureteroureterostomy or ureteropyelostomy. Urinary tract repair is usually protected with a stent for 6 weeks and sometimes a small nephrostomy tube or an omental flap, or both. A suction drain is placed, and antibiotic therapy based on culture and sensitivity results is administered.

Obstruction and Stones

Figure 40–15 is an algorithm for evaluating hydronephrosis in the transplanted kidney. Ureteral obstruction in the immediate postoperative period is due to technical error, edema, a blood clot, unsuspected donor calculus, or perigraft fluid collection. Although endourologic techniques can be successful, a technical error is usually repaired with a stented ureteroneocystostomy. Edema usually resolves within a few days, and ureteral blood clots lyse with naturally produced urokinase.

The management of fluid collections was discussed previously.

Late causes of urinary tract obstruction are periureteral fibrosis, calculi, tumor, fungus ball, lymphocele, chronic ischemia of the distal ureter with stricture, and BK-related polyomavirus nephropathy. Ureteroneocystostomy meatal stenosis can be managed by endoscopic ureteral meatotomy, by percutaneous ureteral dilatation followed by stent placement (Hobart et al, 2000), or by open surgical repair. **There are reports of long-term success of the endourologic treatment of transplant ureteral stenosis** (Streem et al, 1988; Benoit et al, 1993). Failures are usually apparent within 1 year of treatment, and short, anastomotic strictures are the lesions most successfully treated with these techniques. If the stricture is distal and allograft ureteral length is sufficient, a repeat ureteroneocystostomy will do. For recurrent or long strictures, ureteropyelostomy and ureteroureterostomy as described earlier are reasonable options. Vesicopyelostomy, vesicocalycostomy, and interposition of a small bowel segment between the renal pelvis and the bladder (Orton and Middleton, 1982; Ehrlich et al, 1983; Del Pizzo et al, 1998) have all been used as surgical treatments for an obstructed allograft ureter.

Causes of urinary tract calculi after renal transplantation are considered to be persistent hyperparathyroidism, recurrent urinary tract infections, a foreign body such as a suture or staple, obstruction, a habitual decreased fluid intake, and distal renal tubular acidosis (Hefty, 1991). **Because the renal transplant is denervated, the patient will not experience typical renal colic, and the diagnosis is suspected when renal function suddenly deteriorates or transplant pyelonephritis occurs.** Upper tract calculi are managed by the same techniques as calculi in the normal urinary tract; however, negotiation of the transplanted ureter may be difficult or impossible because of tortuosity, thus favoring percutaneous techniques. Extracorporeal shock wave lithotripsy has been used successfully with clever positioning of the patient in the shock wave path (Wheatley et al, 1991). Small bladder calculi are managed by transurethral extraction and irrigation with or without lithotripsy. If a cystolithotomy is selected as the procedure for a medium to large hard stone, the surgeon must take care not to damage the ureteroneocystostomy.

Urinary Tract Infection

Urinary tract infections after renal transplantation are present in up to 40% of patients and have been associated with increased mortality after transplantation (Chuang et al, 2005). In addition to immunosuppression and an indwelling bladder catheter, the following risk factors are often present: advanced recipient age, use of deceased donor kidney, female gender, diabetes mellitus, and preexisting urinary tract abnormalities.

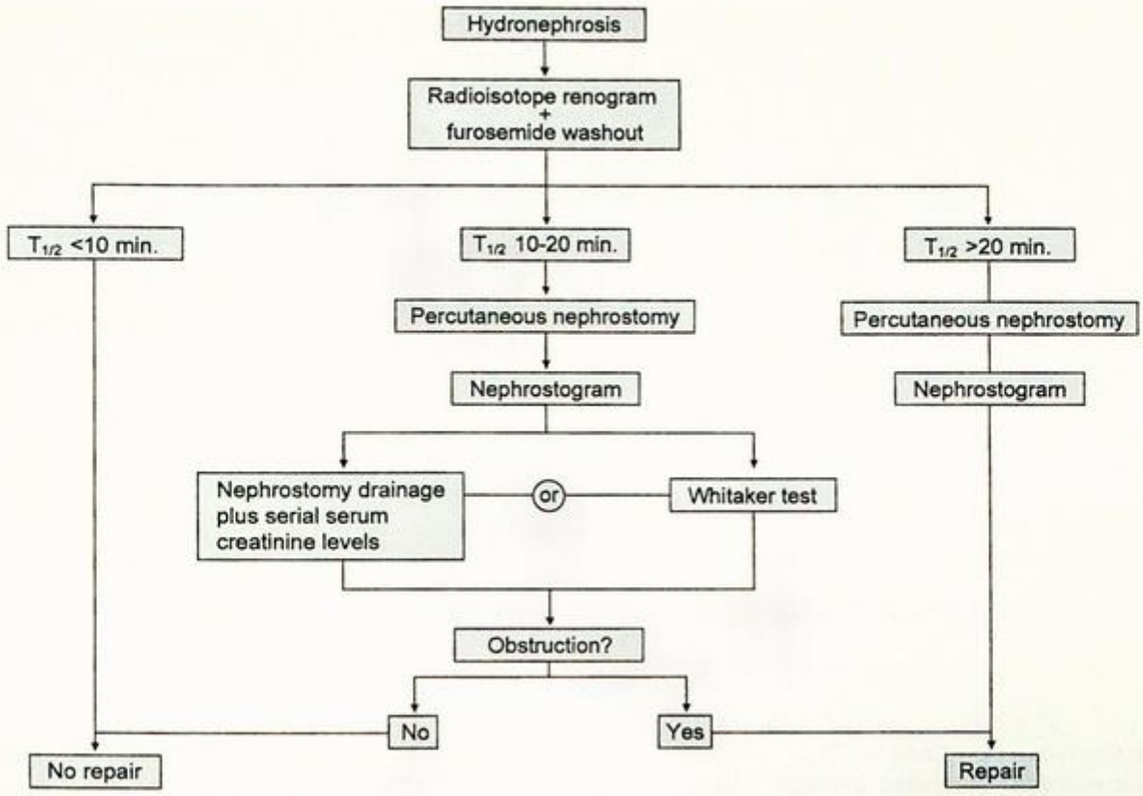

Figure 40–15. Algorithm for evaluation of renal transplant hydronephrosis.

During the first 3 months after renal transplantation, prophylactic broad-spectrum antibiotics such as trimethoprim-sulfamethoxazole are usually prescribed. This drug combination also prevents pulmonary *Pneumocystis carinii* infection. Trimethoprim interferes with the tubular secretion of creatinine, and this can cause an increase in the serum creatinine levels. The urinary tract infections that occur months after transplantation are usually benign and respond readily to conventional antimicrobial therapy, guided by urine culture and sensitivity. **Patients with pyelonephritis should be screened with ultrasonography for obstruction or stone.** Graft dysfunction accompanied by fever can be due to either acute pyelonephritis or acute rejection, and it is important to differentiate between the two because increased immunosuppression during an episode of acute pyelonephritis can result in significant sepsis.

Candida cystitis often responds to foreign body removal and bladder irrigations with amphotericin B with or without oral fluconazole (Wise, 2002). Cyclosporine and tacrolimus doses usually have to be reduced when fluconazole is given because fluconazole interferes with the metabolism of both those immunosuppressants. Tissue-invasive infections often require intravenous administration of fluconazole or amphotericin B.

Hemorrhagic cystitis can be due to adenovirus (Yagasawa et al, 1995). The disease is usually self-limited and resolves within 1 or 2 weeks. Treatment is by forced hydration and diuresis.

BK polyomavirus is an important, recently recognized uropathogen that can be present in 10% to 45% of recipients and cause significant nephropathy in 6% of infected recipients (Trofe et al, 2004). It can be transmitted from the donor or be reactivated in the recipient by immunosuppression. Recognition and treatment can be challenging because the nephropathy often mimics a rejection crisis, and antirejection therapy can exacerbate the disease. It can also present as ureteral obstruction due to fibrosis. Polymerase chain reaction of both blood and urine can identify the infection. Renal biopsy is often inconclusive. Treatment consists of reduction of immunosuppression, antiviral therapy such as with cidofovir, which has significant nephrotoxicity, and leflunomide (Williams et al, 2005).

Vesicoureteral Reflux

Although there is some controversy about the need for antireflux ureteroneocystostomy in kidney transplantation, common urologic thinking is that reflux of infected bladder urine or high-pressure reflux is damaging to a kidney. **The indications for antireflux surgery of the kidney transplant ureter are the same as those for nontransplanted patients** (Reinberg et al, 1990). If the reflux is due to high-pressure voiding, relief of the bladder outlet obstruction or augmentation cystoplasty with intermittent catheterization must be considered. Ureteral advancement techniques, ureteroureterostomy to a nonrefluxing native ureter, and submucosal injection techniques are all possible therapies.

Erectile Dysfunction

Erectile dysfunction after renal transplantation is common (Malavaud et al, 2000) and can be due to any one or a

Table 40–15. Potential Causes of Erectile Dysfunction after Renal Transplantation

Anatomic Location	*Examples*	*Mechanisms*
Central		
Antihypertensives	Clonidine	α_2 Agonist
	Methyldopa	α_2 Agonist, ↑ prolactin
	Propranolol	β Antagonist
Peptides/amino acids	Prednisone	↓ ACTH
↓ Testosterone	Cimetidine	↑ Prolactin
	Cyclosporine	↑ Prolactin
	Sirolimus	Testis atrophy
Anxiety	Stress	↑ Norepinephrine
Autonomic/peripheral nerves	Diabetes mellitus	Axon injury
	Uremia	Axon injury
Cavernosal blood supply		
Internal iliac arterial tree	Renal artery anastomosis	↓ Penis blood flow
Accelerated arteriosclerosis	Prednisone, cyclosporine, propranolol, diabetes mellitus	↑ Cholesterol
Antihypertensives	Any	↓ Penis blood pressure and blood flow
Diuretics	Any	↓ Blood volume and penis blood flow
Cavernosal smooth muscle	Diabetes mellitus, ↑ cholesterol	Impair nitric oxide–mediated relaxation
	Cyclosporine, tacrolimus	↑ Thromboxane A_2
Tunica albuginea of penis	Propranolol	Peyronie's disease

Modified from Barry JM: The evaluation and treatment of erectile dysfunction following organ transplantation. Semin Urol 1994b;12:147.

combination of the factors outlined in Table 40–15. **Factors unique to the transplant recipient are side effects from immunosuppression and a reduction of cavernosal blood supply by the renal arterial anastomosis.** Sirolimus-treated men have been shown to have lower serum testosterone levels, higher follicle-stimulating hormone and luteinizing hormone concentrations, and no difference in serum prolactin levels when compared with non–sirolimus-treated control subjects (Fritsche et al, 2004).

Treatment options for transplant recipients with erectile dysfunction are presented in Table 40–16. A diagnosis and treatment algorithm for erectile dysfunction after renal transplantation is presented in Figure 40–16 and is similar to those for the immunocompetent patient. Sildenafil has been shown to improve glomerular filtration rates in kidney transplant recipients (Rostaing et al, 2000) and not to alter blood levels of cyclosporine or tacrolimus (Cofan et al, 2002). Intracorporeal injections of vasoactive drugs and implantation of penile prostheses have successfully treated this problem (Lasaponara et al, 2004), but the transplant recipient must be warned of the increased risk of infection when either of these invasive treatment options is used.

If a penile prosthesis is chosen as the most appropriate therapy, the following criteria are helpful: stable graft function without a rejection crisis for at least 6 months, low doses of maintenance immunosuppressants, a low probability of device malfunction, no intra-abdominal components, minimal tissue dissection, no skin or urinary tract infections, prophylactic antibiotic therapy (parenteral, intraurethral, and wound irrigation), and postoperative oral antibiotics for 2 weeks. When a stress corticosteroid protocol is used, 25 mg of prednisone (or its equivalent) is given with the preoperative medications and 12 and 24 hours later. Maintenance corticosteroid therapy is resumed on the second postoperative day. The oral doses of cyclosporine or tacrolimus and of azathioprine, mycophenolate mofetil, or rapamycin are not altered. The intravenous doses of cyclosporine and tacrolimus are one third the oral doses, and they are infused over 24 hours. The intravenous doses of azathioprine and mycophenolate mofetil are the same as the oral doses.

Table 40–16. Treatment Options for Transplant Recipients with Erectile Dysfunction

Treatment	*Examples*
Psychotherapy/counseling	Alternate sexual techniques
	Stop alcohol use
	Stop tobacco use
Medication changes	Treat hypertension with calcium antagonists, angiotensin-converting enzyme inhibitors, or α_1 blockers
	Change cimetidine to ranitidine, famotidine, or nizatidine
	Glucocorticoid withdrawal, if possible
Medication additions, if indicated by workup	Testosterone replacement
	Thyroid replacement
	Bromocriptine
	Type 5 phosphodiesterase inhibitors
Vacuum erection devices	
Intracavernous injections	Prostaglandin E_1
Vascular procedures	Angiodilation
	Revascularization
Penile prostheses	Malleable
	Mechanically jointed
	Inflatable without prevesical reservoir

Transplant Immunol Lett 2000;16:7.)

usually become normal, and spermatogenesis improves (Akbari et al, 2003; Kheradmand and Javadneia, 2003). **Among male recipients who have fathered children, there has been no increase in congenital abnormalities in the offspring;** however, it is recommended that impregnation be delayed for at least 1 year after transplantation (Armenti et al, 1998).

Successful renal transplantation usually restores fertility in premenopausal women. In a report based on thousands of pregnancies in renal transplant recipients, Davison and Milne (1997) reported the following: 94% of the conceptions that continued beyond the first trimester ended successfully; 50% of the deliveries were preterm; 30% of the women developed hypertension, preeclampsia, or both; intrauterine growth retardation occurred in about 20%; and rejection crises occurred in 10%. **There were no frequent or predominant abnormalities in the children, the transplanted kidney rarely caused dystocia, and the transplanted kidney was not injured during vaginal delivery.** Pregnancy safety information for immunosuppressive drugs is listed in Table 40–17 (Armenti et al, 2003). Guidelines for successful pregnancy are good general health for 2 years after transplantation, minimal proteinuria, no hypertension, no rejection, no urinary tract obstruction, nearly normal renal function, and low doses of maintenance immunosuppressants.

Table 40–17. Pregnancy Safety and Immunosuppressants

	Pregnancy Category

B, no fetal risk in animals, no controlled studies; C, fetal risk cannot be ruled out; D, evidence of fetal risk.

Data from Armenti VG, Radomski JS, Moritz M, et al: Report from the National Transplantation Pregnancy Registry (NTPR): Outcomes of pregnancy after transplantation. In Cecka JM, Terasaki PI (eds): Clinical Transplants 2002. Los Angeles, UCLA Immunogenetics Center, 2003, p 128; and Physicians Desk Reference, 59th ed. Montvale, NJ, Thomson PDR, 2005.

Pulmonary Infection

Pneumonia in the immunosuppressed kidney transplant recipient is usually due to common bacterial pathogens, however, *Legionella, Nocardia,* mycobacteria, viruses, parasites *(Pneumocystis),* and fungi can all be etiologic agents.

Cancer

Kidney transplant recipients are more likely to develop cancer than age-matched subjects in the general population and patients wait-listed for deceased donor renal transplantation. Among 35,765 first-time recipients of deceased or living donor renal transplants, the rates for most malignancies were higher after kidney transplantation when compared with the general population and with 46,106 patients wait-listed for

kidney transplantation. This was especially true for Kaposi's sarcoma, non-Hodgkins lymphomas, nonmelanoma skin cancers, and kidney cancer (Kasiske et al, 2004).

Although bacille Calmette-Guérin (BCG), a live, attenuated bacterium, has been used successfully to treat superficial bladder cancer in kidney transplant recipients, it should be used with caution, if at all, in immunocompromised transplant recipients because of the risk of systemic infection and the likelihood of diminished therapeutic response. Absorbed thiotepa may have an additive myelosuppressive effect if the patient is also taking azathioprine, mycophenolate mofetil, or sirolimus.

Enterocystoplasty has become recognized as a risk factor for carcinoma in the reconstructed bladder, and it is reasonable to begin bladder cancer surveillance 5 years after the augmentation procedure (Nahas et al, 1999).

KEY POINTS: RENAL TRANSPLANTATION

- The incidence of end-stage renal disease (ESRD) is greater than any urologic malignancy except prostate cancer.
- More patients die annually of ESRD than of any urologic malignancy.
- The first long-term success with human kidney transplantation occurred in 1954.
- Medicare co-insurance has been one of the most significant advances for the treatment of patients with ESRD.
- Preliminary evaluation of ESRD patients for renal transplantation is important to prevent wastage of kidney grafts because of transplantation into unsuitable recipients.
- Protocols are evolving to deal with the issues of ABO incompatibility and positive crossmatches between donors and recipients.
- Laparoscopic-assisted donor nephrectomy has reduced disincentives for living renal donors.
- Urologists must be aware of the urologic problems that may prevent or impair renal transplant technical success.
- Urologists must be aware of the potential genitourinary problems of transplant recipients.

Medical Vascular Complications

Nonsurgical hypertension after renal transplantation is common. Causes of this include medications (corticosteroids, cyclosporine, and tacrolimus), intrinsic renal disease, and rejection.

In spite of aggressive preoperative assessment and treatment, myocardial infarction and stroke continue to be leading causes of death in these patients. Prednisone and cyclosporine increase cardiovascular risk because of the hyperlipidemia associated with these drugs, and post-transplant hyperlipidemia should be treated aggressively with dietary changes and, if necessary, anti-lipid medications.

New Diabetes Mellitus

New diabetes occurs in a significant percentage of kidney transplant recipients (Kasiske et al, 2003). **This is due to the diabetogenic effects of corticosteroids and calcineurin inhibitors.** The incidence of insulin-dependent post-transplant diabetes mellitus is significantly higher in patients treated with tacrolimus than in those treated with cyclosporine.

SUMMARY

Renal transplantation is the best therapy for most patients with ESRD. Morbidity and mortality have been significantly reduced by attention to pretransplantation evaluations, donor surgery, kidney preservation, recipient selection, recipient surgery, histocompatibility, immunosuppression, and the successful management of complications. **Organ shortage continues to be a significant problem.**

41 Etiology, Pathogenesis, and Management of Renal Failure

DAVID A. GOLDFARB, MD • JOSEPH V. NALLY, JR., MD • MARTIN J. SCHREIBER, JR., MD

ACUTE RENAL FAILURE
ACUTE TUBULAR NECROSIS
CLINICAL APPROACH TO THE DIFFERENTIAL DIAGNOSIS OF ACUTE RENAL FAILURE
MANAGEMENT OF ACUTE RENAL FAILURE
CHRONIC RENAL FAILURE

Disorders of renal function are ubiquitous in the contemporary practice of medicine. These can be broadly grouped into two major categories: acute renal failure and chronic renal failure. Urologists are likely to encounter renal function issues and their aberrations on a daily basis. This chapter is designed to give a contemporary insight into the nature of renal failure and its treatment.

ACUTE RENAL FAILURE

Definition

Acute renal failure (ARF) is a common problem in the contemporary practice of medicine and urology in the hospitalized patient. Prospective studies have demonstrated that 2% to 5% of all patients admitted to a general medical/surgical hospital unit will develop ARF (Nolan and Anderson, 1998). In selected patients in the intensive care unit (ICU) after cardiovascular or abdominal vascular surgery, the incidence may exceed 20%. Epidemiologic studies indicate that the development of ARF is associated with significant increases in morbidity (which prolongs hospitalization and increases costs) and mortality (Dimick et al, 2003). The high occurrence and substantial morbidity and mortality of ARF demand a logical approach to its early recognition and prevention, as well as prompt diagnosis and management of its complications.

ARF is defined as a rapid reduction in renal function characterized by progressive azotemia (best measured clinically by serum creatinine [SCr]), which may or may not be accompanied by oliguria. This abrupt decline in renal function occurs over the course of hours to days and results in the failure to excrete nitrogenous wastes from the plasma or to maintain normal volume and electrolyte homeostasis. The ARF can be diagnosed with certainty when the patient's prior renal function is known and the reduction in renal function is documented.

The cardinal feature of ARF is a decline in glomerular filtration rate (GFR). While ideally determined by inulin or radioisotopic clearance techniques, it is usually identified in routine clinical practice by a rise in serum blood urea nitrogen (BUN) or creatinine. **It is important to understand the limitations of these common clinical chemistries for them to be properly interpreted. The correlation between BUN, creatinine, and GFR assumes they are delivered into the serum at a constant rate. Therefore, conditions such as hypercatabolic state and massive trauma that may be seen in surgical patients can affect renal function assessment. BUN may be disproportionately elevated in states of marked volume contraction, in hypercatabolic states, and with marked increases in protein loads seen with gastrointestinal bleeding or total parenteral nutrition. Serum creatinine is produced at a constant rate by muscle and more accurately reflects GFR. When renal function deteriorates, tubular secretion represents an increasing proportion of creatinine excretion. Therefore, creatinine clearance may overestimate GFR as renal function slowly declines when measured in the "steady state."** Both the creatinine clearance and the Cockcroft-Gault calculation may be useful tools to estimate GFR because they take into account the patient's body size, age, and SCr value. For example, the Cockcroft-Gault formula states that creatinine clearance = (140 − age) × weight × (0.85 female) divided by 72 × plasma creatinine (Cockcroft and Gault, 1976). Both methodologies have their disadvantages because the urinary creatinine clearance method is cumbersome and the Cockcroft-Gault method may have a margin of error up to about 30% compared with GFR measured by

formal ^{125}I iothalamate techniques. Recently the Modification of Diet in Renal Disease (MDRD) calculations have been used as a way to estimate GFR (Levey et al, 1999). However, none of these techniques is suitable for estimating GFR in the ARF patient because such a "steady state" does not exist (Hoste et al, 2005). Use of "real time" estimates of GFR using infused radioisotopic plasma disappearance techniques in the ICU patient with ARF has been advocated by some but has not achieved wide clinical acceptance. In clinical practice, the experienced nephrologist infers from a rapidly rising SCr value that the patient's true GFR is approaching zero.

Epidemiology and Classification of ARF

Clinically, it is very useful to separate the causes of ARF into three major categories: prerenal, intrinsic renal, and postrenal. Distinguishing among the three basic categories of ARF is a challenging clinical exercise. Assigning a patient to one of the three categories usually requires a combination of clinical and laboratory evaluations and may require invasive monitoring of central hemodynamics or imaging studies of the genitourinary tract. **The importance of differentiating the major causes of ARF must be stressed, because the initial evaluation and management are tailored to the particular cause.** Because the greatest proportion of hospital-acquired ARF is secondary to acute tubular necrosis (ATN), in this chapter we place special emphasis on the diagnosis, pathophysiology, and management of ATN. For example, a report from Madrid evaluated 748 cases of ARF at 13 tertiary care hospital centers (Liano and Pascual, 1996). The causes of ARF were ATN, 45%; prerenal, 21%; acute or chronic renal failure, 13%; urinary tract obstruction, 10%; glomerulonephritis/vasculitis, 4%; acute interstitial nephritis (AIN), 2%; and atheroembolic renal disease, 1%. Earlier reports had documented that ARF occurs more commonly in the surgical/trauma ICU, medical ICU, and postoperative units.

Prerenal Azotemia

Prerenal azotemia is caused by transient renal hypoperfusion that may induce a fall in GFR and produce urinary sodium avidity. The hallmark of prerenal azotemia is its reversibility with treatment of the underlying cause and the lack of structural damage to the kidney. The "gold standard" is the response to appropriate fluid repletion: return of renal function to the previous baseline within 24 to 72 hours is usually considered to represent prerenal disease.

Under normal circumstances, the kidney can maintain normal renal blood flow (RBF) and GFR down to perfusion pressures of approximately 60 mm Hg. The phenomenon of autoregulation requires a complex interaction of physiologic factors to maintain RBF and GFR. In some hospitalized patients with disordered autoregulation, a reduction in RBF and GFR may occur with modest or even no discernable fall in systemic blood pressure. In the setting of decreased renal perfusion, angiotensin II and vasodilatory prostaglandins play an important role in maintaining glomerular hydrostatic pressure and GFR. The three major determinants of GFR are renal plasma flow, glomerular hydrostatic pressure, and glomerular permeability. **Angiotensin II has selectively greater vasoconstrictor effects on the efferent than afferent arteriole, whereas vasodilatory prostaglandins can cause afferent arteriolar vasodilation. Drugs that selectively block angiotensin II synthesis, such as angiotensin-converting enzyme (ACE) inhibitors or angiotensin II receptor binders (angiotensin II receptor blockers), or that inhibit vasodilatory prostaglandin synthesis may cause ARF. This is prone to occur in clinical settings in which GFR is already compromised** (Toto et al, 1991; Whelton, 1999).

Table 41–1. Prerenal Causes of Acute Renal Failure

Volume Depletion
Surgical: hemorrhage, shock
Gastrointestinal losses: vomiting, diarrhea, fistulas
Renal: overdiuresis, salt-wasting disorders
Cardiac Causes: Primary Decrease in Cardiac Output
Acute disorders: myocardial infarction, arrhythmias, malignant hypertension, tamponade, endocarditis
Chronic disorders: valvular diseases, chronic cardiomyopathy (ischemic heart disease, hypertensive heart disease)
Redistribution of Extracellular Fluid
Hypoalbuminemic states: nephrotic syndrome, advanced liver disease, malnutrition
Physical causes: peritonitis, burns, crush injury
Peripheral vasodilatation: sepsis, antihypertensive agents
Renal artery stenosis (bilateral)

Prerenal azotemia may be encountered in both the volume-depleted and volume-overloaded patient (Table 41–1). True volume depletion may result from renal or extrarenal losses that result in systemic hypotension and renal hypoperfusion. In the volume-overloaded patient, with edematous states such as cirrhosis and congestive heart failure, prerenal azotemia may occur because the kidney perceives that the vascular tree is underfilled (i.e., "ineffective arterial blood volume"). This results in renal hypoperfusion. Prerenal azotemia may also occur owing to high-grade bilateral renal artery stenosis or in states of renal hypoperfusion due to redistribution of extracellular fluid with peripheral vasodilation as seen with sepsis. As noted earlier, ACE inhibitors/angiotensin II receptor blockers and nonsteroidal anti-inflammatory drugs (NSAIDs) may alter the vasoconstrictor effects of angiotensin II and the vasodilatory effects of prostaglandins to produce prerenal azotemia. This is especially the case in elderly patients with impaired GFR, subtle volume depletion, or occult renal artery stenosis.

The pathophysiology of prerenal azotemia relates to the reduction in RBF. Renal hypoperfusion stimulates both the sympathetic nervous system and renin-angiotensin system to cause renal vasoconstriction and sodium avidity. Furthermore, hypotension is a powerful stimulus to the release of antidiuretic hormone, which mediates water reabsorption. Hence, urine production is characterized by low volume, decreased concentration of urinary sodium, increased urinary excretion of creatinine, and a high urine osmolality. Microscopy of the urinary sediment is usually bland. In essence, "prerenal azotemia is a good kidney looking at a bad world."

Therapy for prerenal azotemia is directed at optimizing volume status with isotonic fluids. In patients with the edematous disorders who have prerenal azotemia, special efforts

are directed at treating the underlying disease states (i.e., heart failure, cirrhosis) and optimizing systemic hemodynamics and renal perfusion.

The hepatorenal syndrome (HRS) represents a unique, severe form of prerenal azotemia. HRS refers to the development of ARF in the patient with advanced hepatic disease, often due to cirrhosis but also seen with metastatic tumor or alcoholic hepatitis. The reduction in renal perfusion appears to relate to relative splanchnic vasodilatation, which may be mediated via nitric oxide, the endothelium-derived relaxing factor (Martin et al, 1998; Gines and Arroyo, 1999). HRS is characterized by oliguria, a benign urinalysis, urinary sodium avidity, and a progressive rise in SCr (Cardenas, 2005). HRS is a prerenal disease, because the kidneys are normal histologically and have been successfully used in renal transplantation (Koppel et al, 1969). The diagnosis is one of exclusion, after ATN, acute glomerulonephritis, vasculitis, or correctable forms of reduced renal perfusion have been excluded. Thus, the diagnosis of HRS requires a lack of improvement in renal function after discontinuation of potential nephrotoxins and a trial of fluid repletion. The best hope for reversal of HRS is improvement in hepatic function or successful liver transplantation (Gonwa et al, 1991; Cardenas, 2005); however, not all cases of HRS will resolve with this approach (Pham et al, 2005). Results of medical interventions have been disappointing. Therapy with ACE inhibitors has been complicated by systemic hypotension and reductions in GFR (Gentilini et al, 1993). The antidiuretic hormone analog ornipressin, which should decrease splanchnic dilatation, may also induce renal ischemia (Guevara et al, 1998; Gulberg et al, 1999). Treatment with a prostaglandin analog, misoprostol, has yielded conflicting results, but preliminary evidence with *N*-acetylcysteine suggested improvement in splanchnic dilatation and nitric oxide production in a small series of HRS patients (Holt et al, 1999). Similarly, combination therapy with midodrine (a selective α_1-adrenergic agonist) and octreotide (a somatostatin analog) has yielded preliminary information that it may be safe and effective as compared with renal-dose dopamine in a small series of HRS patients (Angeli et al, 1999). Overall, the impact of medical therapy for HRS has been minimal and the outlook for HRS without orthotopic liver transplantation appears bleak. The role of hemodialysis support appears to be limited to those HRS patients awaiting liver transplantation or resolution of their primary hepatic disease, because survival is generally limited by the severity of liver failure. Hemodialysis is often difficult in HRS because of hemodynamic instability.

Postrenal Azotemia

Obstruction of the urinary tract may cause ARF. To be the cause of ARF, urinary tract obstruction must involve the outflow tract of both kidneys, unless preexisting renal dysfunction is present, in which case the obstruction may involve only a single kidney. Patients with acute urinary tract obstruction may present with hematuria, flank or abdominal pain, or signs of uremia. A high index of suspicion for urinary tract obstruction should exist for patients with prior abdominal or pelvic surgery, neoplasia, or radiation therapy. Although oligoanuria suggests complete obstruction, partial obstruction may exist in the presence of adequate urinary output. Oligoanuria is a powerful diagnostic clue that suggests a differential diagnosis of urinary tract obstruction, severe ATN with cortical necrosis, or bilateral vascular occlusion. Lesions that may cause obstruction can be either intrinsic or extrinsic to the genitourinary tract. If urinary tract obstruction is a diagnostic consideration, the renal ultrasound is sensitive and specific (90% to 95%) in confirming the diagnosis of hydronephrosis. This test may be operator dependent, so the experience of the radiologist is crucial. False-negative tests may be seen with periureteral metastatic disease or retroperitoneal fibrosis (Somerville et al, 1992). Renal radionuclide studies or retrograde pyelography may be helpful in this circumstance. If urinary tract obstruction is a diagnostic consideration, renal ultrasound should be performed, because obstruction represents a potentially reversible cause of ARF.

While urologists are familiar with the various primary pathologies responsible for obstruction, iatrogenic causes should additionally be considered. Any drainage device such as a urethral catheter or ureteral stent should be assessed for patency. Hemorrhage or lymphocele are uncommon sequelae of retroperitoneal surgery but can result in ARF by causing extrinsic compression. **Urinary extravasation or fistula formation is a complication of urinary tract reconstruction. This can cause a rise in the BUN and SCr levels owing to reabsorption, but actual kidney function is preserved.** Diagnosis of urinary extravasation requires analysis of fluid from the area near the reconstructed site. The drain creatinine is compared with the SCr. Ratios of 10:1 are virtually diagnostic for extravasation, but smaller ratios may be observed when the urine has been diluted by other serous fluids. Other ways to confirm urinary extravasation are by intravenous administration of a vital dye excreted by the kidneys (e.g., indigo carmine or methylene blue) or radiographic demonstration of a fistula (isotope renography, retrograde pyelogram, cystogram, computed tomography [CT]). This type of ARF resolves with drainage of the urinoma and definitive treatment of the urinary fistula. The reader is referred to other chapters in this text for more in-depth review of obstructive uropathy.

Intrinsic Renal Disease

The major causes of ARF due to intrinsic renal disease include acute glomerulonephritis (AGN), AIN, and ATN. Because ATN is the most common cause of ARF in the hospitalized patient, special emphasis will be given here to ATN.

Acute Glomerulonephritis

The presence of proteinuria, hematuria, and red blood cell casts is pathognomonic of glomerulonephritis. The importance of the urinalysis in the evaluation of patients with ARF cannot be overemphasized, and the physician must develop skill and expertise in interpreting the microscopic findings. Such skills are critical in the recognition of AGN as the cause of ARF because the diagnosis of AGN has a tremendous impact on disease management.

The combination of AGN (based on urinalysis findings) and a rapid loss of kidney function defines the clinical syndrome of rapidly progressive glomerulonephritis (RPGN). Discussion of the differential diagnosis and management of RPGN is beyond the scope of this chapter (Little and Pusey, 2004). A simplified differential diagnosis of RPGN is summarized in Table 41–2. It is crucial, however, to appreciate the

Table 41–2. Differential Diagnosis of Rapidly Progressive Glomerulonephritis

impact that urinary microscopic findings of AGN have on the aggressive evaluation and management of patients with this type of ARF. This usually includes a renal biopsy as well as detailed serologic evaluation for the presence of systemic vasculitis, collagen vascular disease, and an infectious process. RPGN comprises a group of glomerulonephritides that progress to renal failure in a matter of days to months in the presence of extensive extracapillary proliferation (i.e., crescent formation in a large percent of glomeruli). Patients with RPGN have been divided into three patterns defined by their immunologic pathogenesis: type I, anti–glomerular basement membrane (anti-GBM) disease (e.g., Goodpasture's syndrome); type II, immune complex deposition disease (e.g., systemic lupus erythematosus, post-streptococcal glomerulonephritis); and type III, pauci-immune (e.g., antineutrophil cytoplasmic autoantibody (ANCA)–positive disease, such as Wegener's granulomatosis). Patients are categorized based on the results of the immunofluorescence of the renal biopsies and results of serologic testing for anti-GBM titer, ANCA, lupus serologies, and so on. Specific therapies (including parenteral corticosteroids, cyclophosphamide or other cytotoxic agents, and possibly plasma exchange) tailored to the disease entity diagnosed may be lifesaving. Hence, early recognition of RPGN based on urinalysis findings is critical.

Acute Interstitial Nephritis

The diagnosis of ARF secondary to AIN may be suggested by the urinalysis findings of sterile pyuria, white blood cell casts, and eosinophiluria (using Hansel's stain) (Michel and Kelly, 1998). **AIN is most often induced by drug therapy, although sarcoidosis and streptococcal, viral, or *Legionella* infections may also be responsible. The list of offending drugs associated with ATN is extensive, but the most common causes of AIN include those identified in Table 41–3.** The major histologic changes are interstitial edema and marked interstitial infiltrate of T lymphocytes and monocytes (Laberke and Bohle, 1980). Eosinophilic plasma cells and polymorphonuclear cells may also be detected. Granuloma formation, once thought particular to the renal disease of sarcoidosis, can occur in any form of AIN.

The clinical presentation, although variable, usually involves an abnormal urine sediment (described earlier), fever, and a rising SCr value associated with the administration of the offending drug (Nolan et al, 1986). Rash is seen in about 25% of cases. Eosinophilia and eosinophiluria are present in more than 75% of cases, with the exception of AIN due to NSAIDs, in which fever, rash, and eosinophilia are typically absent. Proteinuria with most drugs is usually modest, with less than 0.5 to 1 g/day. Proteinuria in the nephrotic range has been frequently seen with AIN of NSAIDs (especially fenoprofen) and in selected cases with ampicillin, rifampin, ranitidine, and interferon. It is speculated that increased glomerular capillary permeability is related to cytokine release of the infiltrating T cells (Neilson, 1989).

The development of AIN is not dose dependent, and recurrence can occur with second exposures to the same or related drug. The onset of AIN may occur from 3 to 5 days (especially second exposures) to several weeks after drug therapy.

The diagnosis is usually suspected in the ARF patient with characteristic urinary sediment abnormalities and a history of an offending drug therapy. Although the clinical picture may be highly suggestive of AIN, the diagnosis is confirmed only by renal biopsy. Most clinicians will observe the response to withdrawing the offending agent (Kida et al, 1984). No further evaluation or therapy is required if renal function begins to improve in several days. Lack of response, severe ARF, or uncertainty of diagnosis may be indications for definitive diagnosis with renal biopsy. The role of gallium scanning in AIN remains to be clearly defined, because it is often positive with AIN and negative with ATN, but false-positive and false-negative results may occur.

Initial therapy consists of discontinuing the offending drug with the expectation that renal function will begin to improve in 3 to 7 days (Baker and Pusey, 2004). There are no controlled trials evaluating the efficacy of immunosuppressive therapy in the small number of patients reported with biopsy-proven AIN who did not respond to expectant management. There is

some experimental and suggestive clinical evidence that corticosteroid and/or cytotoxic therapy may be beneficial to hasten recovery of renal function and reduce interstitial fibrosis.

ACUTE TUBULAR NECROSIS

Incidence and Etiology

Overall, ARF may affect 2% to 5% of patients in a tertiary care hospital, and the incidence of ARF in the surgical or medical ICU may exceed 20% to 30%. The majority of all hospital-acquired ARF is secondary to ATN (Myers and Moran, 1986; Uchino et al, 2005). **Renal hypoperfusion and renal ischemia are the most common causes of ATN, although nephrotoxic insults from various agents are being recognized with increasing frequency. A detailed listing of both exogenous and endogenous nephrotoxic compounds is presented in Tables 41–4 and 41–5.**

From Nally JV: Acute renal failure. In Stoller JK, Ahmed M, Longworth DL (eds): The Cleveland Clinic Intensive Review of Internal Medicine, 2nd ed. Philadelphia, Lippincott Williams & Wilkins, 2000, p 567.

Pigment nephropathy may be suspected in the appropriate clinical situation (post-traumatic or atraumatic after intoxications) where there is discrepancy between the finding of hematuria by dipstick and the absence of red blood cells on urinary microscopy. In urology, two clinical circumstances have been identified in association with rhabdomyolysis. This includes protracted extended lithotomy positioning (as seen in urethral stricture cases) (Anema et al, 2000) **and after laparoscopic donor nephrectomy** (Kuang et al, 2002; Troppmann and Perez, 2003). **The combination of renal hypoperfusion and the nephrotoxic insult of myoglobin or hemoglobin within the proximal tubule can result in ATN. Early recognition of this disorder is crucial, because a forced alkaline diuresis is indicated to minimize nephrotoxicity.** Similarly, the tumor lysis syndrome may be suspected in the appropriate clinical setting, when marked hyperuricemia/hyperuricosuria and crystalluria are recognized. A forced alkaline diuresis may limit nephrotoxicity and is usually recommended prophylactically before an aggressive chemotherapy regimen.

The list of potential exogenous nephrotoxic agents is exhaustive (see Table 41–4). Simply stated, a patient who develops ATN while receiving medications should have each medication reviewed for the possibility of nephrotoxicity. The most commonly seen nephrotoxins in the hospitalized patient include radiographic contrast material, antibiotics (especially aminoglycosides and amphotericin B), chemotherapeutic agents, NSAIDs, and ACE inhibitors.

More recently, the potential nephrotoxicity of newer agents, such as acyclovir, protease inhibitors, recombinant interleukin 2 (IL-2), interferon, and selected chemotherapeutic agents, is being appreciated.

In the contemporary practice of hospital-based medicine, recognition of ARF in two special patient populations deserves comment. Patients with human immunodeficiency virus (HIV) infection may develop ARF due to the same causes as uninfected patients, but protease inhibitors have been associated with the development of ARF. Ritonavir and indinavir (as well as acyclovir, foscarnet, and sulfadiazine) have been associated with reversible ARF thought secondary to crystalluria and intrarenal obstruction (Olyaei et al, 2000). In addition, patients treated with indinavir may present with renal colic because indinavir renal stones can be associated with urinary tract obstruction (Kohan et al, 1999).

ARF may be quite common after bone marrow transplantation in some centers. Several nephrologic syndromes may be encountered at various times after bone marrow transplantation. In the perioperative period, ATN due to tumor lysis syndrome, bone marrow infusion, sepsis, or antibiotics (especially aminoglycoside and amphotericin B) is likely (Herget-Rosenthal et al, 2000). At days 10 to 16, ARF is commonly attributed to hepatic veno-occlusive disease resulting from radiation- or chemotherapy-related endothelial cell injury. Clinically, the presentation of this entity mimics HRS. After 4 to 12 months, ARF may be due to hemolytic-uremic syndrome, possibly related to cyclosporine or radiation therapy. Therapies with plasma exchange have been disappointing.

Natural History

The oliguric phase usually begins less than 24 hours after the inciting incident and may last for 1 to 3 weeks. Urine volume averages 150 to 300 mL/day. The oliguric phase may be prolonged in the elderly. During this phase, the clinician must be alert for the expected complications, with special emphasis on metabolic consequences, gastrointestinal bleeding, and infection.

The diuretic phase is characterized by a progressive increase in urine volume, a harbinger of renal recovery. However, the SCr may continue to rise for another 24 to 48 hours before it reaches a plateau and falls. Severe polyuria during this phase is seen less frequently now. Careful management during this phase is crucial, because up to 25% of deaths with ARF may occur in this phase, usually related to fluid and electrolyte abnormalities, as well as infection. Finally, the recovery phase ensues. Renal function returns to near baseline, but abnormalities of urinary concentration and dilution may persist for weeks or months.

Pathophysiology

Knowledge of the basic processes involved in the development of ATN is a prerequisite to understanding contemporary therapies directed at limiting renal damage and promoting more rapid renal recovery (Fig. 41–1). In hospital practice, ischemic ATN is the most commonly encountered form of the disease; therefore, the following discussion will focus on ischemic renal injury.

A variety of biochemical changes occur during ischemia and reperfusion that are responsible for the cell dysfunction observed in ATN (Myers et al, 1984; Myers and Moran, 1986). **The sentinel biochemical event in renal ischemia is the depletion of adenosine triphosphate (ATP), which is the major energy currency for cellular work.** ATP is metabolized to adenosine monophosphate (AMP). During prolonged oxygen deprivation, AMP is further metabolized to the nucleosides adenosine, inosine, and hypoxanthine. These compounds diffuse from the cell, resulting in the loss of the substrate reservoir for ATP synthesis after reperfusion (Brady et al, 1996). Furthermore, hypoxanthine becomes an important substrate in the development of oxygen free radicals during the reperfusion period. Provision of exogenous adenine and inosine decreases cellular injury in experimental renal ischemia (Siegel et al, 1980).

ATP depletion results in impaired function of the plasma membrane and intracellular ATPases that are vital to normal cell function. As a consequence of impairment of the Na^+/K^+-ATPase, cytosolic concentrations of Na^+ and K^+ are altered and cell swelling results (Alejandro et al, 1995). **Dysfunction of the plasma membrane Na^+/Ca^{2+} ATPase and intracellular Ca^{2+} ATPase leads to high intracellular levels of Ca^{2+}. The increase in intracellular Ca^{2+} has been associated with multiple aspects of renal cell injury, including disruption of the cytoskeleton, activation of Ca^{2+}-dependent phospholipases, acceleration of the conversion of xanthine dehydrogenase to xanthine oxidase (potentiating reperfusion injury), and uncoupling oxidative phosphorylation** (Brady et al, 1996). The activation of phospholipases results in damage to the lipid bilayer, which is critical to the normal function of the plasma membrane and intracellular organelles such as mitochondria. Phospholipase activation leads to an accumulation of free fatty acids and of lysophospholipids,

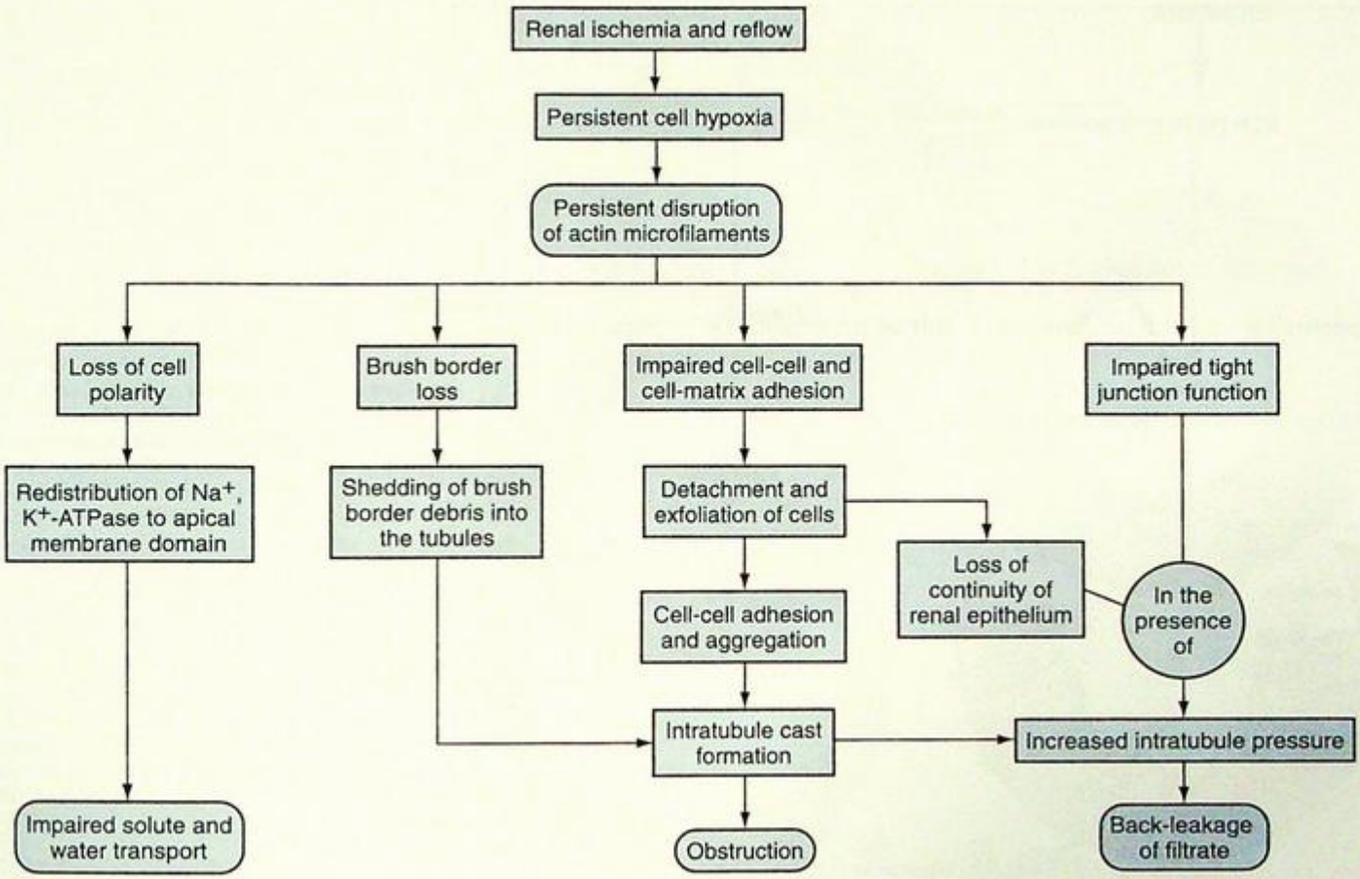

Figure 41–1. Pathophysiology of ischemic acute renal failure. The profound reduction in glomerular filtration rate associated with renal ischemia is due to a combination of intrarenal hemodynamic alterations and tubular epithelial injury leading to tubular obstruction and back-leakage of glomerular ultrafiltrate filtrate. (From Brady HR, Brenner BM, Lieberthal W: Acute renal failure. In Brenner BM [ed]: Brenner & Rector's The Kidney. Philadelphia, WB Saunders, 1996, pp 1200-1252.)

which are detrimental to vital cellular function, although the mechanism of such action is not clear.

Oxidative stress during reperfusion after ischemia is associated with cellular damage (Fig. 41–2). Recall that ATP is metabolized to hypoxanthine. High levels of intracellular Ca^{2+} activate a calmodulin-dependent protease that converts xanthine dehydrogenase to xanthine oxidase (Brady et al, 1996). The conversion of hypoxanthine to xanthine during reperfusion is the major source of superoxide. This is ultimately metabolized to OH^-, which causes cell damage. Finally, the protease calpain is activated and contributes to ischemic renal injury (Edelstein et al, 1997). Calpain regulates membrane channels, kinase activation, and interactions between cytoskeletal proteins.

As the name suggests, ischemic ATN is characterized by renal tubular cell injury. This may be sublethal or lethal. Because obvious necrosis is not a cardinal histopathologic finding in ATN (Racusen et al, 1991), sublethal injury is important. **During normal function of the kidney, the medulla operates at the brink of hypoxia due to the countercurrent diffusion of oxygen from the descending to ascending vasa recta. During prolonged ischemia, medullary hypoxia intensifies and due to the high metabolic requirement of the nephron structures located in the outer medulla, they are most sensitive to injury. The S3 portion of the proximal tubule sustains the most severe injury** (Witzgall et al, 1994). **Other structures that sustain injury in this region include the medullary thick ascending limb (mTAL), which is metabolically active and rich in the energy requiring Na^+/K^+-ATPase.**

Sublethal injury to tubular cells leads to aberrations in the cytoskeletal organization of the tubule cells (Molitoris, 1991) (Fig. 41–3). This is manifest as a loss in the cell polarity. The brush border disappears, and there is redistribution of the basolateral Na^+/K^+-ATPase and integrins (Lieberthal, 1997). As a result, the normal unidirectional transport of salt and water across tubular cells is disrupted and the ability of the renal epithelium to act as a barrier to the free movement of solute and water is lost. The loss of the tight junctions permits backleak of glomerular filtrate, which has been one of the well-established pathophysiologic features of ATN (see Fig. 41–1). In addition to the loss of tight junctions, there is a loss in cell-matrix adhesion (Gailit and Clark, 1993). The redistribution of the integrins disrupts the normal cell adherence to the tubular basement membrane. As a result, abnormal cell-cell adherence develops and contributes to tubular obstruction. The validation of this concept is provided by research demonstrating that an excess of a matrix protein

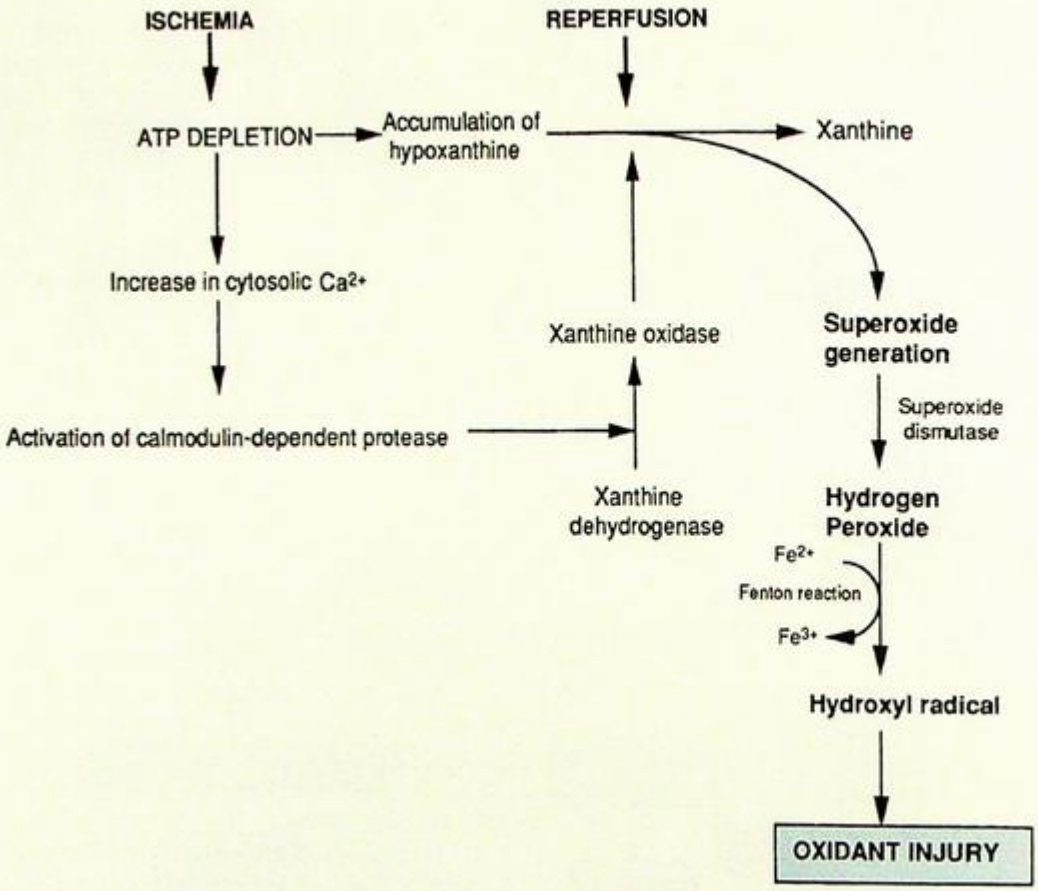

Figure 41–2. The pathophysiology of reperfusion injury. The generation of reactive oxygen species. See text for details. (From Brady HR, Brenner BM, Lieberthal W: Acute renal failure. In Brenner BM [ed]: Brenner & Rector's The Kidney. Philadelphia, WB Saunders, 1996, pp 1200-1252.)

sequence (RGD peptides), which is a critical ligand for the β1 integrin, can ameliorate the reduction in GFR in experimental ATN (Noiri et al, 1994). Conceptually this works because the integrin receptors are saturated by the supplemented matrix protein sequence ligand, making them unavailable for abnormal cell-cell adhesion. This can reduce tubular obstruction and backleak of glomerular filtrate.

After sublethal injury, the kidney has a remarkable capacity for repair of normal structure and function. The study of renal recovery from ATN is a relatively new concept with great potential for clinical application. Increased mitotic activity and epithelial regeneration are notable features of ATN (Thadhani et al, 1996). Certain aspects of renal recovery duplicate events in renal development (Witzgall et al, 1994). A number of growth factors play a role in recovery. Epidermal growth factor, insulin-like growth factor-1, and hepatocyte growth factor have been demonstrated to limit renal injury and accelerate renal recovery in experimental ischemic ATN (Thadhani et al, 1996).

RBF is reduced by 50% or more in ischemic ATN, and the perfusion defect is most marked in the outer medulla. The two predominant reasons for this include vasoconstriction and congestion of the medullary vasculature by leukocytes, red blood cells, and platelets. Ischemic renal injury is marked by intrarenal vasoconstriction as a result of endothelial cell injury. Vasoconstriction results from the imbalance between endothelin (ET) and endothelial-derived nitric oxide (EDNO) (Lieberthal, 1997). Endothelin receptor blockers have been shown to ameliorate ischemic renal damage and improve renal function (Lieberthal, 1997). The endothelial injury sustained in ATN also leads to decreased production of EDNO by constitutive nitric oxide synthase. The decreased EDNO leads directly to vasoconstriction but also permits increased ET production (Lieberthal, 1998).

The persistent hemodynamic abnormalities in ATN are also maintained by congestion of the medullary vasculature. **Current evidence suggests that ischemic injury results in the release of inflammatory mediators that activate adhesion molecules on leukocytes and upregulates their receptors on the endothelium.** Antibodies directed at leukocyte adhesion molecules or their endothelial ligands (i.e., ICAM-1) ameliorate ischemic renal injury (Kelly et al, 1996; Dragun and Haller, 1999). **Neutrophils play an important part in the injury cascade. In models where the effects of neutrophils are eliminated by delivering antibodies to certain chemokines, injury is ameliorated** (Miura et al, 2001). **Interestingly, the tubular epithelium plays an active role in this inflammatory response by generating chemokines that potentiate recruitment of inflammatory cells** (Bonventre and Zuk, 2004). These include monocyte chemoattractant protein-1 (MCP-1), interleukin 8 (IL-8), regulated-upon activation, normal T cells expressed and secreted (RANTES), and epithelial neutrophil-activating protein 78 (ENA-78). In addition to the role of neutrophils there is evolving evidence that lymphocytes are important in the ischemia/reperfusion injury paradigm. Knockout mice lacking CD4+/CD8+ cell adhesion receptors on T lymphocytes are protected from ischemic injury (Rabb et al, 2000). Also, co-stimulatory blockade can ameliorate ischemic injury (Takada et al, 1997). Newer agents are being developed to deal with the early inflammatory events in renal ischemia that may bear practical application, particularly in the setting of renal transplantation.

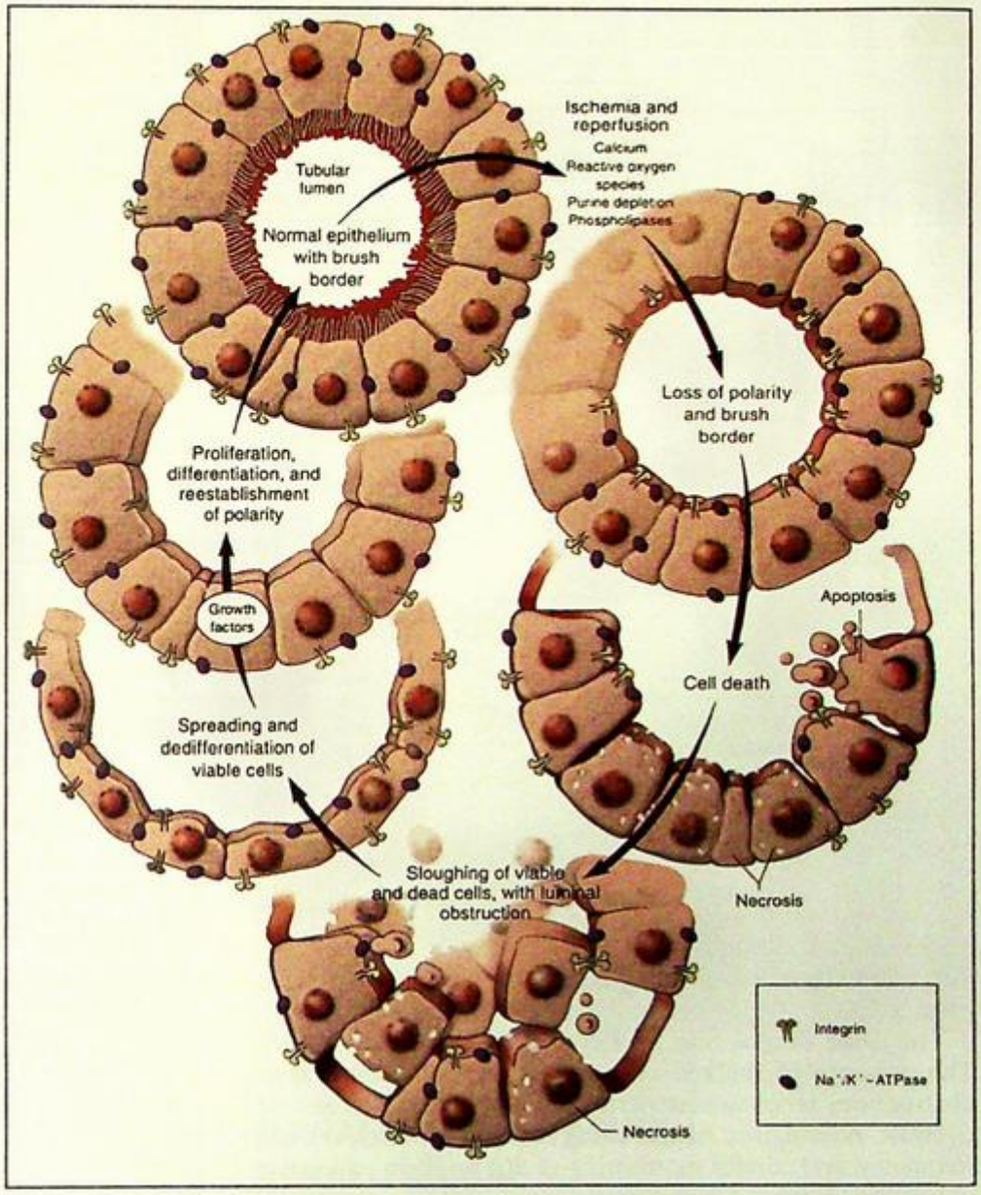

Figure 41–3. Tubular-cell injury and repair in ischemic acute renal failure. After ischemia and reperfusion, morphologic changes occur in the proximal tubules. This includes loss of the brush border, loss of cell polarity, and redistribution of integrins and Na^+/K^+-ATPase to the apical surface. There is sloughing of viable and nonviable cells into the tubular lumen, resulting in the formation of casts and luminal obstruction. The damaged kidney can restore its structure and function. Spreading and dedifferentiation of viable cells occurs during recovery, which duplicates aspects of normal renal development. A variety of growth factors contribute to the restoration of normal renal architecture. (From Thadhani R, Pascual M, Bonventre JV: Acute renal failure. N Engl J Med 1996;334:1448-1460.)

CLINICAL APPROACH TO THE DIFFERENTIAL DIAGNOSIS OF ACUTE RENAL FAILURE

Distinguishing between prerenal, intrinsic renal, and postrenal causes of ARF may prove to be a challenging clinical exercise (Fig. 41–4). **A thorough history and physical examination to assess volume status, cardiovascular hemodynamics, potential nephrotoxic insults, and evidence of systemic disease should be undertaken in ARF patients. All interventions and drug therapies surrounding an ARF event should be outlined against the timeline of changes in renal function. Therefore, it is critical to know the level of preexisting renal function.** One should identify the presence of risk factors known to be associated with ARF, such as advanced age; comorbid conditions (heart failure, liver failure, renal insufficiency, diabetes); radiocontrast agent exposure; therapy with aminoglycoside antibiotics, NSAIDs, or ACE inhibitors; and atheroembolism. In perioperative ARF, critical intraoperative issues to identify include the nature and magnitude of the procedure (open vs. endoscopic), blood loss, hemodynamic stability, integrity of the urinary tract, and intraoperative drug treatment.

On examination, the vital signs and hemodynamic parameters should be critically assessed. Hypotension, particularly orthostatic hypotension, suggests volume depletion and prerenal ARF. Hypertension with advanced renal insufficiency can be an indicator of volume overload, suggesting the need for diuretics or dialysis. A patient's weight is helpful information, and its daily measurement is important in the diagnosis and management of ARF. An acute decrease in weight over days may indicate volume depletion and prerenal ARF. In contrast, increasing weight in association with a rising creatinine level occurs in ATN with volume overload. After major urologic procedures (e.g., cystectomy, nephrectomy, transplantation), measurement of the central venous pressure or pulmonary artery wedge pressure is the most accurate method to assess volume status. Other clinical parameters that correlate with volume status include neck vein

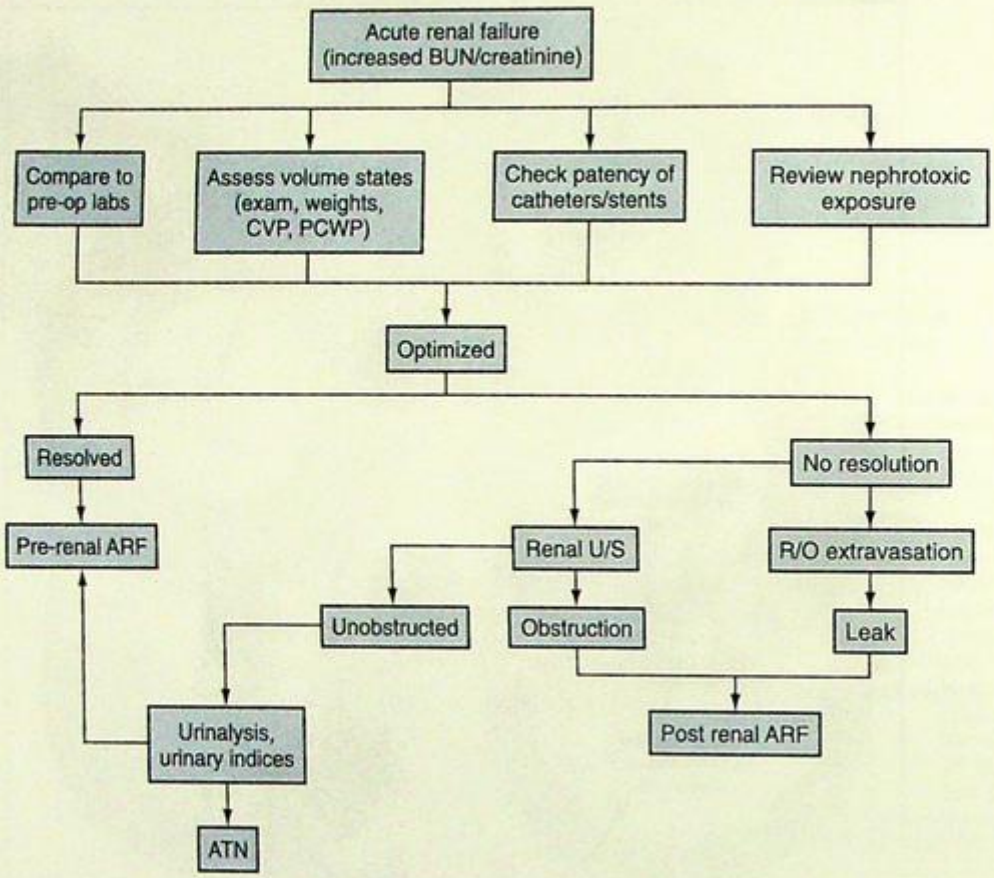

Figure 41–4. Algorithm for the differential diagnosis of acute renal failure. See text for details. BUN, blood urea nitrogen; CVP, central venous pressure; PCWP, pulmonary capillary wedge pressure; ARF, acute renal failure; U/S, ultrasound; R/O, rule out. ATN, acute tubular necrosis. (Modified from Goldfarb DA, O'Hara JF: Etiology, pathogenesis, and management of perioperative acute renal failure. AUA Update Series 2001;XX:lesson 4.)

distention, lung rales, and peripheral edema (pretibial or presacral).

The urine output may be a clue to the diagnosis of ARF. The presence of marked oligoanuria suggests urinary tract obstruction, renovascular occlusion, or cortical necrosis. In contrast, nonoliguric ARF is being recognized with increased frequency, and careful monitoring of SCr levels in patients at risk is of paramount importance.

Examination of the urinalysis results is fundamental to the evaluation of the patient with ARF. The simple urinalysis may distinguish the cause of ARF among the various possibilities. Table 41–6 highlights the various urinary abnormalities associated with the clinical diagnoses. For example, proteinuria, hematuria, and red blood cell casts are pathognomonic of glomerulonephritis. The classic sediment of ATN includes pigmented (muddy brown) granular casts and renal tubular epithelial cells, which may be seen in nearly 80% of cases of oliguric ARF.

Determination of urinary chemistry may be helpful in determining the cause of the ARF. The urine sodium and creatinine levels and osmolality should be measured. The fractional excretion of sodium or the renal failure index should be calculated (Fig. 41–5). Note that a low fractional excretion of sodium (or renal failure index) may be associated with either prerenal azotemia or AGN (Table 41–7). These entities can be separated clinically by examination of the urinalysis results. Conditions associated with prerenal azotemia have bland urinalysis results, whereas proteinuria, red blood cells, and red blood cell casts are seen with AGN. Other causes of ARF associated with a low fractional excretion of sodium include hepatorenal syndrome and selected types of ATN, such as that due to intravenous contrast material, rhabdomyolysis, sepsis, and multisystem organ failure. Both ATN and obstruction may have an increased fractional excretion of sodium or renal failure index. Here, again, the urinalysis is crucial in sorting out the differential diagnosis. ATN has a

$$\text{Fractional Excretion of Sodium } (FE_{Na}) = \frac{U_{Na} \times V}{\frac{U_{creat} \times V}{P_{creat}}} \times 100\%$$

$$\text{Renal Failure Index (RFI)} = \frac{U_{Na} \times P_{creat}}{U_{creat}}$$

Figure 41–5. Urinary indices.

Table 41–6. Urine Sediment in Acute Renal Failure

Sediment Findings	*Diagnosis*
Normal	Prerenal/obstruction
Red blood cell casts, red blood cells	Acute glomerulonephritis/vasculitis
Eosinophils	Acute interstitial nephritis
Pigmented granular casts	Acute tubular necrosis

Table 41–7. Patterns of Urinary Indices in Acute Renal Failure

	Prerenal/Acute Glomerulonephritis	*Acute Tubular Necrosis/ Obstruction*
Urinary [Na^+] mEq/L	<20	>40
Urine: plasma creatinine	>30	<20
Renal failure index	<1	>1
FENa	<1	>1
Urinary osmolality	>500	<400

classic sediment with pigmented coarsely granular casts, but the urinalysis results seen in obstruction are often bland with and without microhematuria.

The urine output may be a clue to the diagnosis of ARF. The presence of marked oligoanuria suggests urinary tract obstruction, renovascular occlusion, or cortical necrosis. In contrast, nonoliguric ARF is being recognized with increased frequency, and careful monitoring of SCr in patients at risk is of paramount importance.

Imaging

A variety of imaging modalities have clinical utility in the evaluation of ARF. The most widely used is renal ultrasonography. This noninvasive and readily available study is fairly sensitive for the identification of hydronephrosis as discussed earlier in the section on postrenal acute renal failure. Duplex ultrasonography of the renal artery is useful for the identification of renal artery stenosis or thrombosis (Carman et al, 2001). The absence of a Doppler signal from the artery is a noninvasive sign to confirm renal artery thrombosis.

Another common imaging study in ARF is the abdominal plain radiograph to identify the presence or location of renal calculi or both. Additionally, the abdominal plain radiograph is particularly helpful to discern the proper position of the stents and drains. **The radionuclide renal scan is a useful imaging study in selected clinical circumstances. ^{99m}Tc-labeled mercaptoacetyltriglycine (MAG3) is a more useful imaging agent in renal insufficiency than ^{99m}Tc-labeled diethylenetriaminepentaacetic acid (DTPA) and is able to evaluate both renal flow and function** (Taylor, 1999). **The renal scan is a simple way to evaluate for renal flow in situations in which renal artery thrombosis is a serious consideration, such as after partial nephrectomy or renal transplantation.** It is especially useful when there is renal insufficiency that prohibits the use of iodinated contrast media (Jafri et al, 1988). Urinary extravasation can also be assessed by isotope renography.

Radiocontrast studies (intravenous pyelography [IVP], CT, angiography) are of limited value during ARF because of their ability to worsen renal insufficiency. Angiography is used to confirm renal artery thrombosis, stenosis, or dissection. Studies such as an IVP yield poor-quality images in azotemic patients, owing to the inability to adequately excrete contrast agent. Notwithstanding, radiocontrast studies are frequently performed just proximal to surgery and may contribute in this manner to perioperative ARF.

MANAGEMENT OF ACUTE RENAL FAILURE

Management of ARF is based on its cause (Alkhunaizi and Schrier, 1996; DuBose et al, 1997). **When ARF is identified as prerenal, correction of the precipitating factors and restoration of renal perfusion usually lead to its resolution. Nephrotoxic drugs should be eliminated when clinically appropriate. Maintaining normal volume status is essential. In the postoperative setting, this implies judicious replacement of crystalloid, colloid, and blood with close monitoring of the central venous pressure. The management of postrenal ARF will depend on its etiology. Any obstruction needs appropriate drainage, and urinary extravasation needs to be controlled.**

The management of ATN focuses on the prevention of complications and providing an environment that is conducive to renal recovery (Table 41–8). Early consultation with a nephrologist improves the outcome of patients with ARF. Mehta and colleagues (2002a) showed that nephrology consultation was delayed in 28% of ICU patients with ARF. Delay in consultation was associated with higher mortality, longer ICU length of stay, and increased number of systems failing at the time of consultation. During the initial evaluation, it is imperative to search for reversible causes, such as volume

depletion, obstruction, and vascular occlusion. During the initial stages, a trial of parenteral hydration with isotonic fluids may correct ARF secondary to prerenal causes. Thereafter, fluid status should be monitored vigilantly to maintain euvolemia. In a patient with oliguria, special attention must be given to avoiding excessive hydration and volume overload that might precipitate the need for dialysis. Consideration may be given to using pharmacologic intervention to convert the patient from an oliguric to a nonoliguric state. In general, increases in urinary volume make it easier to address problems of volume overload, hyperkalemia, and metabolic acidosis. Increases in urine volume may also provide room for supplemental total parenteral nutrition in the critically ill patient. Historically, the morbidity, need for dialysis, and mortality was considered lower in the de novo nonoliguric form of ATN, but recent data challenge this notion (Liangos et al, 2005).

Pharmacologic Intervention

Pharmacologic intervention to convert oliguric ATN to nonoliguric ATN is a salutary goal for the reasons noted earlier. Experimental studies on the use of diuretics, dopamine, atrial natriuretic peptide (ANP), and calcium channel blockers that attempt to convert oliguria to nonoliguric ARF have been performed. The applicability of these experimental studies to patients with ARF remains unproved. **Uncontrolled studies suggest that patients who respond to mannitol, furosemide, or dopamine with an increased urine output have better outcomes than nonresponders** (Cosentino, 1995). The responders may simply have had less severe disease from the outset. Although de novo nonoliguric ARF has been associated with a lower mortality rate, there is little evidence that conversion from an oliguric to nonoliguric state decreased the mortality rate. **For the patients with established ATN, therapy with loop diuretics may increase urine output but has little effect on the severity or duration of the ARF** (Cosentino et al, 1994). Results of clinical trials involving diuretics, dopamine, ANP, and calcium channel blockers for established ATN are reviewed here.

Both loop diuretics and mannitol administration have been proved to minimize the degree of renal injury if given at the time of the ischemic insult (Hanley and Davidson, 1981; Schrier et al, 1984; Cosentino, 1995). **Both diuretics are capable of inducing a diuresis to wash out obstructive debris and casts. Loop diuretics (e.g., ethacrynic acid, furosemide, and bumetanide) exert their pharmacologic effect in the loop of Henle, causing a large solute diuresis. Additionally, they decrease active NaCl transport in the thick ascending limb of Henle and thereby limit energy requirements in the metabolically active segment, which often bears significant ischemic insult.** There are several theoretical reasons why loop diuretics may be of benefit in ARF. Loop diuretics may protect cells of the ascending limb of Henle from hypoxic damage, increase tubular flow to prevent intratubular obstruction, inhibit tubuloglomerular feedback to maintain a favorable GFR, and increase RBF by decreasing renal vascular resistance. The available clinical data do not support an improved outcome in patients who respond to loop diuretics (Shilliday and Allison, 1994). A prospective, randomized placebo-controlled study examining the effect of loop diuretics on renal recovery, dialysis, and death in patients with ARF found no effect (Shilliday et al, 1997). Observational data suggested that diuretic use in critically ill patients with ARF is associated with an increased mortality rate using multivariate analysis and propensity scores (Mehta et al, 2002b). A more recent prospective, multicenter, epidemiologic study found that the use of loop diuretics was not associated with higher mortality (Uchino et al, 2004). Therefore, it is reasonable to give a trial of a loop diuretic in escalating doses, and if the patient does not respond, the drug should not be readministered because large doses of loop diuretics may be ototoxic and the large infusion volume may cause pulmonary edema.

Mannitol, an osmotic diuretic, theoretically ameliorates ARF by flushing intratubular casts, increasing RBF, increasing urine flow, reducing hypoxic cell swelling, protecting mitochondrial function, and scavenging free radicals. Mannitol use continues to be promoted prophylactically in certain high-risk patient groups because of the demonstrated benefit in animal models of ARF (Burke et al, 1983; Shilliday and Allison, 1994). **Mannitol has shown some benefit in the clinical setting of ARF** (Novick, 1983; Weimar et al, 1983), **particularly when administered prophylactically or within a short time after an ischemic or nephrotoxic insult.** The best clinical example of this is its administration before renal artery clamping during partial nephrectomy. However, studies in humans failed to demonstrate the effectiveness of mannitol in prevention or treatment of ischemic or toxic ARF (Shilliday and Allison, 1994; Lee et al, 2004).

Dopamine has selective renal vasodilator properties that cause natriuresis and increased urine output. Low-dose "renal-dose" dopamine (0.4 to 2.0 μg/kg/min) activates dopamine-1 receptors, which induce renal vasodilation and increased RBF. **Objective review of controlled studies demonstrates that these benefits remain speculative** (Denton et al, 1996; Lassnigg et al, 2000). **Bellomo and colleagues** (2000) **reported on 328 critically ill patients with ARF who were randomly assigned to continuous infusion of placebo or low-dose dopamine (2 μg/kg/min). Peak SCr concentration, requirement for dialysis, length of hospital stay, and mortality rate did not differ between the two groups. Also, prophylactic use of low-dose dopamine in patients undergoing coronary artery bypass surgery has not been shown to be effective in preventing the development of renal impairment in these patients** (Woo et al, 2002). Use of dopamine has also been associated with serious cardiac, vascular, and metabolic complications in the critically ill and, therefore, should be used with caution (Power et al, 1999). Other than dopamine, the literature provides little guidance on the effects of other vasoactive agents on the kidney and, thus, there is a need for large randomized, controlled studies to clarify this issue (Lee et al, 2004).

Fenoldopam is a selective dopamine-1 receptor agonist (DA-1) that causes DA-1 receptor–mediated vasodilation and does not stimulate DA-2 or α- or β-adrenergic receptors (Lee et al, 2004). **Fenoldopam reduces renal vascular resistance and increases RBF and fractional excretion of sodium and free water clearance in studies in normal volunteers and hypertensive patients** (Mathur et al, 1999). A few studies in animal models (Singer and Epstein, 1998; Halpenny et al, 2001b) are consistent with the notion that DA-1 agonists may be useful in preventing or treating ARF. Some clinical studies have shown encouraging results with the use of DA-1 agonists in the treatment (Tumlin et al, 2002) and prevention (Kini et

al, 2002a, 2002b) of contrast agent–induced nephropathy and perioperatively in cardiovascular surgery (Halpenny et al, 2001a). A recent multicenter trial, however, did not find any protective benefit of the selective DA-1 agonist fenoldopam mesylate in the prevention of contrast agent–induced renal dysfunction in an at-risk population (Stone et al, 2003). One study showed that when fenoldopam was used prophylactically in patients undergoing aortic surgery its use was associated with improvement in renal function and reductions in dialysis requirements, length of hospital stay, and mortality (Gilbert et al, 2001). Again, because these studies were small, defining fenoldopam's role in clinical situations is difficult without a large-scale randomized controlled trial.

In some animal studies the effects of ischemic ARF could be reversed with the use of an intrarenal arterial infusion of ANP (Nakamoto et al, 1987; Shaw et al, 1987), **but other experimental studies have been contradictory. The proposed mechanism by which this occurs is the vasodilatory action of ANP.** In experimental models of established ATN, the combination of ANP with dopamine to prevent systemic hypotension resulted in a rise in GFR induced by arteriolar vasodilatation. The treated animals also exhibited less tubular necrosis and fewer casts, suggesting tubular recovery was promoted. **The efficacy of ANP in established ATN in humans has been evaluated in two trials** (Rahman et al, 1994). **First was a small randomized trial suggesting a benefit of ANP therapy. More recently, a prospective, multicenter, randomized study with ANP in patients with ATN (oliguric and nonoliguric) has been reported. Overall, there was no established benefit on morbidity and mortality with ANP. However, in a subset of patients with oliguric ATN, clinical improvement was seen with ANP infusion.** Further studies in such a select population did not demonstrate benefit (Lewis et al, 2000). ANP is still considered an investigational drug, and its role in the management of patients with ATN remains uncertain.

Experimental studies suggest the possibility of accelerating the rate of tubular regeneration in ATN by administration of growth factors such as insulin-like growth factor-1 (IGF-1) (Miller et al, 1992) and epidermal growth factor (EGF) (Hammerman, 1999). The recovery process involves both tubular cell regeneration and differentiation into mature functioning cells. The applicability of these observations to human disease remains to be determined. A report of a randomized trial of ARF patients of less than 7 days' duration found no benefit in patients treated with IGF-1 (Hirschberg et al, 1999). In a large randomized, double-blind, placebo-controlled trial in ICUs in 20 teaching hospitals involving 72 patients, it was shown that IGF-1 does not accelerate the recovery of renal function in ARF patients with substantial comorbidities (Hirschberg et al, 1999). Similarly, there is no role for thyroxine in modifying the course and outcome in ARF; in fact, it could have a negative effect on outcome through prolonged suppression of thyroid-stimulating hormone (Acker et al, 2000). **Therefore, based on current evidence, there is no role for the use of growth factors to treat ARF.**

Calcium channel blockers inhibit voltage-gated calcium entry into cells and are reported to reverse vascular constriction, increase GFR, and improve renal plasma flow (Epstein, 1993). A few limited animal studies in experimental ARF generally support a protective benefit of calcium channel blockers. **The clinical benefit of calcium channel blockers most widely studied has been the effect on graft function in renal transplant recipients** (Alkhunaizi and Schrier, 1996).

In summary, review of the data regarding pharmacologic intervention for established ATN supports a trial of isotonic fluid repletion. Judicious use of intravenous loop diuretics may increase urine output, but the ability of these agents to have an impact on improved patient survival in ARF is still unproven. Similarly, the clinical data on "renal-dose" dopamine are scant and do not support its widespread use in established ATN. If a trial of dopamine is considered, it should be limited to a 24- to 48-hour infusion. Additional studies on the use of ANP, ANP with dopamine, calcium channel blockers, and growth factors are warranted to examine their impact on the course of ischemic or nephrotoxic ATN.

Conservative Management

Once the clinical diagnosis of ATN is made, conservative medical management is in order (Table 41–9). **This would include attempts to minimize further renal parenchymal injury, ensure provision of nutrition, maintain the metabolic balance, and promote recovery of renal function.**

Optimizing the patient's volume status is imperative, particularly in patients with oliguric ARF (DiBona, 1994). If such patients are administered large volumes of intravenous fluid or allowed free access to oral fluids, they are at risk for developing fluid overload. In the oliguric patient, fluids should be restricted to total output plus insensible losses. If required, pharmacologic intervention with loop diuretics may promote increases in urinary volume.

Providing adequate nutrition is important for the recovery of the critically ill patient with ARF. Preexisting or hospital-acquired malnutrition is an important factor contributing to high mortality seen in patients with ARF (Druml, 1998a; Star, 1998). ARF not only affects water, electrolyte, and acid-base metabolism but also induces specific alterations in protein and amino acid, carbohydrate, and lipid metabolism (Druml, 1992). The metabolic alterations in ARF

Table 41–9. Conservative Medical Management of Acute Tubular Necrosis

Fluid Balance
Carefully monitor intake/output and weights.
Restrict fluids.
Electrolytes and Acid-Base Balance
Prevent and treat hyperkalemia.
Avoid hyponatremia.
Keep serum bicarbonate > 15 mEq/L.
Minimize hyperphosphatemia.
Treat hypocalcemia only if symptomatic or if intravenous bicarbonate is required.
Uremia and Nutrition
Administer protein (1.0-1.8 g/kg/day) and maintain caloric intake; consider forms of nutritional support.
Keep carbohydrate intake at least 100 g/day to minimize ketosis and endogenous protein catabolism.
Drugs
Review all medications.
Stop magnesium-containing medications.
Adjust dosage for renal failure; readjust with improvement of glomerular filtration rate.

patients are determined not only by acute loss of renal function but also by the underlying disease process (i.e., sepsis, trauma, or multiple-organ failure) and by the type and intensity of renal replacement therapy (RRT) (Druml, 1992, 2005).

The hallmark of metabolic alterations in ARF is activation of protein catabolism with excessive release of amino acids from skeletal muscle and sustained negative nitrogen balance (Druml, 1998b; Price et al, 1998). Hepatic extraction of amino acids from the circulation, gluconeogenesis, and ureagenesis are all increased. Several additional catabolic factors (secretion of catabolic hormones, hyperparathyroidism, suppression and decreased sensitivities to growth factors, and release of inflammatory mediators) are operative in ARF. All of these factors mediate protein breakdown (Cianciaruso et al, 1991).

Frequently, ARF is associated with hyperglycemia caused by insulin resistance (Klouche and Beraud, 1998). When plasma insulin concentration is elevated, maximal insulin-stimulating glucose uptake by skeletal muscle is decreased by 50%. ARF is also associated with accelerated hepatic gluconeogenesis, mainly from conversion of amino acids released during protein catabolism, which cannot be suppressed by exogenous glucose infusions (Druml, 1992).

The triglyceride content of plasma lipoprotein is increased in ARF, whereas total cholesterol and high-density lipoprotein (HDL) cholesterol are decreased (Schneeweiss et al, 1990).The major cause of lipid abnormalities in ARF is impairment of lipolysis. RRTs themselves may have significant metabolic and nutritional consequences.

Appropriate nutritional therapy in patients with ARF may be beneficial in promoting recovery. Caloric intake should be maintained and carbohydrate intake should be at least 100 g/day to minimize ketosis and endogenous protein catabolism. A moderate protein intake of about 1.0 to 1.8 g/kg/day may be required to maintain positive nitrogen balance. Higher protein intakes of up to 2.5 g/kg/day have been needed to improve nitrogen balance in critically ill ARF patients on continuous dialysis, although no survival advantage was noted. **Hence, it should be stressed that a low-protein intake (<0.5 g/kg/day) may be unnecessary and protein intake should not be severely restricted in ARF to limit the need for dialysis.** In terms of types of amino acids utilized, diet or solutions including both essential and nonessential amino acids in standard proportions is recommended. **Dietary phosphorus, potassium, and sodium chloride may be restricted. In the critically ill patient, nutritional support via total parenteral nutrition or enteral feedings should be considered. Prior studies demonstrate that provision of adequate nutrition to the ARF population may improve survival** (Chertow et al, 2000). Patients with ARF are candidates to develop significant electrolyte abnormalities such as hyperkalemia, metabolic acidosis, hyperphosphatemia, and hypocalcemia. These problems may be minimized by the prophylactic institution of a low-potassium diet accompanied by fluid restriction and oral phosphate binders.

Hyperkalemia is the most common and most dangerous electrolyte abnormality in the ARF setting. **If the serum potassium level exceeds 6.0 mEq/L, an electrocardiogram should be performed with subsequent therapy based on the findings. With hyperkalemia, the earliest changes demonstrate peaked T waves with subsequent broadening of the PR interval and eventual QRS broadening, which may mature into a sine wave form. The stages of therapy for acute hyperkalemia with electrocardiographic changes include (1) stabilizing the electrical membrane of the cardiac conduction system, (2) shifting potassium back intracellularly, and (3) eventual elimination of potassium from the body. Stabilizing the membrane of the cardiac conduction system may be accomplished with intravenous calcium salts, which have an immediate effect and a rather short duration of action. Shifting potassium into cells may be accomplished by a combination of intravenous glucose and insulin or intravenous sodium bicarbonate. Elimination of potassium from the body in a patient with ARF may be accomplished via the gastrointestinal tract with a cationic binding resin (Kayexalate). If severe hyperkalemia exists, dialysis may be required.**

Dialytic Interventions

Despite adequate medical therapy, dialysis may be required for patients with severe ARF. **The indications for the initiation of dialysis include volume overload, severe hyperkalemia, severe metabolic acidosis, pericarditis, selected poisonings, and uremic symptomatology.**

The initiation of dialysis for patients with ARF is usually precipitated by one or more of the specific indications. Despite earlier recommendations that patient morbidity and mortality might be improved by early, more intensive dialysis to keep the BUN less than 80 to 100 mg/dL, recent studies fail to document significant benefits. **Therefore, patients with ARF should begin dialysis on detection of severe fluid or electrolyte abnormalities or uremic symptomatology, rather than specific BUN or SCr thresholds. A theoretical concern exists that the dialysis treatment itself may have a detrimental impact on the course of ARF from ATN. Three potential mechanisms have been postulated: a fall in urine volume, dialysis-induced hypotension, and complement activation resulting from the blood-dialysis membrane interaction.** Removal of excess volume and urea may both contribute to the fall in urine volume. Whether this reduction has an impact on clinical recovery of ATN is speculative. Hypotension is a common complication of hemodialysis in patients with ARF. Because autoregulation is impaired in ATN, such patients may be particularly sensitive to renal hypoperfusion, perhaps due to vascular injury of the endothelium and its vasodilatory products, such as prostacyclin and nitric oxide. As a result, recurrent ischemic injury is more likely to occur and possibly delay the restoration of renal function. Complement activation during the blood-dialyzer interaction is a third possible mechanism for dialysis-induced renal injury. Animal models suggest that blood interaction with cuprophane membranes (but not more biocompatible membranes) can lead to neutrophilic infiltration into the kidney and prolong the course of ARF.

Dialysis Prescription and Modality

The contribution of the type of RRTs to clinical outcomes in ARF remains unresolved. Several factors operative during RRT for ARF may impact clinical outcome. These include dialysis modality, dialyzer membrane characteristics, and dosing strategies. Hemodialysis (HD) is the standard dialytic

modality for hemodynamically stable patients with ARF. To perform acute hemodialysis, access to the circulation is required and usually involves placement of a venous catheter in the jugular, subclavian, or femoral vein. Blood is transported by a blood pump to the dialyzer, where it comes into close proximity with the dialysate solution across a semipermeable membrane. Contact of the blood with dialysate allows the removal of solutes by the process of diffusion, driven by a concentration gradient from blood to dialysate. Fluid may also be removed by the process of ultrafiltration driven by a pressure gradient across the dialyzer. HD treatments may be stressful hemodynamically and possibly complicated by hypotension, hypoxia, bleeding related to anticoagulant administered (usually heparin), and dialysis disequilibrium, with its manifestations ranging from cramps and headaches to seizures and coma.

In the hemodynamically unstable patient, slow fluid and solute removal can be achieved with continuous renal replacement therapy (CRRT). In addition to being better tolerated hemodynamically, CRRT is also as efficient at removing solutes over the course of 24 to 48 hours as conventional hemodialysis. Although the clearance rates of some small solutes such as urea are slower, the rates are closer at 24 hours and more urea is removed over 48 hours with CRRT than with a single, intermittent run of standard hemodialysis.

Peritoneal dialysis (PD) permits the removal of solutes and fluid by using the peritoneal membrane as the dialyzer. This process does not require access to the circulation and is generally less stressful hemodynamically than standard HD. For this procedure, dialysate is instilled into the peritoneal space via a catheter, which is percutaneously placed. Fluid is allowed to dwell for a period of time and is then removed, taking with it uremic solutes by diffusion, as well as accomplishing ultrafiltration of fluid from an osmotic pressure gradient induced by high concentrations of glucose in the dialysate. For a noncatabolic patient, the less efficient PD allows the nephrologist to maintain fluid and electrolyte homeostasis while preventing uremic symptomatology.

Nephrologists caring for ARF patients must select a continuous or intermittent method of dialysis. **An analysis of nine published studies comparing CRRT to intermittent HD in patients with ARF showed no significant difference in clinical outcomes between the two groups** (Tonelli et al, 2002). **A more recent meta-analysis of 13 clinical trials, totaling 1400 patients, also observed no mortality difference between CRRT and intermittent HD. However, after adjusting for severity of illness and study quality, mortality seemed to be lower in the CRRT group** (Kellum et al, 2002). Similarly, a recent well-designed study of 80 critically ill patients with ARF found no difference in survival or renal recovery between continuous venovenous hemodialysis (CVVHD) and intermittent HD groups (Augustine et al, 2004).

Dialysis membranes may be classified as cellulose-derived or non–cellulose-derived membranes. The non–cellulose-derived membranes are synthetic polymers and are generally more biocompatible but more expensive. **A meta-analysis of clinical trials comparing biocompatible versus nonbiocompatible membranes found no difference in mortality between groups** (Jaber et al, 2002). **Given the profound morbidity of patients with ARF, if a survival advantage attributable to biocompatible membranes exists, it is at best small.** Similarly, high-flux membranes have not demonstrated a survival benefit, recovery of renal function, or duration of dialysis (Ponikvar et al, 2001).

The dose of dialysis may be important in outcome. Several studies have attempted to link urea removal to clinical outcomes in patients with ARF. Earlier reports suggested that critically ill patients with ARF may benefit with adequate dialysis dosage. More recently, a trial of 172 patients with ARF who were randomized to either daily or alternate-day dialysis using biocompatible high-flux dialyzers was reported (Schiffl, 2002). Overall mortality was significantly improved in the daily dialysis group, which had a higher weekly dose of delivered dialysis. This is the first study to demonstrate that the amount of dialysis is an independent determinant of mortality in critically ill patients with ARF.

Prognosis of ATN

The prognosis of ATN is dependent on the underlying primary disease that resulted in the ARF, as well as any complications that arise (e.g., infection, cardiovascular, gastrointestinal bleeding, or CNS). The mortality rate for patients with ATN is nearly 50% (Biesenbach et al, 1992). This pessimistic outlook has changed very little in the past 4 decades, despite the advent of effective dialysis (Lewers et al, 1970; Liano et al, 1993; Liano and Pascual 1996; Uchino et al, 2005). Mortality rates remain high today despite effective control of uremia, since we are caring for an older, sicker population with severe concomitant illnesses. Mortality rates have been quantified as high as 75% recently in several series in the ICU population. Higher mortality rates are seen in elderly patients and in patients with respiratory failure, multiple-organ failure, preexisting chronic diseases, and systemic hypotension (Obialo et al, 1999). In a prospective multicenter study of mortality with critically ill patients with ATN, the factors predictive of early mortality were male gender, oliguria, mechanical ventilation, acute myocardial infarction, cerebrovascular accident/seizure, and chronic immunosuppression (Parker et al, 1998). Leading causes of death include bronchopulmonary infections, sepsis, cardiovascular disease, and bleeding disorders. Of patients who survive ATN, nearly half will have a complete recovery of renal function and a majority of the remainder have an incomplete recovery (Fig. 41–6) (Spurney et al, 1991). Only about 5% of all ARF patients require chronic maintenance dialysis. In short, with ARF "you either die or you get better."

A separate question is whether the development of ARF itself directly contributes to mortality. The answer appears to be a resounding "Yes!" In a prospective study of 183 patients who developed ARF after exposure to an intravenous contrast agent, the in-hospital mortality rate was substantially higher in the ARF group (34% vs. 7%) than a matched control group (Levy et al, 1996). This effect persisted after the adjustment of other comorbid diseases (relative risk = 5.5). The development of ARF is also known to increase morbidity of patients, to prolong hospitalizations, and to increase hospital costs.

Prevention of ATN

Because the management of ATN is primarily one of conservative care and support, special attention should be

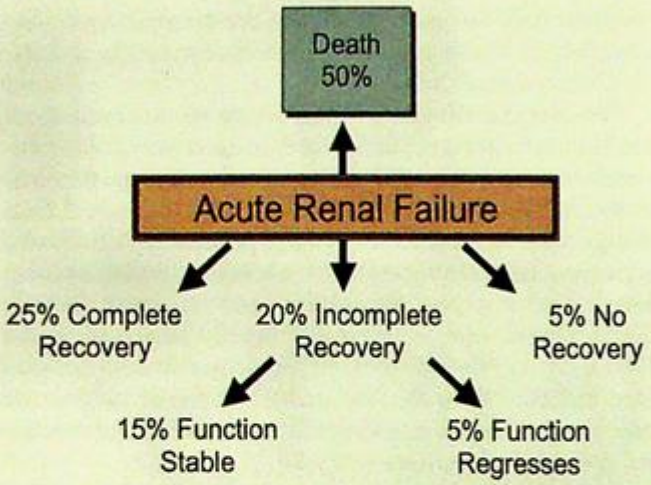

Figure 41–6. Prognosis of acute tubular necrosis.

focused on the prevention of ARF. Patients at high risk (i.e., patients with preexisting azotemia, the elderly, volume-depleted individuals, diabetics) warrant careful clinical consideration of the relative risks and benefits of diagnostic or therapeutic interventions that have a potential for nephrotoxicity. This is especially true for patients at risk undergoing cardiac catheterization or other diagnostic studies requiring intravenous contrast material. Several recent studies deserve comment.

A study by Solomon and coworkers (1994) confirmed that intravenous hydration with saline was critical in diminishing the nephrotoxic effects of coronary arteriography for patients with preexisting azotemia. The addition of either a loop diuretic or mannitol did not improve outcome. Rudnick and associates (1995) published a prospective, randomized trial of nearly 1200 well-hydrated patients undergoing cardiac catheterization to examine the effects of the newer nonionic contrast material. Patients were stratified for the presence or absence of azotemia (SCr ≥ 1.5 mg/dL) or diabetes mellitus. In patients without azotemia (with or without diabetes mellitus), the incidence of contrast agent–induced renal dysfunction was low (i.e., <1% to 2%) with either the ionic or nonionic contrast material. In contrast, those with preexisting azotemia had a 50% reduction in contrast agent–associated renal dysfunction with the nonionic material. These data suggest that in azotemic patients who require cardiac angiography, a protocol of intravenous hydration and use of a nonionic contrast material appear warranted.

In addition to these maneuvers in high-risk patients, pretreatment with *N*-acetylcysteine (600 mg orally twice daily for 48 hours) has been shown to reduce the incidence of radiocontrast agent–induced nephropathy (Tepel et al, 2000). A meta-analysis of randomized clinical trials using *N*-acetylcysteine in patients with reduced renal function clearly showed risk reduction for acute radiocontrast injury (Alonso et al, 2004). In contradistinction, a separately conducted meta-analysis of randomized controlled trials using *N*-acetylcysteine for the prevention of radiocontrast agent–induced nephropathy did not warrant a strong recommendation for its clinical use (Kshirsagar et al, 2004).

Recent trials compared the benefits of two hydration protocols in reducing radiocontrast agent–induced nephropathy. A trial involving 1620 patients undergoing coronary angioplasty demonstrated a benefit of isotonic hydration as superior to half-isotonic hydration in prevention of nephropathy (Mueller et al, 2002). **A smaller, single-center prospective randomized trial showed the benefit of intravenous hydration with sodium bicarbonate over sodium chloride given 1 hour before contrast agent exposure in the prophylaxis of contrast agent–induced renal dysfunction** (Merten et al, 2004). **The latter protocol has the advantage of timing because it was initiated 1 hour before the anticipated contrast study, rather than requiring 48 hours of pretreatment with *N*-acetylcysteine.** A recent multicenter trial did not find any protective benefit of the selective DA-1 agonist fenoldopam mesylate in the prevention of contrast agent–induced renal dysfunction in an at-risk population (Stone et al, 2003). Similarly, a meta-analysis did not find any compelling benefit for the use of theophylline, an adenosine antagonist, in the prevention of contrast agent–induced nephropathy (Bagshaw and Ghali, 2005). In the aggregate, the

KEY POINTS: ACUTE RENAL FAILURE

- Creatinine as an assessment of renal function needs to be interpreted in the context of clinical events that are occurring in the patient.
- Acute renal failure is categorized based on pathophysiology as prerenal, postrenal, or intrinsic renal. The etiology and the pathogenesis determine management.
- Prerenal azotemia is transient renal hypoperfusion and responds well to isotonic fluid replacement.
- In considering postrenal causes of ARF, do not forget fistula as an iatrogenic cause.
- The inflammatory response is important in the pathogenesis of ATN and may become a future target for therapeutic intervention.
- Conservative management predominates for ATN. This entails dialysis support as needed with prevention of complications.
- Review of the data regarding pharmacologic intervention for established ATN supports a trial of isotonic fluid repletion. Judicious use of intravenous loop diuretics may increase urine output, but the ability of these agents to have an impact on improved patient survival in ARF is still not proven. Similarly, the clinical data on "renal-dose" dopamine are scant and do not support its widespread use in established ATN.
- Recommendations for the azotemic patients who require radiocontrast procedures warrant a protocol of intravenous hydration and the use of nonionic contrast material in the lowest dose possible. Treatment with *N*-acetylcysteine for 48 hours before the procedure and/or special hydration with prestudy sodium bicarbonate deserving of further study.

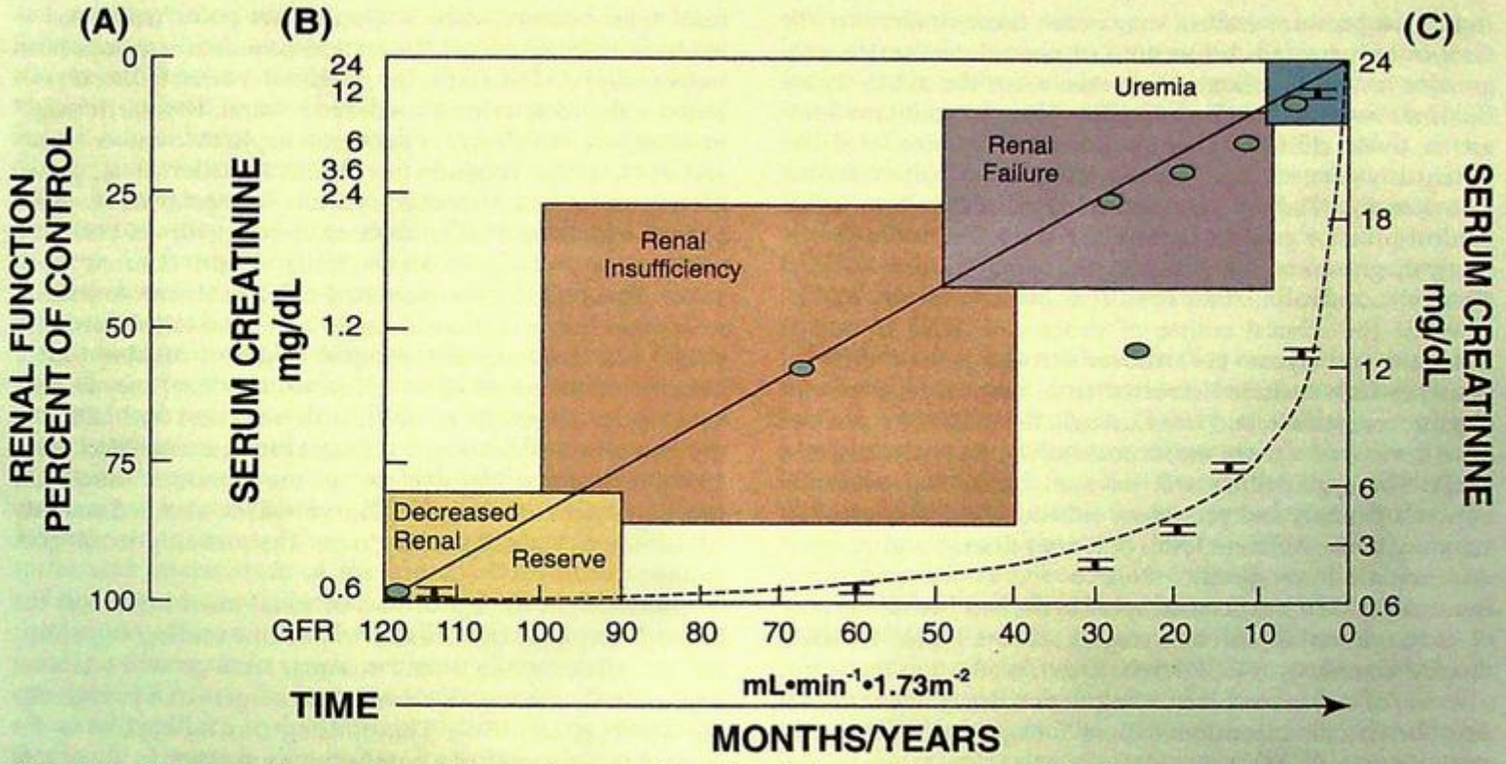

Figure 41–7. The course of progressive renal disease. The course of a patient who began with normal renal function corresponding to a serum creatinine concentration of 0.6 mg/dL and glomerular filtation rate (GFR) of 120 mL/min/1.73 m^2 is shown. *Y-axes:* The geometric serum creatinine ordinate at the left (B) applies to the solid line of identity *(open circles)* and the *rectangles* depict the various stages of progressive renal disease. The serum creatinine ordinate at the right side of the figure (C) should be used with the *dashed curve (ax-heads)* only. The ordinate at the extreme left (A), which describes the percentage of renal function remaining, applies generally. *Line of identity:* This line shows a decrease in function from 100% to 9% of normal corresponding to the diminution in GFR from 120 to 0 mL/min/1.73 m^2. The matching creatinine scale (A) is geometric. *Dashed curve:* Because GFR equals the daily creatinine excretion/serum creatinine concentration and because the creatinine excretion is equal to daily production, which is constant, this equation is of the form $y = k/x$, which defines a hyperbola. This relationship remains valid over the course of chronic renal disease unless the creatinine production changes. The curve emphasizes that large changes in GFR may produce small and clinically imperceptible changes in serum creatinine concentration when overall renal function is near normal. Conversely, trivial changes in GFR produce large changes in serum creatinine concentration when the GFR is low. The rate of progression throughout the delineated stages depends on the nature of the underlying renal disease, host factors, treatment, and compliance with the medical regimen. (From Kimmel PL: Management of the patient with chronic renal disease. In Greenberg A [ed]: Primer on Kidney Disease, 2nd ed. San Diego, CA, Academic Press, 1998, p 434.)

aforementioned recommendations for the azotemic patients who require radiocontrast procedures warrant a protocol of intravenous hydration and the use of nonionic contrast material in the lowest dose possible. Treatment with *N*-acetylcysteine for 48 hours before the procedure and/or special hydration with prestudy sodium bicarbonate are deserving of further study.

CHRONIC RENAL FAILURE

Approximately 20 million individuals in the United States have chronic kidney disease (CKD). The diagnosis of CKD implies a persistent abnormality in GFR with a wide spectrum of causes. The Workgroup of the U.S. National Kidney Foundation, Kidney Disease Outcomes Quality Initiative (K/DOQI) Advisory Board recommended that "chronic kidney disease" should be defined as sustained kidney damage greater than 3 months resulting in a GFR of less than 60 mL/min/1.73 m^2 (National Kidney Foundation, 2002). After an initial kidney insult, if the acute injury does not completely resolve, a continuing attrition of functional nephrons occurs over time. Figure 41–7 depicts the renal failure continuum consisting of several stages of functional deterioration associated with specific clinical and biochemical abnormalities. Small changes in the SCr measurement correlate with significant alterations in the GFR when renal function is greater than 60 mL/min. This concept is illustrated by the SCr ordinate on the left side of Figure 41–7 matched to the GFR line of identity crossing through the four different phases of progressive renal disease. However, the relationship between the SCr level and the GFR changes as the renal function deteriorates to less than 60 mL/min. As noted on the right side of Figure 41–7, changes in the GFR (dashed, curved line) are represented by significantly larger increases in SCr level depicted on the right ordinate. This is especially true in CKD as the GFR decreases to levels below 30 mL/min. Although an initial insult may decrease an individual's renal reserve, biochemical abnormalities are uncommon before the "renal insufficiency" stage. Once severe "renal failure" occurs, clinical symptoms become more common.

The degree of adaptation taking place at each stage determines the extent of clinical and biochemical abnormalities. When kidney function is minimally impaired (≤ 60%), physiologic adaptation is complete. As the GFR falls usually below 20% of normal, progressive anorexia with nausea, salt retention, acidosis, insomnia, anemia, muscle fatigue, and worsen-

ing blood pressure control may occur. Structurally, after the GFR in humans falls below 50% of normal, a relentless progressive loss of function ensues even when the initial disease becomes inactive (Mitch et al, 1976). There is significant interest in those clinical and public health initiatives that can potentially identify and prevent progressive kidney failure. The National Kidney Foundation developed and published clinical practice guidelines for CKD in 2002 to more consistently diagnose and treat CKD and its comorbidities (National Kidney Foundation, 2002; Patel et al, 2002; Eknoyan, 2003).

While the clinical course of progressive renal disease as illustrated in Figure 41–7 moves through several different phases, which include decreased renal reserve, renal insufficiency, renal failure, and frank uremia, the K/DOQI guidelines have developed a more uniform classification of the stages of CKD. These guidelines will have an impact on education between patients and providers, enhance the public's understanding of the different levels of kidney disease, and promote dissemination of specific research results for each stage. Because the GFR has been accepted as the best overall measure of kidney function, the new staging schema (Table 41–10) is divided according to GFR levels. This classification represents a series of evidence-based clinical practice guidelines that describe specific recommendations for optimal CKD patient care (Patel et al, 2002).

Renal Mass Reduction and Chronic Kidney Disease

Recent evidence supports the view that deficits in nephron number predispose to progressive renal disease and hypertension (Chertow et al, 1996). Nephron number averages approximately 600,000 per kidney in the normal kidney with standard deviation of more than 200,000 (Nyengaard et al, 1992). Conceptually, partial ablation of renal mass through renal insult or surgical partial nephrectomy initiates a cycle of progressive glomerular injury in the remnant kidney. In this setting, the injury is associated with hyperfiltration, glomerular hypertrophy, and systemic hypertension (Brenner and Mackenzie, 1997). In human studies, Novick and associates (1991) demonstrated that with a greater than 50% reduction in total renal mass, the extent of proteinuria correlated directly with the duration of follow-up and inversely with the amount of renal tissue remaining. This discovery suggests that ongoing renal injury occurs when a specific "set point" reduction in nephron number occurs. In certain population groups birth weight may be a risk factor for progressive renal failure if associated with intrauterine growth retardation. Low birth weight can lead to a 20% decrease in overall nephron number (Lopes and Port, 1995; Hughson et al, 2003; Keller et al, 2003). Glomerular size in African Americans is larger than in whites, possibly reflecting smaller nephron number (Pesce, 1998) and perhaps attributable to lower birth weight (Garrett et al, 1994). Theoretically, the increased risk for African Americans to develop "nephrosclerosis" could be linked to this low birth weight risk concept. Even allograft nephron number (donor kidney size compared with recipient body size) may be relevant in the development of chronic rejection and failure in the human transplantation setting (Brenner and Mackenzie, 1997). When the body mass of the donor is small, the functional demands on the allograft will be strained and may contribute to ongoing injury over time, leading to allograft failure.

Interestingly, the age at loss of renal mass influences the kidney's response in humans. In patients undergoing unilateral nephrectomy for Wilms' tumors, renal growth was most marked in those individuals who had surgery at a younger age (Di Tullio et al, 1996). This finding can be applied to the contrasting observations comparing outcomes in congenital solitary kidney versus surgical unilateral nephrectomy. The volume of glomeruli in a congenital solitary kidney is five to six times that observed in a normal kidney (Bhathena et al, 1985). This increase in volume with decreased nephron number could explain the higher risk for ongoing parenchymal injury compared with surgical nephrectomy cases. These reports support the concept that the true response to decreased renal mass in humans varies according to age at time of reduction, underlying conditions (causative agent, etiology), and the actual degree of reduction.

Mechanisms of Progression

Apoptosis (programmed cell death) triggered by ischemia, toxins, or endogenous mediators of damage can be the initial insult that causes renal damage. Apoptotic cell death is an active process under molecular control of regulatory proteins and is characterized by both morphologic and functional changes. These changes usually occur as a response to the cell

Table 41–10. Clinical Action Plan for Chronic Kidney Disease by Glomerular Filtration Rate Levels

Stage	Description	GFR (mL/min/1.73 m²)	Action
	At increased risk	≥90 (with CKD risk factors)	Screening, CKD risk reduction
1	Kidney damage with normal or increased GFR	≥90	Diagnosis and treatment, treatment of comorbid conditions, slowing progression, cardiovascular risk reduction
2	Kidney damage with mild decrease in GFR	60 to 89	Estimating progression
3	Moderate decrease in GFR	30 to 59	Evaluating and treating complications
4	Severe decrease in GFR	15 to 29	Evaluating and treating complications
5	Kidney failure	<15 (or dialysis)	Replacement (if uremia present)

Shaded area identifies patients who have chronic kidney disease; nonshaded area designates individuals who are at increased risk for developing CKD. CKD is defined as either kidney damage or GFR < 60 mL/min/1.73 m² for ≥ 3 months. Kidney damage is defined as pathologic abnormalities or markers of damage, including abnormalities in blood or urine tests or imaging studies.

From National Kidney Foundation: Clinical practice guidelines for chronic kidney disease: Evaluation, classification and stratification. Am J Kidney Dis 2002;39:S19.

and microenvironment in which the presence of certain "lethal factors" (e.g., tumor necrosis factor, Fas-ligand) or the absence of "survivor factors" (e.g., EGF, IGF-1, IGF-2, basic fibroblast growth factor [bFGF]) promote apoptosis. Lethal factors can either activate specific cell death receptors or damage the cells in the absence of receptor activation (Ortiz, 2000). Although growth factors regulate hypertrophy and cell proliferation, they may also mediate apoptosis as a healing response. Understanding the role and regulation of apoptosis in renal disease will be a central theme in designing future therapeutic agents.

A reduction in nephron mass follows cell death. Figure 41–8 illustrates the mosaic of events that occur with progressive nephron mass loss linking sympathetic nervous system activation, renal structural remodeling, altered gene expression/regulation, and several additional regulatory mechanisms for progression. Renal protective interventions are designed to counter those events that adversely affect the cortex and interstitium of the kidney. Both hemodynamic and nonhemodynamic factors are involved in the sustained renal injury after an initial insult. The hemodynamic events causing an increase in single nephron glomerular filtration rate (SNGFR) include increased glomerular plasma flow rates and capillary hydrostatic pressures in the remaining glomeruli. Elevated glomerular hydrostatic pressure is a major factor in renal injury after renal mass reduction (Meyer and Rennke, 1988). However, hyperfiltration alone in response to decreased nephron mass is not sufficient to induce pathologic glomerulosclerosis and interstitial fibrosis. Neurogenic factors and hypertension also play a significant role in ongoing renal injury. Increases in angiotensin II and nitric oxide (NO) activate the sympathetic nervous system (SNS), which plays a dominant role in the pathogenesis of hypertension in CKD (Myers et al, 1975). The rise in central SNS activity is generated by increased local expression of nitric oxide synthase (NOS)-mRNA and NO production coupled to an upregulation of NO production by interleukin-1 (IL-1) in the brain (Campese, 2000).

Nonhemodynamic mechanisms for renal injury involve a number of complex interactions for remodeling: these include structural changes (injury modeling), multiple growth factors, and cytokines. Abnormal glomerular growth is associated with, and may be a marker for, the activation of these specific mechanisms leading to sclerosis during the remodeling phase after renal injury (Fogo, 2000). Injury remodeling, involving both glomerular hyperplasia (increase in cell number) and glomerular hypertrophy (increase in cell size), can occur within 2 days of a significant decrease in overall renal mass (5/6 nephrectomy). Glomerular growth can occur because of increases in any of the cellular components. Structural changes in the glomeruli during remodeling include increased extracellular matrix (ECM) production, glomerular hypertrophy, glomerular proliferation (increase in cell number: epithelial, endothelial, mesangial cells), and

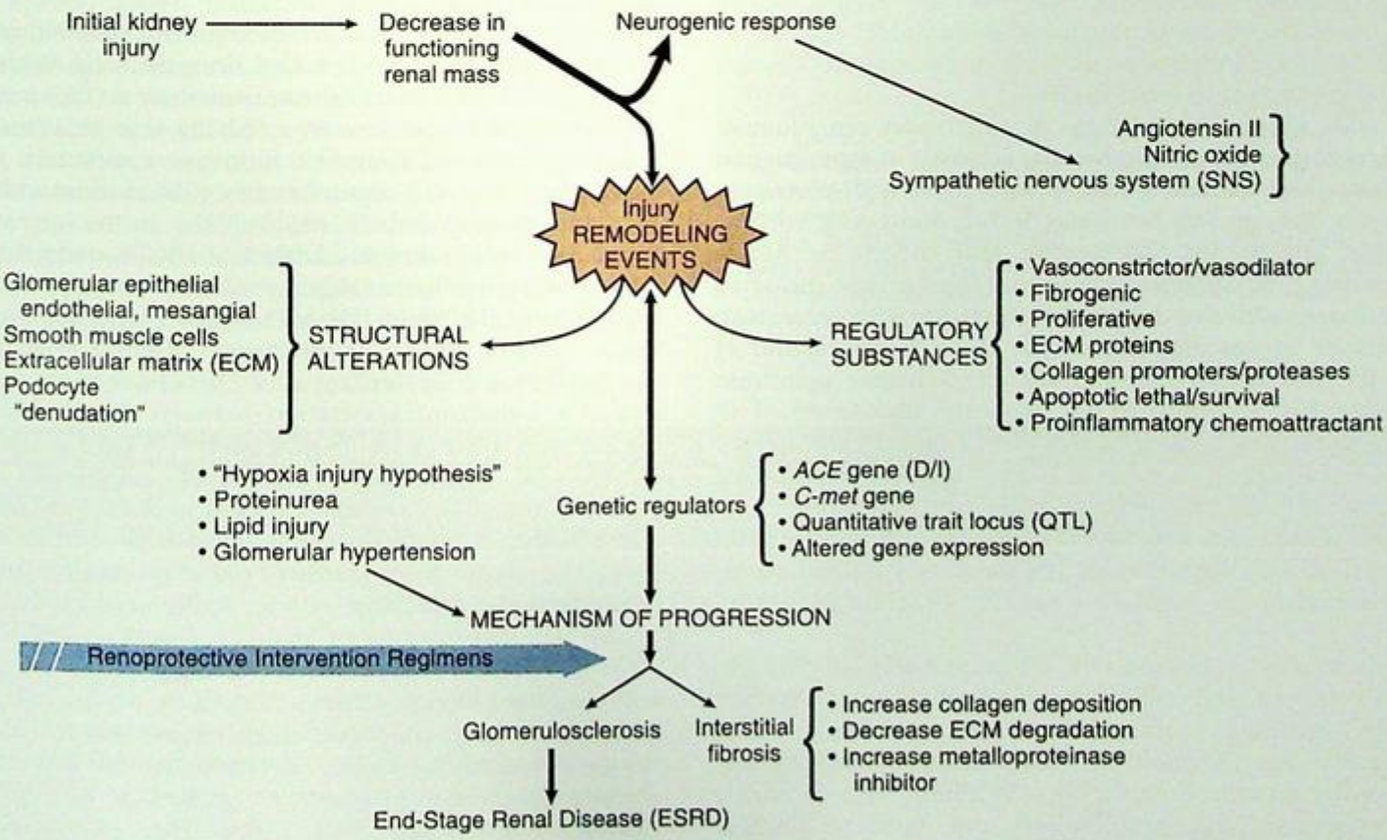

Figure 41–8. Kidney injury mosaic for progressive renal failure. *Fibrogenic factors:* Transforming growth factor-β (TGF-β), hepatocyte growth factor (HGF), matrix metalloproteinases (MMP-2 and MMP-9), nuclear factor-κB (NF-κB). *Vasoconstrictors:* Basic fibroblastic growth factor (bFGF), TGF-β, angiotensin II. *Vasodilators:* Prostaglandin E_1 (PGE_1), nitric oxide (NO). *Proliferative factors:* Vascular endothelial growth factors (VEGF), epidermal growth factor (EGF), growth factor (GF). *ECM expanders:* Platelet-derived growth factor (PDGF), TGF-β. *Glomerular cell proliferation:* Angiotensin II, bFGF, PDGF, and EGF. *Collagen promoting:* PDGF, TGF-β, MMP-2. *Chemoattractant:* Macrophage colony-stimulating factor (MCSF), chemoattractant protein-1. *Apoptotic lethal factors:* Fas-ligand. *Apoptotic survival factors:* Epithelial growth factor, bFGF, PDGF, insulin-like growth factor-1, insulin-like growth factor-2.

glomerular basement membrane (GBM) modification (Harris et al, 1992).

Foam cells are frequently located in segments of the glomerulus undergoing sclerosis and in the interstitium of diseased kidneys. Oxidized low-density lipoprotein (LDL) stimulates inflammation and fibrogenic cytokine production and can cause an increase in cell apoptosis, and the production of endothelin and thromboxane. It also causes an increase in the release of renin from juxtaglomerular cells, thus enhancing vasoconstriction (Keane, 2000).

Many diseases have been associated with an imbalance of ECM synthesis and degradation. The glomerular mesangial cell responds to varied growth factors by proliferation and increased ECM production. An increase in collagen deposition and a decrease in the degradation of ECM components lead to interstitial fibrosis. The degree of tubular interstitial fibrosis has been closely correlated with the reduction in GFR in many different animal and human studies. Angiotensin II upregulates transforming growth factor-β1 (TGF-β1), which is a potent fibrogenic factor playing a key role in the pathogenesis of interstitial fibrosis. The major physiologic regulators of ECM degradation in the glomerulus are matrix metalloproteinases (MMPs) (Lenz, 2000). MMPs are distinct, matrix-degrading enzymes such as stromelysins, gelatinases, elastases, and interstitial collagenases. Changes in MMP expression or activity can alter ECM turnover, which, in turn, may lead to glomerular scarring and a decline in renal function. MMPs may also indirectly affect regulation of certain growth factors, which play a role in ECM turnover. Conceptually, progressive glomerular sclerosis may result from this shift in ECM turnover (attributable to MMP imbalance) toward increased matrix accumulation, a decreased filtration area, and progressive renal failure.

A wide range of conditions or substances can promote intrarenal growth and glomerular sclerosis in experimental models. These include a loss of renal mass, high-protein or high-salt diet, growth hormone, IGF-1, androgens, corticosteroids, angiotensin, aldosterone, and endothelin. Aldosterone may promote fibrosis by several mechanisms, including plasminogen activator inhibitor-1 expression with consequent alterations of vascular fibrinolysis through stimulation of TGF-β1 and reactive oxygen species. Whereas significant evidence has accumulated to implicate angiotensin II in mediating renal disease, recent evidence suggests aldosterone is also an important factor in causing progressive renal disease through both hemodynamic and direct cellular actions. Circulating aldosterone may mediate vascular fibrosis by a direct interaction with high-affinity, low-capacity corticoid receptors located in the cytosol of vascular fibroblasts (Epstein, 2001).

Angiotensin II upregulates the expression of multiple growth factors and cytokines. A number of cell-specific growth responses (glomerular cells, endothelial cells, glomerular visceral epithelial cells, mesangial cells) regulate glomerular growth. Endothelial cells inhibit smooth muscle cell migration and proliferation and produce vascular endothelial growth factors, nitric oxide, endothelin, and platelet-derived growth factor (PDGF) (Fogo, 1999). Vascular endothelial growth factors stimulate angiogenesis, whereas endothelin promotes hypertrophy and increased mesangial cell matrix.

In addition to regulatory substances, additional hypotheses have been developed to explain progression of different renal diseases. Fine and associates (1998) proposed a "chronic hypoxia hypothesis," suggesting that chronic oxygen deprivation to the tubular interstitial compartment can result in scarring. Within glomeruli, blood flow and oxygen delivery into the interstitial capillary network are reduced, resulting in lowered oxygen tension in the remaining vasodilated glomeruli with a high-flow tubular capillary system (hyperfiltration). Postglomerular capillaries exposed to the elevated pressure and increased flow develop endothelial swelling and functional changes that infringe on distal blood flow and oxygen delivery, resulting in ischemia over time.

Genetic Factors

Family members of patients with kidney disease are disproportionately affected with progressive renal failure. The familial clustering of nephropathy has been reported in diabetes, hypertension, systemic lupus erythematosus, and HIV-associated nephropathy. Interestingly, **an individual's family history of end-stage renal disease (ESRD) is a better predictor of the future risk for renal failure than is blood pressure or blood glucose** (Freedman et al, 1997; Satko and Freedman, 2004). A study sponsored by the National Kidney Foundation of Singapore, which screened over 210,000 adults with renal disease, demonstrated a significant relationship between a family history and proteinuria with the potential for future renal failure (Ramirez et al, 2002).

Our understanding of those mechanisms involved in progression to sclerosis has expanded since the early 1990s. It is now clear that genetic traits may contribute to the structural and functional adaptations to a reduction in renal mass. In diabetes, genetic signaling in response to a metabolic injury may explain why only approximately 40% of those with type 1 diabetes develop diabetic nephropathy. In the Appropriate Blood Pressure Control and Diabetic (ABCD) study, the ACE DD genotype was the strongest predictor for the presence of nephropathy (14.2% of DD homozygotes have nephropathy versus 7.8% of non-DD homozygotes) (Jeffers et al, 1997). The Génétique de la Néphropathie Diabétique study demonstrated a significant association between the D-allele frequency and progressive nephropathy in type 2 diabetics (Marre et al, 1997). Even in nondiabetic glomerular injury (IgA nephropathy) there was a greater reduction in GFR and worse biopsy in patients carrying the D allele. Not only does the DD genotype impart increased risk of progression, but this genotype is also associated with an earlier need for dialysis.

The National Institute of Diabetic, Digestive, and Kidney Disease (NIDDK) is currently recruiting diabetic siblings for a family-based linkage analysis of diabetic nephropathy. It is hoped that a large, collaborative genetic analysis will identify the genes underlying diabetic nephropathy and determine if the loci identified in prior smaller studies can be duplicated (Satko and Freedman, 2004, 2005). The National Kidney Foundation sponsored the Kidney Early Evaluation Program (KEEP) and the Southeastern Kidney Council/ESRD Network. These programs are currently screening high-risk American populations assessing the link between family history and kidney dis[illegible] (Brown et al, 2003).

Studies in human renal disease have begun to map the loci of key growth factors. Zidek and colleagues (1998) uncovered a quantitative trait locus on chromosome 2 of a mouse model that is linked to genetic modulation of kidney compensatory growth. This quantitative trait locus is located close to the gene for ACE, growth hormone, and neurogrowth factor receptor (Schena et al, 1999), all of which influence renal growth. **Furthermore, altered gene expression in certain pathophysiologic settings that induce upregulation or inhibition of various growth factors may regulate the degree of response to an initial renal injury.** This may lead to hypertrophy, proliferation, or an increase in ECM. These growth factors include platelet-derived growth factor (PDGF), TGF-β, TGF-α, IGF-1, EGF, IL-1 and IL-6, tumor necrosis factor-α (TNF-α), angiotensin II, and endothelin. Angiotensin II, PDGF, and TGF-β play key roles in sclerosis and fibrosis. IGF-1, fibroblast growth factor (FGF), PDGF, and EGF may be altered in diabetes mellitus, leading to progressive renal injury and kidney failure in this patient cohort.

Therefore, a more thorough understanding of susceptibility genes, regulatory genes for kidney disease progression, and treatment response genes may significantly improve our approach to CKD in the future.

Etiology of CKD

The causes of progressive CKD parallel the most common causes of ESRD. Table 41–11 lists the incident causes of ESRD of varied causes by diagnosis from the year 2004 (U.S. Renal Data System, 2004). **Diabetes mellitus and hypertension account for the largest percentage of cases (76.2%) followed by glomerular diseases (8.9%). In patients younger than age 40 years, CKD is most commonly caused by focal segmental glomerulosclerosis (FSGS), systemic lupus erythematosus (SLE), and then congenital abnormalities of the urinary tract or membranous glomerulonephritis.** Membranoproliferative glomerulonephritis (MPGN), scleroderma, and autosomal dominant polycystic kidney disease (ADPKD) account for the majority of cases of CKD developing in patients between the ages of 40 and 55 years. In the cohort of patients older than 55 years, atheroembolic disease, paraproteinemia (multiple myeloma, amyloid), nephrosclerosis, and analgesic nephropathy are the main causes of CKD. Table 41–12 (National Kidney Foundation, 2002) illustrates the prevalence of individuals with multiple different diseases who are at increased risk for CKD. The number of individuals older than the age of 70 developing CKD is growing exponentially.

The primary parenchymal renal diseases that have the greatest propensity to progress are FSGS, RPGN, chronic glomerulonephritis, and MPGN. The development of CKD in patients with minimal change disease is rare in children and adults with a corticosteroid-responsive clinical course. Patients at highest risk are those who do not respond to corticosteroid therapy or who become late nonresponders. The course of untreated FSGS is usually progressive to ESRD. Both children and adults usually develop ESRD 5 to 20 years from presentation. Malignant FSGS on biopsy exhibits a more rapid

Table 41–11. Incidence of Reported End-Stage Renal Disease by Detailed Primary Renal Diagnosis, 1998-2002

Diagnosis	%
Diabetes mellitus	49.3*
Hypertensive/large vessel disease	26.9
Glomerulonephritis	8.9
Secondary glomerulonephritis/vasculitis	2.2

course to ESRD in 2 to 3 years. Those features associated with a more accelerated course are proteinuria greater than 10 to 15 g/day, SCr greater than 1.5 mg/dL at presentation, significant interstitial fibrosis, and glomerular sclerosis on biopsy.

Although MPGN type 1 is a slowly progressive disease, type 2 is more aggressive with a higher percentage of sclerotic glomeruli, crescent number, and greater degree of interstitial fibrosis. These features portend a poor outcome. Progressive renal insufficiency can occur in 20% to 25% of patients, with MPGN progressing to ESRD over 20 years. At presentation, it is difficult to predict the renal outcome in most membranous patients compared with those with MPGN.

Forty percent of individuals with IgA nephropathy progress to ESRD after approximately 20 years of clinical disease. Markers of poor outcomes are persistent hypertension, proteinuria greater than 2 g/24 hr, initial abnormal SCr value at time of biopsy, and severe sclerotic changes and interstitial fibrosis on biopsy.

A number of systemic diseases involve the kidney and can lead to progressive renal insufficiency (Table 41–13). **Progressive deterioration in renal function can occur in systemic vasculitis due to Goodpasture's syndrome, Wegener's granulomatosis, Henoch-Schönlein purpura, and cryoglobulinemia with or without hepatitis C.** Serologic tests (cryoglobulins, ANCA analysis, immune complex markers, antibodies to hepatitis B or C, antistreptolysin O, and hemolytic complement levels CH50 and C3) and biopsy of the temporal artery or kidney are useful in classifying the clinical presentation into the correct vasculitis category. A significant glomerular insult on biopsy coupled with a poor response to therapy signifies patients at risk for developing worsening renal dysfunction and eventual ESRD.

Table 41–13. Causes of Progressive Chronic Kidney Disease

Tubulointerstitial

Hematopoietic: sickle cell disease, lymphoproliferative, dysproteinemia, neoplastic
Urologic: ureteral obstructions, reflux, prune-belly syndrome, prostatic hypertrophy
Vascular: radiation, hypertension, atheroemboli
Metabolic: cystinosis, oxalosis, uric acid nephropathy, hypercalcemia
Immunologic: renal allograft rejection, Sjögren's syndrome
Toxic: analgesic, nonsteroidal anti-inflammatory drugs, chemotherapy
Immunosuppression: tacrolimus, cyclosporine
Heavy metals: lead, lithium

Hereditary

Sickle cell disease
Cystic disease: autosomal dominant polycystic kidney disease, medullary cystic disease
Alport's syndrome
Karyomegalic interstitial nephritis

Primary Renal Disease

Glomerular: idiopathic glomerulonephritis
Minimal change disease
Focal segmental glomerulosclerosis
Membranous glomerulonephritis
IgA nephropathy

Systemic Diseases

Diabetes mellitus
Infection-related glomerulonephritis
Systemic lupus erythematosus, Henoch-Schönlein purpura, systemic sclerosis
Dysproteinemias/amyloid
Thrombotic microangiopathies
Vasculitis: crescentic glomerulonephritis, acute diffuse glomerulonephritis, antineutrophil cytoplasmic antibody glomerulonephritis (microscopic polyangiitis), Wegener's granulomatosis, Churg-Strauss syndrome, Goodpasture's syndrome, granular cell arteritis

Forty-nine percent of all new patients entered into the Medicare ESRD program from 1998 to 2002 were classified with diabetic nephropathy. Once proteinuria develops and renal function declines, 50% of patients will reach ESRD between 7 to 10 years after the onset of proteinuria in type 1 diabetes. In most patients with type 2 diabetes the time of onset is unknown, thus complicating the ability to predict the course of renal failure. Moreover, a significant percent have concomitant risk factors (smoking, hypertension, hyperlipidemia) along with the proteinuria (>3 g) and nephrosclerosis, which may accelerate the time to ESRD.

Monoclonal immunoglobulins or light chains in both the serum and urine are observed in dysproteinemic states of light-chain nephropathy, amyloid, and cryoglobulinemia. Patients usually present with undiagnosed increases in SCr level and proteinuria and are usually older than 40 years. Treatment of light-chain deposition disease (LCDD) is suboptimal, with a significant percentage of patients progressing to ESRD if their presenting SCr values were greater than 4 mg/dL.

Malignancies of the gastrointestinal tract, breast, renal cell, prostate, skin, and so on can mediate an immune complex nephropathy potentially leading to CKD. Urologic, gynecologic, and lymphoproliferative malignancies can also result in renal injury and progressive chronic renal insufficiency. Non-Hodgkin's lymphoma is associated with membranous glomerulonephritis, and retroperitoneal tumors can cause ureteral obstruction and parenchymal infiltration or both.

Certain hereditary diseases (sickle cell nephropathy; ADPKD; medullary cystic and acquired cystic diseases; aplastic, dysplastic or hypoplastic kidneys) can also lead to CKD. ADPKD is the most common hereditary renal disorder leading to ESRD. Gene linkage may be helpful in identifying the ADPKD gene loci on the short arm of chromosome 16. This test can be carried out in utero in children and in adults before cyst development. Only about 50% of ADPKD patients progress to renal failure. Risk factors for progression include male gender, African origin, early age at presentation, *ADPKD1* gene, hypertension, and gross hematuria. Diverticular disease, cardiac valvular disease, and intracranial aneurysms are more common in ADPKD patients than in the general population and need to be considered in their care.

Medullary cystic disease sometimes can be confused with the benign condition of medullary sponge kidney. Medullary cystic disease presents in childhood with tubular cystic lesions at the cortical medullary junction and can be most accurately detected by kidney biopsy. The kidneys are usually small and the disease progresses to ESRD at a variable rate.

Tubular interstitial disease accounts for 3.8% of patients with CKD. Clinical manifestations depend on the degree of involvement, the tubular sites involved, and the level of compensation that the uninvolved areas provide. The diagnosis of

chronic interstitial nephritis depends on the urinalysis and clinical history. The urine findings are variable and white blood cells may be present. Obtaining an accurate medication history is essential, considering the broad range of causes. Three to 20 percent of patients treated with lithium over time develop CKD (Boton et al, 1987). Chronic lead nephropathy may demonstrate a protracted course that is gradually irreversible, as evidenced by small contracted kidneys. Lead nephropathy can be associated with renal adenocarcinoma. Another form of chronic interstitial nephritis that progresses to ESRD is analgesic nephropathy. The course in analgesic nephropathy is variable, depending on the number of pills consumed.

Obstructive uropathy involving the ureter, bladder, or urethra can lead to progressive renal insufficiency. Undetected ureteropelvic junction obstruction and posterior urethral valves are the most common types of congenital causes for progressive renal failure. Newer spiral CT methods may prove helpful in identification of the obstructing lesion. The percentage of ESRD population attributable to reflux nephropathy and nonreflux nephropathy has increased since the early 1990s (Craig et al, 2000). The rate of deterioration has been significantly associated with age, with a downward trend in incidence as age decreases. Women with reflux nephropathy demonstrate an increased risk of accelerated progression during pregnancy if the SCr value is ≥2.49 mg/dL. The risk for permanent renal failure increases with the duration of obstruction. Regaining renal function after obstruction is dependent on both the degree and duration of obstruction (<2 weeks) and preservation of specific tubular acidifying abilities. Vesicoureteral reflux may result in CKD from renal scarring. Vesicoureteral reflux may be either unilateral or bilateral, and progression to renal failure is related to the severity of reflux. Renal biopsy can be diagnostic as well as prognostic in obstructive neuropathy when relief of obstruction is not followed by restoration of renal function to baseline.

Over time, untreated urolithiasis can result in CKD. Gupta and colleagues (1994) reviewed the natural history of 33 urinary stone patients with a presenting SCr value greater than 2.0 mg/dL before surgical intervention and after placement of ureteral stent or percutaneous nephrostomy tube. The mean decrease in SCr with treatment was 1.2 mg/dL. There was no statistical difference in the rate of decrease between patients with pretreatment SCr levels of 2 to 2.9 mg/dL versus those with levels greater than 3 mg/dL.

Renal artery stenosis can result in progressive azotemia (Olin, 2002). "Flash" pulmonary edema with oliguria and azotemia may suggest the presence of bilateral renal artery stenosis, warranting further evaluation. Usually, when the SCr is greater than 3 mg/dL there is an underlying parenchymal abnormality contributing to kidney failure, in addition to the renal artery stenosis. Dejani and colleagues (2000) have reported that only 25% of elderly patients with CKD (SCr greater than 2 mg/dL) and proximal renal artery stenosis improved with renal revascularization. Renal artery stenting can improve the GFR of treated kidney, although the overall GFR may not change, perhaps reflecting the differential function of the contralateral kidney counterbalanced by the beneficial effect of the treated kidney (Grubb, 2000; Dharnidharka et al, 2002; Leertouwer et al, 2002).

Accurately monitoring the rate of decline in residual renal function (RRF) is important to determine whether the observed change in RRF is consistent with the natural history of the underlying disease or the result of an acute insult. If the RRF decline is inconsistent, an evaluation to uncover an alternate cause is warranted. Patients with CKD are at risk for ARF from a broad range of causes. Nephrotoxic agents, infection, volume depletion, hypotension, progressive renal artery stenosis, hypercalcemia, and hyperuricemia may all lead to worsening of underlying stable CKD, as shown in Table 41–14.

Table 41–14. Factors Associated with Acute Deteriorations in Chronic Kidney Disease

Nephrotoxic
Contrast agents
Pharmacologic agents
Aminoglycoside antibiotics
Nonsteroidal anti-inflammatory drugs
Cyclooxygenase-2 inhibitors
Chemotherapeutic agents
Anti-rejection agents (cyclosporine, tacrolimus)
Anesthetic agents
Autoregulatory Dysfunction
Angiotensin-converting enzyme inhibitors
Angiotensin receptor blocker
Anatomic/Structural
Autosomal dominant polycystic kidney disease and angiotensin-converting enzyme inhibitors
Obstruction
Progressive renal artery stenosis
Renal vein thrombosis
Nephrolithiasis
Hemodynamic/Perfusion Disorders
Congestive heart failure
Perioperative hypotension
Volume depletion
Gastrointestinal: bleeding, diarrhea, vomiting
Excessive diuresis
Sepsis with vasodilation
Parenchymal Injury
Acute myocardial infarction
Valvular dysfunction
Superimposed "new" glomerulonephritis
Interstitial
Hypercalcemia
Hyperuricosuria
Atheroemboli
Drug-Induced

Cimetidine

Clinical Assessment of CKD (Function, Proteinuria, Radiology, and Biopsy)

In practice, once the GFR decreases to less than 60 mL/min/1.73 m^2 for 3 months or more, patients are classified as having CKD. The adjusted relative risk from a population survey adjusted for age, proteinuria, hematuria, and hypertension found that changes in GFR occurred at a cutoff SCr clearance value of 1.2 mg/dL (105 μm/L for women) and 1.4 mg/dL (125 μm/L for men) (Couchoud et al, 1999). However, in extrapolating SCr values to the actual GFR, the relationship may not be linear (see Fig. 41–7).

Other measurements that complement the SCr value may give a better index to the underlying, predicted GFR. Creatinine clearance, creatinine clearance plus urea clearance divided by 2, GFR measurements (inulin iothalamate), and cystatin C all provide information on the level of renal dysfunction. Although the iothalamate GFR is the "gold standard" for measuring renal function, a dedicated staff and laboratory are mandatory to implement this test. The Cockcroft-Gault formula [creatinine clearance = (140 − age) × weight × (0.85 if female) divided by 72 × plasma creatinine] is widely used throughout the world to estimate RRF (Cockcroft and Gault, 1976). Cystatin C, a 13-kD nonglycosylated basic protein produced by all tissues, may have an advantage in detecting minor alterations in GFR, whereas SCr may be more accurate at lower levels of GFR (Grubb, 2000; Dharnidharka et al, 2002; Stevens and Levey, 2005).

Most forms of CKD gradually and inevitably progress to ESRD over a 2- to 10-year time course, depending on the underlying renal lesion responsible for the CKD, combined with patient-specific factors. The K/DOQI staging and the approach to treatment of CKD depend on the assessment of GFR (function assessment), level of proteinuria, and clinical comorbidities. **The National Institutes of Health (NIH) Consensus Conference of 1993 recommended that patients with CKD be referred to a nephrologist when the SCr value has increased to 1.5 mg/dL in females and 2.0 mg/dL in males** (National Institutes of Health, 1994).

Function Assessment

Although the SCr level is widely used as an index of RRF, the measured value is affected by factors other than the GFR. At any given GFR the SCr concentration is significantly higher in men than in women and in blacks than in whites. Total creatinine clearance (TCrCl) usually exceeds the GFR because of tubular secretion, whereas the urea clearance is usually lower than the GFR because of tubular reabsorption. The mean of the creatinine and the urea clearance is a more accurate estimate of the GFR than either is separately. Factors associated with creatinine excretion (age, gender, ethnicity, tubular creatinine secretion and inhibition) may affect the accuracy of standard SCr measurements. **The MDRD study equation to predict the GFR incorporates SCr concentration, demographic characteristics (age, gender, ethnicity), and other serum factors (urea, serum albumin). It is more accurate than other more widely used predictive equations or parameters (SCr level, 1/SCr, TCrCl + Urea clearance/2, Cockcroft-Gault formula).** The MDRD equation for demographic and serum variables is:

$$GFR = 170 \times [P_{Cr}]^{-0.999} \times [age]^{-0.176} \times [0.762 \text{ if patient is female}] \times [1.180 \text{ if patient is black}] \times [SUN]^{-0.170} \times [Alb]^{-0.318}$$

Although the MDRD equation is better than other standard measures for GFR, it is inaccurate for patients not in a steady state for creatinine balance or those with a medical condition interfering with creatinine excretion or creatinine assay or both (diabetic ketoacidosis, or therapy with certain cephalosporins) (Levey et al, 1999).

Individuals with nephrosclerosis appear to progress at individual rates until their GFR decreases to less than 40 mL/min. Most glomerular diseases that result in eventual ESRD progress slowly over 5 to 10 years. Patients presenting with RPGN, accelerated FSGS, Goodpasture's syndrome, or Wegener's granulomatosis can reach ESRD over a period of several months. In the MDRD study of 249 patients with a wide variety of nondiabetic renal disease, the GFR declined in 85% of patients whose initial GFR ranged from 13 to 55 mL/min (Hunsicker et al, 1997). The average rate of decline in nondiabetic renal disease was 4 mL/min/yr in patients whose disease progressed.

Considering the current K/DOQI staging of renal function linked to level of GFR, a number of medical centers and commercial laboratories are using estimated GFR (eGFR) from SCr as a primary method of reporting kidney function because of inadequacies in SCr alone. The MDRD study equation is used most commonly to estimate GFR. The estimation of GFR from the MDRD study equation is not appropriate for patients who have rapidly changing kidney function, are at the extremes of age and body size, exhibit malnutrition or obesity, are paraplegic or quadriplegic, consume a vegetarian diet, or have diseases that have an impact on the skeletal muscle status. Moreover, in sick, hospitalized patients with moderately advanced renal failure, the Cockcroft-Gault, MDRD equations, and eGFR perform poorly when estimating GFR in this patient population and are not reliable measurements of RRF (Poggio et al, 2005). In instances when the eGFR may not be accurate, a 24-hour urine collection for creatinine plus urea clearance divided by 2 is recommended.

Proteinuria

Increased excretion of albumin is a sensitive marker for CKD attributable to diabetes mellitus, glomerular disease, interstitial disease, and hypertension. The American Diabetes Association and the National Kidney Foundation have recommended screening assessment using proteinuria measurement to detect CKD (Levey et al, 1998; American Diabetes Association, 2001). In adults albuminuria can be identified by the use of albumin dipstick, urinary albumin concentration (UAC), albumin/creatinine ratio (ACR) measured in a spot morning urine sample, or urinary albumin excretion greater than or equal to 30 mg over 24 hours (Gansevoort et al, 2005). Traditionally the cutoff value indicating a urinary albumin excretion greater than 30 mg/24 hr has been 3 mg/L (Keane and Eknoyan, 1999). The standard urine protein dipstick is insensitive for low concentrations of albumin (<10 mg/dL) and for some immunoglobulin light chains. Dehydration, hematuria, exercise, infection, and extremely alkaline urine (pH > 8) can cause false positive dipstick readings.

Radiographic Assessment

The radiographic assessment of CKD patients should take into account the impact of contrast on RRF. Imaging techniques in CKD are usually utilized for investigation of new ARF or for investigation of potential problems in nonrenal sites (e.g., cardiac catheterization, peripheral vascular concerns, abdominal investigations). Contrast material can induce worsening of underlying renal disease to the point of requiring RRT. **All patients with abnormal SCr greater than 2 mg/dL should be considered for alternative diagnostic testing and prophylactic preventive strategies to avoid worsening renal function.** Specific measures may help lower the risk for ARF in patients with CKD undergoing radiographic assessment. These include volume expansion, hydration with intravenous administration of normal saline solution (sodium chloride 0.9%), one-half strength saline solution (sodium chloride 0.45%), sodium bicarbonate solution, infusion of mannitol, administration of atrial natriuretic peptide, loop diuretics, calcium antagonists, theophylline, dopamine, *N*-acetylcysteine, low-osmolar contrast, iso-osmolar contrast media, use of gadolinium-based contrast medium, CO_2 angiography, hemodialysis shortly after contrast agent administration, and avoidance of short intervals between contrast studies (Thomsen, 2003; Liss et al, 2005). (See previous discussion in the section on prevention of ATN for recommendations.)

A number of reports have emphasized the value of normal saline solution hydration in patients with CKD and diabetes mellitus to generate a urine flow rate of 100 to 150 mL/hr, thus decreasing the risk for contrast agent–induced nephropathy (Solomon et al, 1994). Merely hydrating patients without ensuring effective urine flow is less valuable. There is no additional benefit to mannitol in the diabetic patient undergoing radiocontrast procedures; however, sodium bicarbonate solution infusion along with *N*-acetylcysteine may be of help. The antioxidant *N*-acetylcysteine (600 mg orally twice a day on the day before and on the day of administration of the contrast agent) along with hydration using a 0.45% saline solution intravenously may decrease the risk of ARF from radiographic contrast agents in this patient group (Tepel et al, 2000; Efrati et al, 2003).

Urinalysis and Kidney Biopsy

The urine sediment examination is helpful in detection of CKD and the identification of the type of kidney disease. All patients with CKD should undergo a urinary sediment examination. Cells can originate from the kidney or from other sites within the urinary tract. The presence of a red blood cell cast strongly suggests glomerulonephritis especially if the red blood cells are dysmorphic. Urinary eosinophils are usually associated with allergic tubular interstitial nephritis. If the urinalysis is negative, despite the patient's having apparent CKD, a second specimen should be examined at another time. The urine sediment should be examined because urinary dipsticks cannot detect tubular epithelial cells (that are casts in the urine), crystals, fungus, or parasites.

A renal biopsy is not usually performed to evaluate asymptomatic hematuria but is warranted if the GFR is less than 60 mL/min/1.73 m^2 and the urinalysis is abnormal. The approach to performing kidney biopsy whether closed (CT-guided, ultrasound-guided) or open (standard or laparoscopic) depends on the overall clinical status, body habitus, patient's clotting parameters, and cumulative experience of the physician. The structural severity of glomerular injury and the immunopathologic category of disease are helpful in predicting renal outcome.

Renal Protective Strategies

Regardless of the nature of the initial insult, once a critical number of nephrons is destroyed, a steady decline in GFR occurs as the progressive loss in viable nephrons occurs. Strategies for delaying the relentless loss in nephron mass (Brenner, 2003) are inconsistently employed across a population with CKD. **And yet, it is becoming increasingly clear that well-designed renal assessment and management programs are feasible and can be systematically applied to large numbers of CKD patients to decrease the rate of progression.**

A report of the International Society of Nephrology 2004 Consensus Workshop on Prevention of Progression of Renal Disease (Li et al, 2005) identified a number of therapeutic measures to prevent the progression of CKD, including lifestyle modifications, blood pressure control, glycemic control, reduction of proteinuria, protein restriction, lipid control, avoidance of nephrotoxic agents, early referral to a nephrologist, correction of anemia, optimization of calcium-phosphorus product, correction of acidosis, and maintenance of fluid balance.

Various pharmacologic trials comparing different medications have shown that patients with better blood pressure control have significantly slower rates of deteriorating kidney function. Yet all agents have not been shown to slow progression based on blood pressure effect alone. Clinical trials have suggested that reducing mean arterial pressure to 82 mm Hg (125/75 mm Hg) provides more optimal renal function stability in patients with diabetes and proteinuria (>1.5 g/day), compared with more conventional mean arterial pressure targets of 107 mm Hg (140/90 mm Hg).

Conceptually, angiotensin II is critical in causing progressive renal disease by both hemodynamic and nonhemodynamic mechanisms. Blockade of the renin-angiotensin system contributes to preservation of renal function by decreasing glomerular pressure and proteinuria. Because proteinuria plays a sentinel role in renal scarring, a reduction in proteinuria correlates with slowing of disease progression (Fine et al, 2000). A recent meta-analysis of randomized clinical trials confirmed the predictive value of proteinuria and the renal protective effect of proteinuria reduction by ACE inhibitor therapy in large patient series (Chiurchiu et al, 2005). Clinical research findings support the view that preservation of renal function through angiotensin blockade can be achieved in patients with either diabetes mellitus or nondiabetic nephropathy (Kshirsagar et al, 2000b). Reductions in proteinuria are greater with ACE inhibitors than with any other antihypertensive agent at the same level of blood pressure control. Multiple ACE inhibitors have been evaluated in CKD. In the Microalbuminuria Cardiovascular and Renal Outcomes—Heart Outcome Prevention Evaluation (MICRO-HOPE) a subset of 35,077 patients with diabetes mellitus and microalbuminuria were treated with ramipril (Heart Outcomes

Prevention Evaluation Study Investigators, 2000). Ramipril reduced the progression from microalbuminuria to overt nephropathy by 24% ($P = .027$). In the ACE Inhibitor in Progression of Renal Insufficiency (AIPRI) study, only part of the risk reduction in the ACE inhibitor group could be explained by the antihypertensive or antiproteinuric effect (Maschio et al, 1996). The AIPRI group performed a meta-analysis of 11 randomized clinical trials consisting of 17,060 patients with nondiabetic renal disease. This study concluded that antihypertensive regimens containing ACE inhibitors are more effective in slowing progression than regimens without ACE inhibitors. This same finding was observed in the Ramipril Efficacy in Nephropathy (REIN) study (GISEN Group, 1997).

Jafar and associates (1999) proposed that ACE inhibitors act by mechanisms in addition to their blood pressure lowering and antiproteinuric effects. ACE inhibitors also prevent the slow decline in Po_2 within the kidney. Considering the "hypoxia injury hypothesis," a potentially important renoprotective mechanism of ACE inhibition could stem from this improvement in interstitial capillary Po_2 levels, therefore decreasing the risk of renal sclerosis.

Angiotensin receptor blockers (ARBs) inhibit the type I angiotensin II receptor. Two large prospective, randomized trials have demonstrated that ARBs delay the progression of CKD in type 2 diabetic patients with overt nephropathy (Lewis et al, 2001; Parving et al, 2001). The Irbesartan Diabetic Nephropathy Trial (IDNT) examined the effect of ARBs (irbesartan) versus conventional therapy or the calcium channel blocker amlodipine in 1715 patients with type 2 diabetes. The doubling of SCr was 29% ($P = .009$) and 39% ($P < .001$) less than the risk in placebo and amlodipine-treated groups, respectively. Moreover, the Microalbuminuria Reduction with Valsartan (MARVEL) trial (Parving et al, 2001) supported the view that ARBs can potentially retard the progression of CKD in patients with type 2 diabetes.

Combining ACE inhibitors and ARBs has led to further reductions in CKD progression, along with blood pressure, proteinuria, and microalbuminuria (Campbell et al, 2003; Segura et al, 2003). Some CKD patients on ACE inhibitors may experience an acute decrease in RRF with low renal perfusion states due to dehydration, congestive heart failure, and hypotension. Individuals with bilateral renal artery stenosis and ADPKD patients with cyst size larger than 10 cm may also experience a decrease in RRF while on ACE inhibitor therapy. A rise in SCr of more than 1 mg/dL after beginning ACE inhibitor therapy should prompt a clinical evaluation to explain the change in baseline function.

An intricate relationship exists between hemodynamic factors that regulate vascular tone and metabolic factors that govern circulating lipids. It is now apparent that the 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors reduce production of molecules involved in fibrogenesis, reduce mesangial and smooth muscle cell proliferation, and decrease production of integrin adhesion molecules (Keane, 2000). Also, HMG-CoA reductase inhibition modulates small G-protein isoprenylation (involved in early gene product C-*fos* and C-*jun* transcription factors) and changes in cell-cycle regulatory proteins. These are involved in intracellular cholesterol metabolism and cell damage at the membrane level. **In view of these findings, HMG-CoA reductase drugs should be part of the CKD treatment regimen.**

For over 25 years it has been known that protein restriction can ameliorate many symptoms of renal insufficiency and prevent its progression. However, without regular dietary consultation, patients on a low-protein diet may experience a decrease in protein intake and deterioration of several nutritional parameters. A number of different diets have been used to help slow the progression of CKD. These dietary formulations include low-protein (0.6 g protein/kg ideal body weight) diets, very low-protein diet (0.3 g protein/kg/day predominantly vegetable protein) supplemented with essential amino acids, or very low-protein diet supplemented with both essential amino acids and nitrogen-free analogs of amino acids (ketoacids). **The overall dietary requirement in CKD is approximately 0.6 g of protein/kg/day.** A recent in-depth analysis of the MDRD study results did note that each 0.2 g/kg/day reduction in protein intake was associated with a 29% slower rate of loss of GFR and a 51% prolongation in the time to dialysis for nondiabetic patients (Mitch, 2000). Two additional studies have demonstrated the beneficial effect of dietary protein restriction on retarding the progression of CKD in both diabetic and nondiabetic patients (Pedrini et al, 1996; Kasiske et al, 1998).

Table 41–15 summarizes a comprehensive strategy to achieve renal protection in patients with CKD (Jafar et al, 1999; Zandi-Nejad and Brenner, 2005). The comprehensive strategy illustrates specific interventions, treatment approaches, monitoring, and target benchmarks of treatment. Future therapies may mobilize progenitor cells for natural "renal repair" similar to those initiatives involving the heart and peripheral arterial disease (Kale et al, 2003; Zandi-Nejad and Brenner, 2005). The progenitor cells from the bone marrow may integrate after ischemic injury with potential for a functional improvement in the insulted organ remodeling. Progenitor cells may amplify biochemical signaling cascades (i.e., vascular and endothelial growth factor, IGF-1, stromal cell–derived factor [SDF]) involved in rescue. Optimal organ targeting will require an ability to amplify the progenitor cell impact. Newer pharmacologic strategies of manipulating resident progenitor cells to treat ischemic renal disease, regenerate glomeruli or tubules, or address transplant vascular disease may offer hope for improved renal reserve in the future (Masuya et al, 2003; Regele and Bohmig, 2003). Preventing renal injury in at-risk settings may also be a direction of treatment for the future. Experimental data in an ischemia-reperfusion rat kidney model have shown that a single systemic dose of erythropoietin before ischemia or just before perfusion prevents injury (Sharples et al, 2004). These findings may have major implications in the prophylaxis against ischemic injury of tubules in humans.

Preoperative Evaluation of CKD/ESRD

In CKD patients scheduled for an elective surgical procedure, a thorough preoperative assessment to define risk is warranted. Preoperative risk falls into three categories: patient-specific, procedure-specific, and anesthesia-specific risks (Bronson, 2000). CKD patients should be closely evaluated because they may have multiple comorbidities that would affect outcome. The risk of a specific procedure is propor-

Table 41–15. Comprehensive Renoprotection Strategy

Focus Area	*Goal*	*Treatment*
Blood pressure control	<130/80 if proteinuria < 1 g/day <125/75 if proteinuria > 1 g/day	Angiotensin-converting enzyme inhibitor Angiotensin receptor blocker Salt restriction Diuresis
Reduction in proteinuria	<0.5 g/day	Angiotensin-converting enzyme inhibitor Angiotensin receptor blocker ? Aldosterone blockade
Glycemic control	HbA_{1c} < 7%	Oral hypoglycemic agents Diet Insulin
Dietary protein restriction	0.6 to 0.8 g/kg/d*	Dietary consult
Lipid lowering	Low-density lipoprotein level ≥ 70 mg/dL†	Statin†‡ Triglyceride-lowering agent
Anemia management	Hemoglobin > 12 g/dL	Erythropoietin Iron
Lifestyle modifications	Ideal body weight* Smoking cessation Exercise three times per week Depression modification	Weight loss program (dietary counseling, surgery) Antidepressants
Calcium × phosphorus product	<4.5 mmol/L <55 mg/dL Phosphorus < 5.5 mg/dL (1.78 mmol) Intact parathyroid hormone level of 70 to 110 pg/mL (CKD stage 4) 30-70 pg/mL (CKD stage 3) 25(OH)vitamin D > 30 ng/mL	Vitamin D supplementation Use of dietary phosphorus restriction Phosphate binders

*Avoid malnutrition.
†Consider measuring nontraditional risk factors: homocysteine, lipoprotein A, C-reactive protein, fibrinogen.

tional to the physiologic stress associated with the procedure. The American Society of Anesthesiologists' physical status scale defines five classes, each with a specific 7-day mortality from 0.07% (no organic or psychiatric disease) to 33.58% (moribund with little chance of survival). However, this scale does not consider procedure-related risks. There is no set risk profile specific for CKD. In general, procedures associated with a higher level of risk include major joint replacement, craniotomy, cardiac procedures, large bowel procedure, and exploratory laparotomies. The anesthesia-specific risk takes into account the effects of anesthetic agents and physiologic responses to a host of possible operative events such as hypotension, hypertension, blood loss, tachycardia, hypoxia, myocardial depression, and the acute worsening of renal function. In the CKD/ESRD population the major predictors of cardiac events are the presence of active ischemia, poor left ventricular function, and baseline ventricular arrhythmia.

Formal cardiac testing may be warranted preoperatively for patients with established ischemia, ventricular arrhythmias, and abnormal left ventricular ejection fraction. While it is preferable to obtain an exercise imaging study rather than pharmacologic imaging study, a significant percentage of CKD/ESRD patients will not achieve maximal predicted heart rate secondary to limited exercise capacity and medications. Pharmacologic testing with dobutamine stress echocardiography may be the best screening test for coronary disease in CKD (Marwick et al, 1998). A negative study had a low frequency of events over the short term (Chertow et al, 1997).

Hypertension also plays a role in determining operative risk. A blood pressure value of 180/110 mm Hg or more is associated with a greater risk for preoperative ischemic events. When possible, surgery should be delayed to bring blood pressure down to an acceptable level in patients with hypertension and CKD.

CKD patients with chronic obstructive pulmonary disease, active asthma, or a current infection are at high risk for pulmonary complications. Upper abdominal and thoracic surgery carry the greatest risk of compromising pulmonary function. If the forced expiratory volume vital capacity in 1 second (FEV_1) is greater than 2 L, the risk of a complication is low. An FEV_1 less than 1 L is associated with a significantly greater risk. Discontinuing smoking at least 3 months before surgery can significantly decrease the risk of pulmonary complications.

CKD patients with diabetes mellitus should achieve optimal control (<200 mg/dL) before surgery. The risk for infectious complications increases with blood glucose level greater than 300 mg/dL. CKD patients with diabetes on oral hypoglycemic agents should be carefully monitored because hypoglycemia with sepsis and/or malnutrition can markedly increase morbidity and mortality.

Elective surgery should be avoided in CKD/ESRD patients in a malnourished state. Serum albumin levels less than 3.5 g/dL, prealbumin levels less than 30 mg/dL, protein-nitrogen appearance or protein catabolic rate less than 0.8 g/kg/day, and subjective global nutritional assessment

score of less than 5 signify malnutrition. Nutritional (protein/calorie) supplements should be used preoperatively to improve the baseline nutritional status. In the setting of anorexia, all offending drugs should be eliminated and consideration given for using pharmacologic appetite-stimulating agents (megestrol acetate).

Drug dosing in CKD/ESRD should be closely monitored to avoid both reversible and irreversible toxicities. Avoiding drugs that have the potential to accelerate loss of RRF is of paramount importance. The risk of adverse events may be linked to the patient's degree of residual renal dysfunction. Uremic toxins may modulate cytokine P450 enzyme activity, decrease glomerular filtration of drugs, and alter tubular secretion. High-risk therapies in the setting of CKD/ESRD include ACE inhibitors, radiographic contrast media, volume depletion, NSAIDs, cyclooxygenase-2 inhibitors, and aminoglycosides.

Conservative Management: Prevention of Uremic Complications

A comprehensive approach to achieving optimal renal care begins with the early detection of renal failure followed by the initiation of interventions that delay progression, prevent uremic complications, modify comorbidities, and, when necessary, prepare patients for RRT to optimize patient survival. The components of an optimal disease management program are depicted in Figure 41–9 (Pereira, 2000).

Decreased GFR is associated with complications in most organ systems. The most important complications include high blood pressure, anemia, malnutrition, bone disease, neuropathy, and alterations in quality of life. As the patient moves from stage 2 to higher stages, he or she is more likely to develop additional comorbidities. The level of scrutiny and search for comorbidities increases as the stage of kidney disease advances. A number of factors increase cardiovascular risk. These include diabetes mellitus, hypertension, dyslipidemia, smoking, physical activity, psychological factors, anemia, arterial stiffness, vascular/valvular calcifications, and calcium and metabolic bone disease status.

The seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC VII) has defined hypertension in adults and the general population as systolic blood pressure of 140 to 159 mm Hg and diastolic blood pressure of 90 to 99 mm Hg. Normal blood pressure is defined as less than 120/80 mm Hg. A new category, "Prehypertension," is defined as 120 to 139 mm Hg systolic and 80 to 89 mm Hg diastolic (Chobanian et al, 2003). In patients with CKD, particularly those with proteinuria greater than 1 g in 24 hours, the target blood pressure goal (125/75 mm Hg) provides maximal protection against progression of renal disease (Klahr et al, 1994). Aggressive blood pressure control should also be a goal for patients on dialysis (K/DOQI stage 5), as outlined in Figure 41–10.

Data have shown that mild renal failure (SCr ≥ 1.4 but < 2.4 mg/dL) in high-risk patients had a 40% increase in the risk of cardiovascular death, myocardial infarction, or stroke compared with those patients with lower SCr levels (Mann et al, 2001). Because a large percentage of patients with CKD die of cardiovascular events before reaching dialysis (>60%), attention to risk factors is critical to extend survival. For optimal control of blood pressure a combination regimen that includes a diuretic, ACE inhibitor, or ARB is essential not only to achieving blood pressure control but also to retard the rate of progression of CKD. If the SCr is elevated (GFR less than 30 mL/min), a loop diuretic should be substituted for a standard thiazide.

Traditional atherosclerotic risk factors are frequently present in CKD. Low HDL level, elevated homocysteine level,

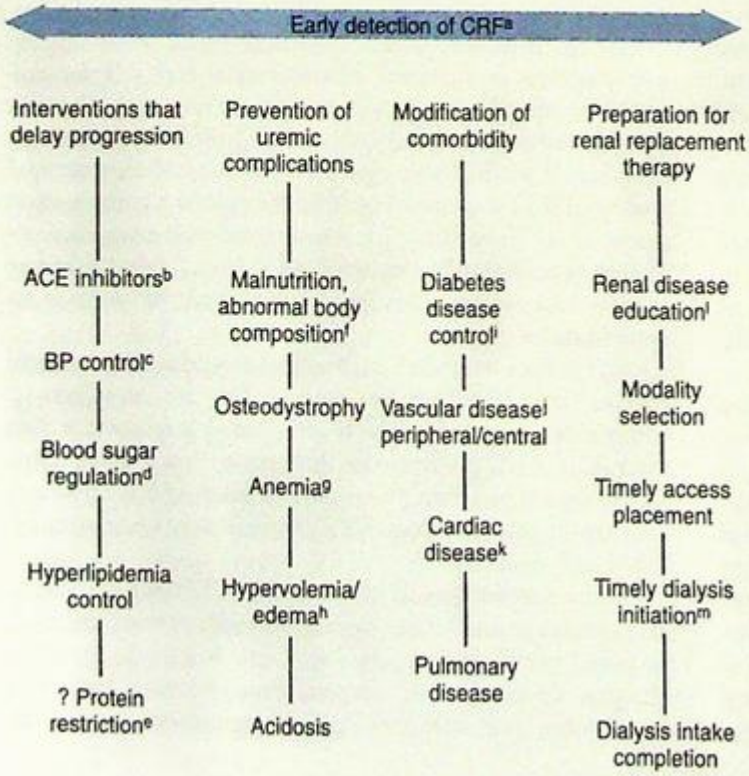

Figure 41–9. Optimization of kidney disease care. *a.* Screening high-risk patients; serum creatinine >1.2 mg/dL. *b.* May require higher doses of angiotensin-converting enzyme inhibitors (or ATI-receptor blockers) to achieve target blood pressure. *c.* Control blood pressure: target level: mean arterial pressure less than or equal to 92 mm Hg. *d.* Blood sugar target of HbA_{1c} less than 7%, glucose before meals of 80 to 120 mg/dL, glucose at bedtime of 100 to 140 mg/dL. *e.* Protein restriction, 0.67 g/kg/day with dietary consultation and objective measurements to avoid malnutrition. *f.* Parameters should include serum albumin plus subjective global assessment, anthropometrics or measurements of lean body mass (fat-free mass). *g.* Pre–end-stage renal disease target hematocrit greater than or equal to 30%, end-stage renal disease target hematocrit 30% to 36%. *h.* Effective volume equilibration is essential to avoid congestive heart failure, cellulitis/limb loss; increased admissions may require early initiation of dialysis. *i.* Avoid neuropathy, foot abnormalities, blindness. *j.* Peripheral vascular disease increases the risk for coronary artery disease; evaluate peripheral vascular flow. *k.* Echocardiography to assess left ventricular hypertrophy; dobutamine stress echocardiogram for addressing ischemia; screening in high-risk individuals. *l.* Refer for education when creatinine clearance is less than 25 mL/min; referral to nephrology for screening evaluation. *m.* Initiate dialysis when K_rT/V_{Urea} is less than 2.0 with signs of malnutrition. (Adapted from Pereira BJ: Optimization of pre-ESRD care: The key to improved dialysis outcomes. Kidney Int 2000;57:351-365.)

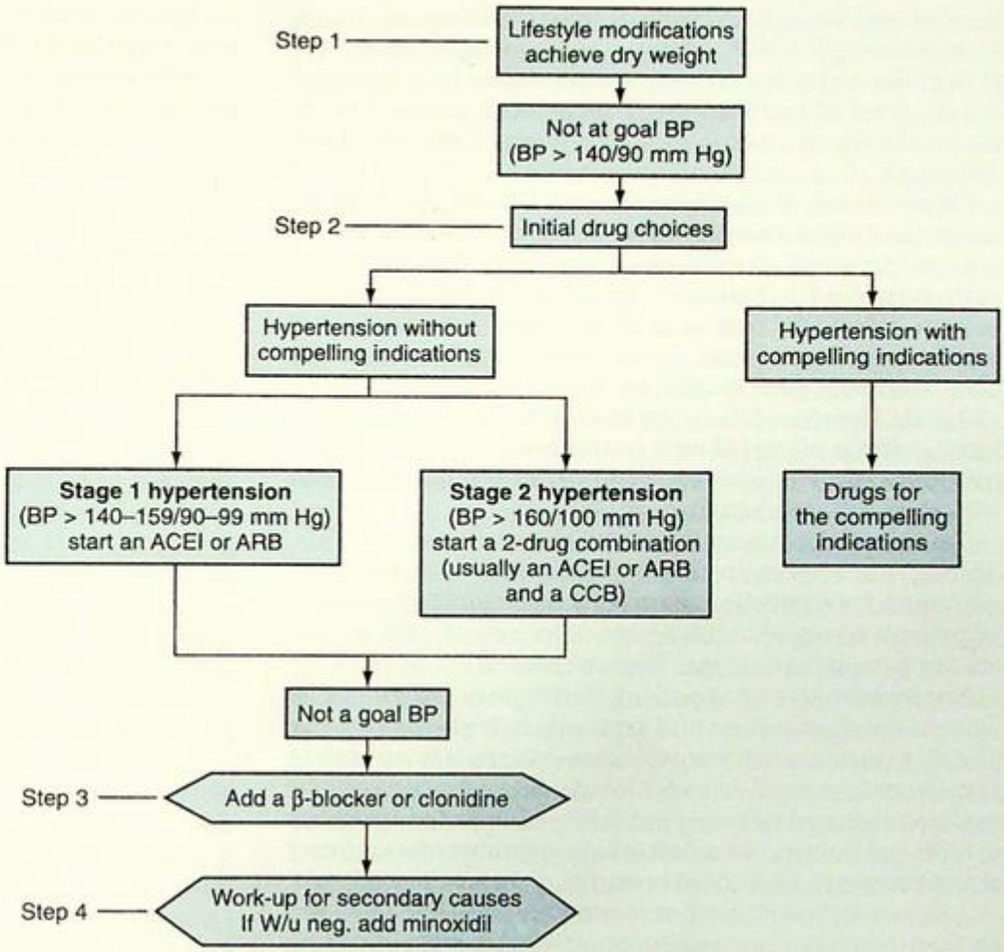

Figure 41–10. Algorithm for blood pressure management in chronic kidney disease. BP, blood pressure; ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; CCB, calcium channel blocker. (From National Kidney Foundation: Clinical practice guidelines for chronic kidney disease: Evaluation, classification and stratification. Am J Kidney Dis 2002;39[2].)

elevated LDL level, and elevated lipoprotein A level all define patients at high risk for cardiovascular events warranting lipid-lowering therapy and close cardiovascular screening (i.e., stress echocardiography, cardiac echocardiography). The Executive Summary of the Third Report of the National Cholesterol Education Program (NCEP) (2001) suggested that based on results from the Heart Protection study and the PROVE-IT study that additional benefit may be achieved by reducing LDL cholesterol levels to substantially below 100 mg/L especially in high-risk patients. Not only should medications be used by patients before stage 5 of CKD, but they also should be maintained once the patient starts dialysis or undergoes a kidney transplant. A meta-analysis comparing the efficacy of various antilipidemic therapies for PD, HD, and transplant recipients demonstrated the effectiveness of HMG-CoA reductase inhibitors (Massy and Kasiske, 1996). Both statin and fibric acid derivatives have proven effective, although individual differences mandate periodic monitoring of fasting lipid levels and liver function tests.

Cigarette smoking is universally recognized as an independent risk factor for cardiovascular disease and should be discouraged with this disease. There is a significant association between current smoking and cardiovascular outcomes that further emphasizes the importance of smoking cessation.

Both vascular calcification and valvular calcifications have been found to be more common in CKD patients and impact on survival (Blacher et al, 1999; London et al, 2004). While there are no randomized trials that have evaluated whether treatment of calcium-phosphorus abnormalities or reduction in the use of calcium-based phosphate binders reduces the risk of cardiovascular disease outcomes, the recommendation from K/DOQI clinical practice guidelines for bone metabolism and disease in CKD is that non–calcium-based binders be used if there is evidence of severe vascular calcification (National Kidney Foundation, 2003). The stage of CKD in which bone disease begins to develop has not been well documented nor has a consensus been reached regarding the optimal screening methods for identifying early abnormalities of calcium-phosphorus metabolism and bone disease in CKD patients. Below a GFR of approximately 60 mL/min/1.73 m^2 there is a higher prevalence of abnormalities of bone metabolism.

Being overweight and obese are associated with increasing risks for a variety of cardiovascular complications and with higher all-cause mortality. Weight reduction is an important lifestyle modification for overweight patients. Although protein-energy malnutrition and wasting are common among CKD patients, no single nutritional marker is helpful in defining malnutrition. Changes in lean body mass over time in CKD may signal not only worsening uremia but also an increased risk for cardiovascular disease. Specific methods for evaluating raising nutritional status include multifrequency bioimpedance (BIA), dual x-ray absorptiometry (DEXA), subjective global assessment (SGA), and hand-grip strength (HGS).

All patients with CKD should follow the American Diabetes Association's guidelines for blood glucose control. Recommendations have been based on evidence from the Diabetes

Control and Complications Trial (DCCT) (National Kidney Foundation, 1993; U.K. Prospective Diabetes Study Group, 1998). The target for diabetes control should be a hemoglobin A_{1C} level of less than 7%, a preprandial glucose level of 80 to 100 mg/dL, and a bedtime glucose level of 100 to 140 mg/dL.

Observational studies have shown an association between anemia and adverse cardiovascular outcomes in CKD patients. It is unclear whether treatment of anemia prevents cardiovascular events in CKD patients. Recombinant human erythropoietin (rHu-EPO) is most likely to benefit the CKD patient who is symptomatic with a hematocrit value less than 30%. The treatment goal should be to achieve hemoglobin of ~12 g/dL. Hypertension can be more difficult to control as the hemoglobin is increased with erythropoietin therapy. Hypertension worsens in approximately 23.5% of patients treated with rHU-EPO (Eschbach et al, 1987).

Cardiovascular disease begins early in the course of CKD. Among patients with creatinine clearance of less than 25 to 30 mL/min, left ventricular hypertrophy is present in 38% to 45% of patients compared with a prevalence rate of 16% to 31% among patients with higher levels of RRF.

Noninvasive testing of patients with kidney failure for cardiovascular disease is helpful especially in high-risk patients. The diagnostic accuracy of perfusion imaging is lower than in patients not in renal failure. Dobutamine echocardiography has been reported to have a sensitivity of 96% and specificity of 86% and is the preferred screening instrument for coronary artery disease in CKD/ESRD patients.

Aggressively addressing comorbidities in CKD that may shorten survival is critical to extending life years for these patients.

Initiation of Renal Replacement Therapy

The K/DOQI guidelines recommend that dialysis be initiated when weekly renal K_rT/V_{Urea} (K_rT = kidney excretion over a 24-hour time period; V_{Urea} = urea distribution volume) decreases to less than 2, unless all three of the following criteria are met: (1) stable or increased edema-free body weight, (2) a random protein equivalent of total nitrogen appearance greater than 0.8 kg/day, and (3) an absence of clinical symptoms and signs attributable to uremia. The patient should begin some form of RRT if the K_rT/V_{Urea} value is less than 2 and greater than 6% involuntary reduction in edema-free weight exists, or if the patient is at less than 9% of standard body weight for National Health and Nutrition Examination III, or there is a reduction of serum albumin level by more than 0.3 g/dL. Despite these recommendations, a significant percentage of patients have RRF less than 10 mL/min/1.73 m^2 at the start of dialysis. Obrador and colleagues (1999) examined data on 90,897 patients who began dialysis in the United States from April 1995 to September 1997. The mean ± standard deviation SCr level at initiation was 8.5 ± 3.8 mg/dL. The mean predicted GFR was 7.1 ± 3.1 mL/min/1.73 m^2. Historically, mortality among late referrals is consistently higher than among those with more timely initiated RRT patterns. Holland and Lam (2000) identified independent predictors of delayed referral among a retrospective cohort of 362 predialysis patients, including age ≥50 years, female gender, and congestive heart failure.

The rationale for timely initiation of RRT is based on several different, independent lines of evidence. As renal function declines, spontaneous dietary protein restriction occurs. Declining renal function is associated with abnormal protein metabolism, malnutrition, and poor clinical outcomes. A lower serum albumin level correlates with an increased mortality risk for both HD and PD patients (Port, 1994).

End-Stage Renal Disease Demographics and Treatment Options

There is a steady growth of ESRD patients (stage 5) on RRT throughout the world. The incidence in the United States is 330 new cases per million of population. The ESRD program in the United States comprises 431,284 patients: 308,910 on dialysis and 122,374 with a functioning transplant. In the United States the number of transplants continues to grow, with 16,004 performed in 2004 (9,357 from deceased donors and 6,647 from living donors). Transplants from living donors in the United States now constitute 41% of all transplants performed. Schena and associates (1999) demonstrated that differences in the distribution of patients receiving RRT throughout the world are influenced by the level of gross domestic product. Diabetes is the primary cause of ESRD in 44% of patients initiated on ESRD therapy. The number of new patients beginning dialysis has increased 139% since 1988 (U.S. Renal Data System, 2004). The most common diseases responsible for ESRD vary depending on the country of origin, as noted from worldwide registries depicted in Table 41–16.

Critically important to all ESRD patients worldwide is a thorough understanding by the physician of dialysis practices that yield improved outcomes. The Dialysis Outcomes and Practice Patterns (DOPPS) study is a prospective, longitudinal study of hemodialysis practices from seven countries with large populations of dialysis patients (France, Germany, Italy, Japan, Spain, United Kingdom, and the United States) (Young, 2000). Linking the DOPPS scope of work with the K/DOQI goals will help to develop continuous quality improvement

programs and provide direct feedback to participating dialysis centers worldwide (Port and Eknoyan, 2004). The DOPPS has collected information that will have an impact on those issues that relate to anemia management, modifiable hemodialysis practices to optimize outcome, vascular access, mortality and hospitalization, nutritional indicators, depression assessment, prescription utilization, acidosis, and vitamin prescriptions.

The mortality rate of RRT patients is strongly influenced by the percentage of enrolled diabetic patients, the dialysis dose, the type of hemodialytic membrane, erythropoietin therapy, and the nutritional status. Adjusted mortality rates of prevalent dialysis patients in the United States continue to fall for those with less than 5 years on therapy. But since 1994, mortality increased in patients on dialysis for greater than or equal to 5 years. Rates for patients on the modality 5 years or more have increased 14% since their lowest point in 1994 to a 2002 level of 286 deaths per 1000-patient-years. This observation may signal a need for more attention to comorbidities that develop in patients over time on dialysis (lipid disorders, worsening diabetes, vascular disease, cardiovascular disease, and infectious complications).

Poor long-term survival of ESRD patients is illustrated by comparing the expected remaining lifetime on dialysis or transplant with the general U.S. population (Table 41–17). The expected remaining lifetime for white dialysis patients was only one-fourth to one-sixth that of the general population, with differences being highest among women age 40 to 65 years. By modality, the expected lifetimes for transplant patients are double those of dialysis patients among black males and more than three times as high for white males age 20 and older. Expected remaining lifetimes in transplant patients are still, however, only 52% to 69% of those of the general population. Compared with males, females have poorer outcomes in terms of more frequent hospitalizations, frequency of anemia, vascular access problems, malnutrition, poorer quality of life, and access to transplantation (Sehgal, 2000).

Multiple different RRTs are available for treatment of ESRD patients. The most commonly utilized RRTs are HD, PD, and renal transplantation. Other treatment options include hemodiafiltration (combination of intermittent hemofiltration with simultaneous HD) and nocturnal home HD (slow flow HD for extended period overnight). **Outcome comparison suggests that renal transplantation is still the best overall treatment for ESRD patients, despite advances in dialytic options.** The time on dialysis may have an impact on the success of replacement therapy. Patients on HD for more than 10 years have a poorer outcome when transplanted compared with individuals receiving transplants with less time on dialysis. This finding is probably related to fixed vascular defects that occur in patients on chronic dialysis therapy. Reports confirm that longer waiting time on dialysis negatively impacts on post-transplant graft and patient survival (Meier-Kriesche et al, 2000). This effect was independent of age, race, donor characteristics, and original disease. Therefore, patients who reach ESRD should undergo preemptive transplantation or transplantation as soon as possible, once on dialysis.

In comparing outcomes between different RRTs for nondiabetic patients, it is essential to consider the type of statistical model used to evaluate mortality (Cox proportional hazards regression versus Poisson regression), the type of analysis employed (intent to treat versus as treated), and the type of study patient (prevalent vs. incident) (Vonesh et al, 2000). Vonesh and associates (2004) reported that specific results are closely linked to stratification by age and modality. Appropriate patient selection is critical to optimizing the life-years per patient with ESRD. PD has an early survival advantage compared with HD, whereas patients older than 45 with diabetes may have a survival advantage (in months) if started on HD.

Not all patients will benefit from RRT. Recommendations for withholding or withdrawing dialysis from suboptimal adult ESRD patients were recently published. These were based on feedback from the U.S. Renal Physicians Association (RPA) and American Society of Nephrology (ASN) in conjunction with broad representation from ESRD patients, family, and non-nephrologists (Galla, 2000).

Currently in the United States 92% of dialysis patients are treated with HD and 8% with PD. Between 1998 and 2002 the prevalent HD and transplant population grew 3.2% and 4.3%, respectively, whereas the PD population decreased almost 3.5% per year. **The renal disease continuum** (see Fig. 41–11) **demonstrates the critical junctures in renal disease care extending from the early diagnosis to management of the patient on dialysis. Processes of care for each stage should be developed from evidence-based recommendations and linked to auditing tools that can provide organizations and health care teams ongoing feedback for optimizing results. The concept of RRT assignment in an integrated fashion is a key to prolonging ESRD survival. An integrated approach combining HD, PD, and renal transplant over the life of an ESRD patient may provide the best approach to optimizing survival. An integrated care approach whereby patients are started on PD and transferred in a timely fashion to HD, when PD- or patient-related problems occur, demonstrates an increase in survival compared with those remaining on HD for their entire life span** (Van Biesen et al, 2000). Table 41–18 indicates transition points that may stimulate transfer from one modality to another. RRF is preserved longer on PD than on HD. Blood pressure is better controlled and ventricular arrhythmias are observed less often on PD than on HD. Weight gain and inadequate dialysis after 3 years are more common on PD than with HD. Although vascular access problems and hemodynamic instability are the most common reasons for transfer to PD from HD, other reasons include infection (peritonitis, catheter, tunnel infections), inadequate dialysis, and catheter malfunction. K/DOQI has established specific guideline recommendations for both HD and PD. Quality guidelines are established for HD adequacy, PD adequacy, vascular access, anemia management, bone metabolism, and nutrition.

In 1997, the NKF's DOQI clinical guidelines on HD and PD were published. For HD, DOQI recommended a single pool K_rT/V_{Urea} of 1.3, urea reduction ratio (URR) more than 70%, allowing for errors or compliance problems in delivering the recommended dose of at least 1.2. Barriers to adequate HD include underprescription, inadequate vascular access, dialysis membrane, clotting, shortened treatment times, and "no show." The projected 2005 DOQI guidelines for PD will require a weekly K_rT/V_{Urea} of more than 1.7. Typically, patients with high- to high-average transport characteristics are ideal

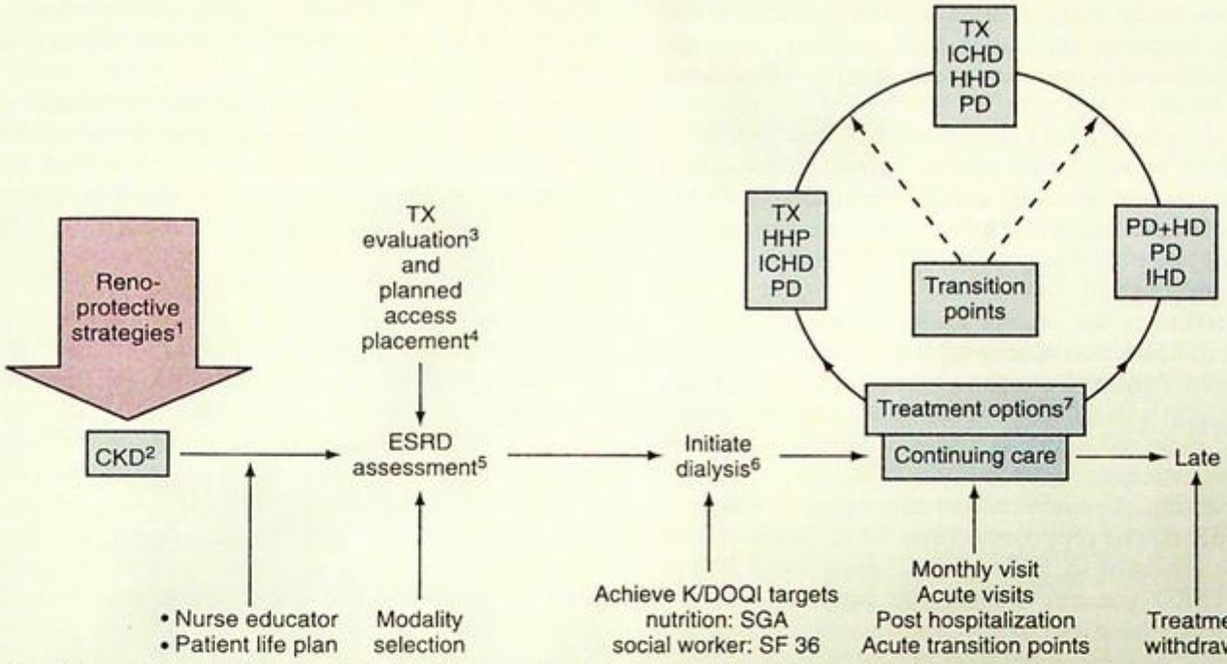

Figure 41–11. Kidney disease continuum. (1) Population screening (serum creatinine >1.2 mg/dL), delay progression (stage 1: 60 to 90 mL/min/1.73 m^2). (2) Preserve residual renal function, educate, assess comorbidities (stage 3, 4: 30 to 59 mL/min/1.73 m^2). (3) Preemptive transplant. (4) Peritoneal dialysis/hemodialysis modalities. (5) Evaluate complication/risk; residual renal function 15 to 29 mL/min/1.73 m^2: prepare for renal replacement therapy. (6) Initiate dialysis. K_rT/V_{Urea} (residual renal function) less than 2, avoid uremic complications, define physician problem-based care (stage 5: <15 mL/min/1.73 m^2). (7) Integrate different therapies over time dependent on critical junctures to extend survival years and control comorbidities: malnutrition, uncontrolled blood pressure, inadequate solute/water removal, access failure, residual renal function preservation.

Table 41–18. Transition Points for Modality Transfers

Peritoneal Dialysis Transfer to Hemodialysis:
Recurrent infection
Catheter malfunction
Ultrafiltration failure
Adequacy (solute) failure
Psychological burnout
Activities of daily living failure
Hospitalization/surgery
Uncontrolled diabetes
Bond composition morbidity delta
Hypotension
Hemodialysis Transfer to Peritoneal Dialysis
Recurrent congestive heart failure
Access failure (steal, recurrent [3], lower extremity, option)
Hypercoagulability
Malnutrition
Intradialysis hypotension
Nursing home care

candidates for automated PD, which uses an automated cycling device to perform dialysis exchanges at night. Low- to low-average transport characteristic patients seem to do best on the standard manual exchanges performed during the day. Several options are available to help PD patients meet adequacy targets combining standard manual exchanges with automated cycling devices.

Hospitalization Risk in CKD/ESRD

CKD patients are 10 times more likely to be hospitalized; and, on average, hospitalization lasts 1 day longer compared with non–renal failure patients (Thamer et al, 1996). Hospital admissions for ESRD patients in the United States have remained relatively stable since 1993, and the number of hospital days has fallen 12% for HD patients, 16% for transplant, and 19% for PD patients. ESRD patients secondary to diabetes are admitted most frequently—2.3 times per year in 2002. Inpatient hospital care accounts for 41% of the total ESRD costs (Bruns et al, 1998). The total hospital discharges by general diagnostic related charges from 1996 to 1998 for ESRD patients in the United States showed that the four most common causes for admission were circulatory (36.4%), renal system (15.6%), respiratory system (7.4%), and infection (5.7%). Patients undergoing RRT are often hospitalized with general medical problems most often stemming from comorbid conditions. The length of stay for HD patients differed by the medical service to which they were admitted. Overall costs for hospitalization tended to be less on the nephrology service than on internal medicine service (6.3 days vs. 8.1 days) (Kshirsagar et al, 2000a). Total cost per admission was $2,848 more for an HD admission to internal medicine service versus nephrology service and, yet, the risk of readmission was not significantly higher.

Rocco and coworkers (1996) identified specific risk factors for hospital utilization in chronic dialysis patients from a cohort of 1572 patients in Network VI (states of North Carolina, South Carolina, and Georgia). **By using multiple regression analysis, the strongest predictors of the number of hospitalizations per year of patient risk included low serum albumin, decreased activity level, diabetes mellitus as a primary cause of ESRD, peripheral vascular disease, white race, increasing age, and congestive heart failure.** Both nutritional status (serum albumin, creatinine, transferrin, prealbu-

min, and lean body mass [bioelectrical impedance]) and inflammatory response (i.e., C-reactive protein) are independent predictors of hospitalization in chronic HD patients (Ikizler et al, 1999).

Sarnak and Jaber (2000) demonstrated that mortality rates secondary to sepsis are one to several hundredfold higher in dialysis patients (HD and PD) compared with the general population. Renal transplant recipients have sepsis-associated mortality rates approximately 20-fold higher than the general population but 15-fold lower than dialysis patients. Infection is the second leading cause of death in patients with ESRD. Sepsis accounts for more than 75% of the infection deaths. Acquired immune deficiencies with uremia, advanced age, and a broad array of comorbid conditions contribute to the observed infection risk and admission rate for kidney disease patients.

Acute worsening of renal function may occur in hospitalized CKD patients. The proposed criteria for initiation of RRT in this setting are listed in Table 41–19 (Bellomo and Ronco, 1998). For ESRD patients undergoing high-risk surgery, sequential daily dialysis for 3 days preoperatively should be entertained to optimize fluid and ensure stable serum potassium and solute levels.

In patients requiring RRT, aggressive volume and solute control are essential to achieving optimal postoperative recovery. Outpatient dialysis schedules may not meet the needs of in-hospital patients. Some individuals may require more intensive therapy either daily or continuously if hemodynamically unstable. A number of different therapies can be utilized to treat critically ill patients requiring RRT (Table 41–20). Ideally, the BUN-to-albumin ratio should decrease to less than 17 through aggressive dialysis. Patients with serum albumin levels less than 3 g/dL with correspondingly low prealbumin values less than 25 g/dL should undergo enteral feedings or aggressive oral supplementation. Total parenteral nutrition may be used if the gastrointestinal tract is nonfunctional. Aggressive ultrafiltration either alone or in conjunction with regular HD should be implemented to control edema and decrease the risk for intubation or reintubation, congestive heart failure, and related infectious complications.

Pulmonary diffusion capacity and pulmonary capillary blood volume are compromised in diabetic CKD patients preoperatively. Low FIO_2 and high central venous pressures are indicators of pulmonary compromise. The alveolar oxygen gradient and respiratory index are more abnormal postoperatively in diabetics versus nondiabetics at similar volume levels. Therefore, smaller elevations in pulmonary capillary wedge pressure carry more significant pulmonary morbidity in diabetics versus nondiabetics, warranting close attention to volume status. CKD patients have a poorly responsive ventilator control system, which impedes timely ventilator weaning (Seki et al, 1993). Therefore re-intubation has a significantly higher morbidity and mortality in CKD and should be avoided. Other preventive strategies involve vaccinations (Pneumovax, influenza, hepatitis), hypertension control, identification of high-risk patients for congestive heart failure, early treatment of upper respiratory tract infection/

Table 41–19. Proposed Criteria for Initiation of Renal Replacement Therapy

Oliguria (urine output < 200 mL/12 hr)
Anuria or extreme oliguria (urine output < 50 mL/12 hr)
Hyperkalemia ($[K^+]$ > 6.5 mmol/L)
Severe acidemia (pH < 7.1)
Azotemia ([urea] > 30 mmol/L)
Clinically significant organ (especially lung) edema
Uremic encephalopathy
Uremic pericarditis
Uremic neuropathy/myopathy
Severe dysnatremia ([Na] > 160 or < 115 mmol/L)
Drug overdose with dialyzable toxin

From Bellomo R, Ronco C: Indications and criteria for initiating renal replacement therapy in the intensive care unit. Kidney Int Suppl 1998;66: S106-S109.

Table 41–20. Defining Therapies for Acute Renal Failure in Patients with Chronic Kidney Disease

Therapy	*Definition*	*Indication*	*Modality Option*
Hemodialysis (HD)	Convective-based process across semipermeable membrane	Solute/H_2O removal Hyperkalemia	IHD, DHD, CAVHD, CVVHD
Hemofiltration	Convective-based solute removal with plasma water filtered across highly permeable membrane	Volume control, acid-base disorders, azotemia, congestive heart failure, multiple organ failure	IHD, CVVH, CAVH
Hemodiafiltration	Convective and diffusive process across semipermeable membrane, increased small and large molecule removal	Acidosis, possible multiple organ failure, ARDS, dialysis instability	IHDF, CAVHDF, CVVHDF
Ultrafiltration (UF)	Plasma water removal, 2 to 5 L/24 hr	Fluid removal, congestive heart failure, total body anasarca, intubation or re-intubation risk	SCUF, CVVUF, IUF
Sustained low efficiency dialysis	Slow, convective-based process across semipermeable membrane	IHD treatment failure due to hypotension or inadequate clearance	SLED
Peritoneal dialysis (PD)	Diffusive and convective transport across peritoneal membrane	Azotemia, volume control, hypotension, without access to continuous hemodialysis treatments	CAPD, CCPD (APD)

ARDS, acute respiratory distress syndrome; IHD, intermittent HD; DHD, daily HD; CAVH, continuous arteriovenous hemofiltration; CVVHD, continuous venovenous HD; IHDF, intermittent hemodiafiltration; CAVHDF, continuous arteriovenous diafiltration; CVVHDF, continuous venovenous hemodiafiltration, SCUF, slow continuous ultrafiltration; CVVUF, continuous venovenous ultrafiltration; IUF, intermittent ultrafiltration; SLED, sustained low efficiency dialysis; CAPD, continuous ambulatory peritoneal dialysis; CCPD, continuous cyclic peritoneal dialysis; APD, automated peritoneal dialysis.

bronchitis, and optimization of functional status (vision assessment, exercise, cognitive stability). Identifying patients with risk characteristics that lead to hospitalization and designing a management plan to modify risk are essential and deserving of further study.

KEY POINTS: CHRONIC RENAL FAILURE

- The National Kidney Foundation developed and published clinical practice guidelines for CKD in 2002 to more consistently diagnose and treat CKD and its comorbidities.
- At a set point (usually >50% reduction in GFR), a relentless progressive loss of renal function ensues even when the initial insult becomes inactive: the hyperfiltration hypothesis.
- Progression of renal insufficiency involves hemodynamic and nonhemodynamic mechanisms.
- ACE inhibitors are the most effective agents in slowing the progression of renal disease by both hemodynamic and nonhemodynamic mechanisms.
- The most common causes of CKD are diabetes and hypertension.
- Comorbidities associated with CKD need treatment to optimize survival and diminish morbidity. This includes managing hypertension, blood lipids, smoking cessation, target weight, anemia, and glycemic control.
- Major surgical interventions mandate thorough medical evaluation, particularly cardiovascular health. The best cardiac noninvasive screening assessment is a dobutamine echocardiogram.

URINARY LITHIASIS AND ENDOUROLOGY

42 Urinary Lithiasis: Etiology, Epidemiology, and Pathogenesis

MARGARET S. PEARLE, MD, PhD • YAIR LOTAN, MD

EPIDEMIOLOGY OF RENAL CALCULI
PHYSICOCHEMISTRY
MINERAL METABOLISM
PATHOGENESIS OF UPPER URINARY TRACT CALCULI

Although stone disease is one of the most common afflictions of modern society, it has been described since antiquity. With Westernization of global culture, however, the site of stone formation has migrated from the lower to the upper urinary tract and the disease once limited to men is increasingly gender blind. Revolutionary advances in the minimally invasive and noninvasive management of stone disease over the past 2 decades have greatly facilitated the ease with which stones are removed. However, surgical treatments, although they remove the offending stone, do little to alter the course of the disease. Indeed the overall estimated annual expenditure for individuals with claims corresponding to a diagnosis of nephrolithiasis was nearly $2.1 billion in 2000, reflecting a 50% increase since 1994 (Pearle et al, 2005). Given the frequency with which stones recur, the development of a medical prophylactic program to prevent stone recurrences is desirable. To this end, a thorough understanding of the etiology, epidemiology, and pathogenesis of urinary tract stone disease is necessary.

EPIDEMIOLOGY OF RENAL CALCULI

The lifetime prevalence of kidney stone disease is estimated at 1% to 15%, with the probability of having a stone varying according to age, gender, race, and geographic location. **In the United States, the prevalence of stone disease has been estimated at 10% to 15%** (Norlin et al, 1976; Sierakowski et al, 1978; Johnson et al, 1979). Using data derived from the United States National Health and Nutrition Examination Survey dataset (NHANES II and III), Stamatelou and colleagues (2003) established a 5.2% prevalence of kidney stone disease from 1988 to 1994, which represents a 37% increase from 1976 to 1980 for which a 3.8% prevalence rate was determined. The finding of an increase in the prevalence of stone disease has been observed by others (Norlin et al, 1976; Yoshida and Okada, 1990; Serio et al, 1999; Trinchieri et al, 2000).

Gender

Stone disease typically affects adult men more commonly than adult women. By a variety of indicators, including inpatient admissions, outpatient office visits, and emergency department visits, men are affected two to three times more frequently than women (Hiatt et al, 1982; Soucie et al, 1994; Pearle et al, 2005). However, there is some evidence that the difference in incidence between men and women is narrowing. Using the National Inpatient Sample dataset representing hospital discharges, Scales and colleagues found that while overall population-adjusted discharges for a diagnosis of renal or ureteral calculus increased by only 1.6% from 1997 to 2002, discharges for women increased by 17%, whereas discharges for men decreased by 8.1% (Scales et al, 2005). This trend reflects a change in the ratio of male-to-female discharges from 1.7 in 1997 to 1.3 in 2002. Indeed, in 2002, hospital discharges were the same for men and women in this dataset. Whether trends in hospital discharges accurately reflect trends in the overall prevalence of the disease, however, is not clear. Stamatelou and associates (2003) also noted a slight decrease in the male-to-female ratio of stone disease, from 1.75 (between 1976 and 1980) to 1.54 (between 1988 and 1994) using the NHANES dataset.

Race/Ethnicity

Racial/ethnic differences in the incidence of stone disease have been observed. **Among U.S. men, Soucie and colleagues** (1994) **found the highest prevalence of stone disease in whites, followed by Hispanics, Asians, and African Americans, who had prevalences of 70%, 63%, and 44% of whites, respectively.** Among U.S. women, the prevalence was highest among whites but lowest among Asian women (about half that of whites). Others found an even higher differential (threefold to fourfold) between whites and African Americans (Sarmina et al, 1987). Interestingly, despite differences in prevalence of stone disease according to ethnicity, Maloney

and colleagues (2005) observed a remarkably similar incidence of metabolic abnormalities between white and nonwhite stone formers from the same geographic region, although the distribution of abnormalities differed, suggesting that dietary and other environmental factors may outweigh the contribution of ethnicity in determining stone risk.

The gender distribution of stone disease varies according to race. Sarmina and colleagues (1987) noted a male-to-female ratio among whites of 2.3 and among African Americans of 0.65. Michaels and coworkers (1994) also noted a reversal of the male predisposition to stone disease in Hispanics and African Americans, reporting a male-to-female ratio of 1.8 among Asians, 1.6 among whites, 0.7 among Hispanics, and 0.5 among African Americans, among a group of patients undergoing extracorporal shock wave lithotripsy. Soucie and associates (1994) observed a similar trend in the male-to-female ratio of the lifetime incidence of stone disease of 3.4 among Asians, 2.6 among whites, 2.1 among Hispanics, and 1.8 among African Americans, although the actual ratios differed in the two studies. Dall'era and colleagues (2005) reviewed emergency department records to identify patients presenting with symptomatic renal or ureteral calculi and found a male-to-female ratio of 1.17 among Hispanic patients compared with 2.05 for white patients.

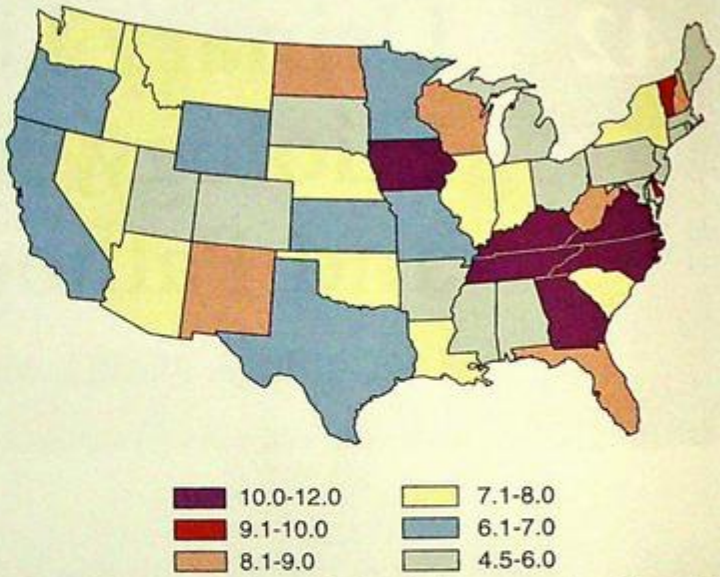

Figure 42–1. Geographic distribution of urinary tract stone disease in the U.S. veteran population from 1983 to 1986. Data are expressed as urinary tract stone patients per 1000 hospital discharges. (From Mandel NS, Mandel GS: Urinary tract stone disease in the United States veteran population: II. Geographical analysis of variations in composition. J Urol 1989;142:1516.)

Age

Stone occurrence is relatively uncommon before age 20 but peaks in incidence in the fourth to sixth decades of life (Marshall et al, 1975; Johnson et al, 1979; Hiatt et al, 1982). It has been observed that women show a bimodal distribution of stone disease, demonstrating a second peak in incidence in the sixth decade of life, corresponding to the onset of menopause (Marshall et al, 1975; Johnson et al, 1979). This finding, and the lower incidence of stone disease in women compared with men, has been attributed to the protective effect of estrogen against stone formation in premenopausal women, owing to enhanced renal calcium absorption and reduced bone resorption (McKane et al, 1995; Nordin et al, 1999). Indeed, Heller and colleagues (2002) identified lower urinary saturation of calcium oxalate and brushite in women compared with men. Moreover, urinary calcium was lower in women than in men until age 50, after which it reached equivalence in the two groups. Estrogen-treated postmenopausal women had lower urinary calcium and saturation of calcium oxalate than untreated women.

Alternatively, Fan and associates (1999) found that androgens increased and estrogens decreased urinary and serum oxalate in an experimental rat model, perhaps accounting for the reduced risk of stone formation in women. However, Van Aswegen and coworkers (1989) found lower levels of urinary testosterone in stone formers compared with non–stone-forming control subjects, further confusing the issue.

Geography

The geographic distribution of stone disease tends to roughly follow environmental risk factors; **a higher prevalence of stone disease is found in hot, arid, or dry climates such as the mountains, desert, or tropical areas.** However, genetic factors and dietary influences may outweigh the effects of geography. Finlayson (1974) reviewed several worldwide geographic surveys and found that areas of high stone prevalence included the United States, British Isles, Scandinavian and Mediterranean countries, northern India and Pakistan, northern Australia, Central Europe, portions of the Malay peninsula, and China. Within the United States, **Mandel and Mandel** (1989a, 1989b) **identified the highest rates of hospital discharge for patients with calcium oxalate stones in the Southeast and for uric acid stones in the East, among the veteran patient population. Soucie and associates** (1994) **found increasing age-adjusted prevalence rates in both men and women going from north to south and west to east, with the highest prevalence observed in the Southeast** (Fig. 42–1). After controlling for other risk factors, the authors determined that ambient temperature and sunlight were independently associated with stone prevalence (Soucie et al, 1996).

Climate

Seasonal variation in stone disease is likely related to temperature by way of fluid losses through perspiration and perhaps by sunlight-induced increases in vitamin D. Prince and Scardino (1960) noted the highest incidence of stone disease in the summer months, July through September, with the peak occurring within 1 to 2 months of maximal mean temperatures (Prince et al, 1956). Likewise, Bateson (1973) reported a peak incidence of stone disease between December and March in Australia, corresponding to the summer season.

The study of military personnel translocated to desert locations has provided a unique opportunity to study the effect of climate on a defined population. Pierce and Bloom (1944) reported that American soldiers in an undisclosed desert location had an increase in symptomatic episodes of renal colic during the summer season. Another study of military personnel who developed symptomatic stones after arrival in Kuwait and Iraq disclosed a mean time interval to stone formation of

93 days (Evans et al, 2005). Finally, Parry and Lister (1975) measured urinary calcium and magnesium levels in soldiers before and 10 days after transfer to the Persian Gulf and noted increased urinary calcium levels from baseline in those soldiers transferred during the summer months but not among those transferred during the "cold season," which was attributed to sunlight-induced increased production of 1,25-dihydroxyvitamin D_3 ($1,25[OH]_2D_3$). Thus it is likely that climate and geography influence the prevalence of stone disease indirectly, through effects on temperature and possibly sunlight.

Occupation

Heat exposure and dehydration constitute occupational risk factors for stone disease as well. Cooks and engineering room personnel, both of whom are exposed to high temperatures, were found to have the highest rates of stone formation among personnel of the Royal Navy (Blacklock, 1969). Likewise, Atan and colleagues (2005) found a significantly higher incidence of stones among steel workers exposed to high temperatures (8%) compared with those working in normal temperatures (0.9%). Metabolic evaluation of these two groups of workers showed a higher incidence of low urine volume and hypocitraturia among the workers in the hot area. Borghi and colleagues (1993) also noted differences in the incidence of stone disease and urinary stone risk factors among workers at a glass plant who were or were not chronically exposed to high temperatures causing massive perspiration. Those exposed to high temperatures exhibited lower urine volumes and pH, higher uric acid levels, and higher urine specific gravity, leading to higher urinary saturation of uric acid. Accordingly, those workers who formed stones had a remarkably high incidence of uric acid stones (38%).

Individuals with sedentary occupations, such as those in managerial or professional positions, have been found to carry an increased risk of stone formation for unclear reasons (Blacklock, 1969). This finding is consistent with the work of Robertson and associates (1980b), who reported an increased risk of stone disease in affluent individuals, countries, and societies, which may be reflective of a more indulgent diet and lifestyle.

Body Mass Index and Weight

The association of body size and incidence of stone disease has been investigated. In two large prospective cohort studies of men and women, **the prevalence and incident risk of stone disease were directly correlated with weight and body mass index in both sexes, although the magnitude of the association was greater in women than men** (Curhan et al, 1998; Taylor et al, 2005). Although these investigators identified a reduced risk of incident stone formation with high intake of fluid (men and women) and low protein intake (men) (Curhan et al, 1993, 1997), they found that obesity and weight gain were independent risk factors for incident stone formation and could not be accounted for by diet alone (Taylor et al, 2005). Recent evidence linking obesity and insulin resistance with low urine pH and uric acid stones (Maalouf et al, 2004a, 2004b) as well as an association between hyperinsulinemia and hypercalciuria (Kerstetter et al, 1991; Shimamoto et al, 1995; Nowicki et al, 1998) could account for an increased risk of uric acid and/or calcium stones in obese patients.

Water

The beneficial effect of a high fluid intake on stone prevention has long been recognized. In two large observational studies, fluid intake was found to be inversely related to the risk of incident kidney stone formation (Curhan et al, 1993, 1997). Furthermore, in a prospective, randomized trial assessing the effect of fluid intake on stone recurrence among first-time idiopathic calcium stone formers, urine volume was significantly higher in the group assigned to a high fluid intake compared with the control group receiving no recommendations, and, accordingly, stone recurrence rates were significantly lower (12% vs. 27%, respectively) (Borghi et al, 1996).

Geographic differences in the incidence of stone disease have been ascribed in some cases to differences in the mineral and electrolyte content of water in different areas. Although several investigators reported a lower incidence of stone disease in geographic regions with a "hard" water supply compared with a "soft" water supply, where water "hardness" is determined by content of calcium carbonate (Churchill et al, 1978; Sierakowski et al, 1979), others found no difference. Schwartz and coworkers (2002) found no association between water hardness and incidence of stone episodes, although they did observe a correlation between water hardness and urinary magnesium, calcium, and citrate levels.

KEY POINTS: EPIDEMIOLOGY

- Upper urinary tract stones occur more commonly in men than women by a ratio of 2 to 3:1.
- Whites have the highest incidence of upper tract stones compared with Asians, Hispanics, and African Americans.
- Prevalence of stone disease shows geographic variability, with the highest prevalence of stone disease in the Southeast.
- The risk of stone disease correlates with weight and body mass index.

PHYSICOCHEMISTRY

The physical process of stone formation is a complex cascade of events that occurs as the glomerular filtrate traverses the nephron. It begins with urine that becomes supersaturated with respect to stone-forming salts, such that dissolved ions or molecules precipitate out of solution and form crystals or nuclei. Once formed, crystals may flow out with the urine or become retained in the kidney at anchoring sites that promote growth and aggregation, ultimately leading to stone formation. The discussion that follows describes the process of stone formation from a physicochemical standpoint.

State of Saturation

A solution containing ions or molecules of a sparingly soluble salt is described by the *concentration product*, which is a mathematical expression of the product of the concentrations of the pure chemical components (ions or molecules) of the salt. For example, the concentration product (CP) expression for sodium chloride is $CP = [Na^+][Cl^-]$. A pure aqueous solution of a salt is considered *saturated* when it reaches the point at which no further added salt crystals will dissolve. The concentration product at the point of saturation is called the *thermodynamic solubility product*, K_{sp}, which is the point at which the dissolved and crystalline components are in equilibrium for a specific set of conditions. At this point, addition of further crystals to the saturated solution will cause the crystals to precipitate unless the conditions of the solution, such as pH or temperature, are changed.

In urine, despite concentration products of stone-forming salt components, such as calcium oxalate, that exceed the solubility product, crystallization does not necessarily occur because of the presence of inhibitors and other molecules that allow higher concentrations of calcium oxalate to be held in solution before precipitation or crystallization occurs. In this state of saturation, urine is considered to be *metastable* with respect to the salt. As concentrations of the salt increase further, the point at which it can no longer be held in solution is reached and crystals form. The concentration product at this point is called the *formation product*, K_f.

The solubility product and the formation product differentiate the three major states of saturation in urine: undersaturated, metastable, and unstable (Fig. 42–2). Below the solubility product, crystals will not form under any circumstances and dissolution of crystals is theoretically possible. At concentrations above the formation product, the solution is unstable and crystals will form. In the metastable range, between the solubility product and the formation product and in which the concentration products of most common stone components reside, spontaneous nucleation or precipitation does not occur despite urine that is supersaturated. It is in this area that modulation of factors controlling stone formation can take place and therapeutic intervention is directed.

In the metastable range of concentration products, although crystal growth can occur on existing crystals, de novo formation of crystals cannot occur in the length of time it normally takes for the filtered urine to reach the bladder. However, crystal formation can occur in this range under certain circumstances. First, in parts of the nephron local concentration products may exceed the formation product for long enough time periods to allow nucleation to occur. Second, local areas of obstruction or stasis in the upper

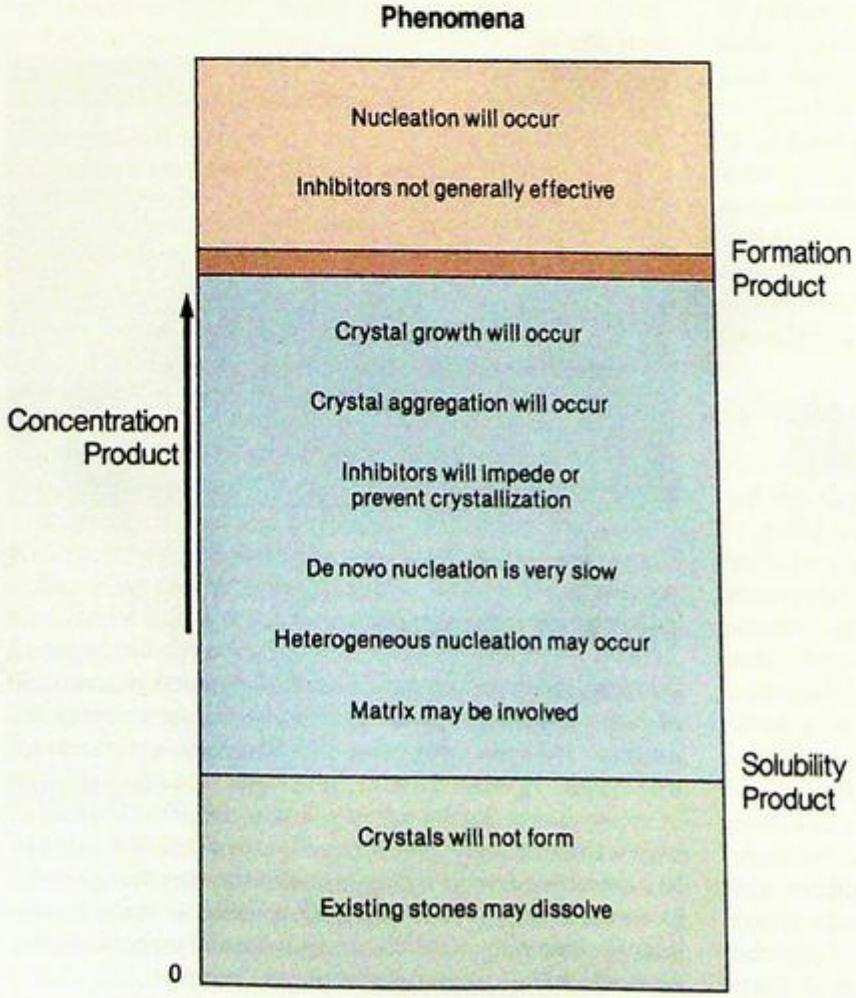

Figure 42–2. States of saturation. Listed are solid-solution phenomena that are likely to occur at a given range of concentration products. Three general situations are considered: (1) concentrations less than the solubility product (undersaturation), (2) concentrations that are metastable with respect to de novo precipitation (between the solubility product and the formation product), and (3) concentrations that are greater than the formation product (unstable). (From Meyer JL: Physicochemistry of stone formation. In Resnick MI, Pak CYC [eds]: Urolithiasis: A Medical and Surgical Reference. Philadelphia, WB Saunders, 1990, pp 11-34.)

urinary tract may prolong urinary transit time and allow crystal formation to occur in the metastable urine. Finally, microscopic impurities or other constituents in the urine can facilitate the nucleation process by adsorption of the crystal components in a geometric way that resembles the native crystal. The energy required for this "heterogeneous nucleation" process is much less than that required for "homogeneous nucleation."

To estimate the state of saturation for any given crystal system, such as calcium oxalate or calcium phosphate, Pak and Chu (1973) developed a mathematical formula, the *activity product ratio*, that takes into account urine pH and the ionic activities of all major ion species directly involved in the stone-forming process or those that affect the overall ionic strength of the urine. Finlayson subsequently developed a computer program to measure the state of saturation, EQUIL 2, which is commonly used today (Werness et al, 1985). The *relative saturation ratio* or *concentration product ratio* is defined as the ratio of the concentration product of the urine to the solubility product of the specified stone-forming salt. A reduction in the numerator will lead to undersaturation of the urine with respect to the stone-forming salt and consequently reduce the likelihood of precipitation. This can be accomplished by reducing the urinary concentrations of the stone components (e.g., calcium or oxalate), by reducing the filtered load, or by increasing urinary reabsorption. In addition, complexation with substances such as citrate, reduce available free ionic calcium and decrease the relative saturation ratio. On the other hand, manipulation of factors such as pH can significantly impact the concentration of ions such as phosphate, the generation of which is highly pH dependent. Manipulation of pH has little effect on oxalate concentration, however, because oxalic acid is a strong acid (pK = 4) and pH changes within the physiologic range will have little effect on oxalate concentration.

Historically, urinary oxalate has been considered a more important contributor to calcium oxalate stone formation than urinary calcium (Nordin et al, 1972; Robertson and Peacock, 1980). This assumption is based on the findings of Nordin and colleagues (1972), who noted that a rise in urinary calcium concentration had less of an effect than a rise in oxalate concentration in increasing urinary saturation of calcium oxalate. They further showed that at high urinary calcium concentrations the saturation of calcium oxalate reached a plateau that did not exceed the theoretic formation product of calcium oxalate, whereas high oxalate concentrations did, thereby increasing the risk of calcium oxalate crystal formation. Pak and colleagues (2004), however, challenged the notion that urinary oxalate exerts a greater pathogenetic role than calcium in calcium oxalate stone formation. They demonstrated that the choice of stability constant used for calculating relative saturation ratio determines the relative effects of urinary calcium and oxalate concentration. Using the commonly accepted stability constant of 2.746×10^3 (used in the EQUIL 2 program), the effect of urinary calcium and oxalate proved to be equivalent. Thus, they concluded that **urinary calcium and oxalate are both important and equal contributors to calcium oxalate stone formation.** As such, reduction in both calcium and oxalate will be effective in reducing the relative saturation ratio, and intervention to prevent stone formation can be directed at either.

Nucleation and Crystal Growth, Aggregation, and Retention

In normal human urine, the concentration of calcium oxalate is four times higher than its solubility in water. Urinary factors favoring stone formation, including low volume and citrate and increased calcium, oxalate, phosphate and uric acid, all increase calcium oxalate supersaturation. Once the concentration product of calcium oxalate exceeds the solubility product, crystallization can potentially occur. However, in the presence of urinary inhibitors and other substances, calcium oxalate precipitation occurs only when supersaturation exceeds the solubility by 7 to 11 times.

Homogeneous nucleation is the process by which nuclei form in pure solution. Nuclei are the earliest crystal structure that will not dissolve. Small nuclei are unstable; below a critical size threshold, dissolution of the crystal is favored over crystal growth. If the driving force (supersaturation level) and the stability of the nuclei are adequate and the lag time to nucleation is sufficiently short compared with the transit time of urine through the nephron, the nuclei will persist. Inhibitors, like citrate, destablilize nuclei, whereas promoters stabilize nuclei by providing a surface with a binding site that accommodates the crystal structure of the nucleus. In urine, crystal nuclei usually form through heterogeneous nucleation by adsorption onto existing surfaces of epithelial cells (Umekawa et al, 2001), cell debris (Fasano et al, 2001), or other crystals (Kok, 1997).

Within the time frame of transit of urine through the nephron, estimated at 5 to 7 minutes, crystals cannot grow to reach a size sufficient to occlude the tubular lumen. However, if enough nuclei form and grow, aggregation of the crystals will form larger particles within minutes that can occlude the tubular lumen. Inhibitors can prevent the process of crystal growth or aggregation. Magnesium and citrate inhibit crystal aggregation. Nephrocalcin, an acidic glycoprotein made in the kidney, inhibits calcium oxalate nucleation, growth, and aggregation (Nakagawa et al, 1987; Asplin et al, 1991). Tamm-Horsfall mucoprotein, the most abundant protein in urine, inhibits aggregation (Hess et al, 1991), and uropontin inhibits crystal growth (Shiraga et al, 1992). Bikunin, the light chain of inter-alpha inhibitor, has been shown to be an efficient inhibitor of crystal nucleation and aggregation.

Opposing views regarding the formation and growth of crystal particles have led to controversy over the concept of free crystal particle growth versus fixed particle growth. Although it was initially concluded that free particle stone formation was impossible within the normal transit time through the nephron (Finlayson et al, 1978b), later recalculation using current nephron dimensions, supersaturation, and crystal growth rates determined that crystalline particles can be formed that are large enough to be retained during normal transit time through the kidney (Kok and Khan, 1994).

Fixed particle growth theory presupposes an anchoring site to which crystals bind, thereby prolonging the time the crystals are exposed to supersaturated urine and facilitating crystal growth and aggregation. A number of mechanisms have been proposed to account for crystal fixation. One favored theory proposes that oxalate-induced injury to renal tubular epithelial cells promotes adherence of calcium oxalate crystals (Miller et al, 2000). In animal models of stone formation in

which administration of high oxalate loads leads to calcium oxalate crystal formation, elevated urinary levels of enzyme markers of cell injury, including *N*-acetyl-β-glucosidase and alkaline phosphatase, imply damage to renal tubular epithelial cells (Khan et al, 1992; Thamilselvan and Khan, 1998). Although the exact mechanism of oxalate-induced cell injury is not known, several studies have suggested that it is mediated by free radical formation (Thamilselvan and Khan, 1998; Thamilselvan et al, 1999). Not only are high concentrations of oxalate toxic to renal tubular cells, but calcium oxalate crystals themselves have also been shown to promote damage to cells (Khan et al, 1993, 1999; Thamilselvan and Khan, 1998; Thamilselvan et al, 1999). Despite these findings in animal models and in-vitro systems, **evidence for oxalate-induced tubular damage in humans has been lacking.** Indeed, Holmes and Assimos (2004) observed no increase in markers of oxidative stress or renal cell injury in normal individuals after ingestion of a large oxalate load, although the response in stone formers has not yet been determined.

How oxalate-induced renal tubular cell damage potentially promotes crystal retention is not known. Randall (1937) first observed areas of damage associated with subepithelial plaques on the renal papillae. Later, structural analyses in hyperoxaluric rats demonstrated crystals attached to the injured epithelium lining the collecting ducts (Khan, 1991). In-vitro studies confirmed increased binding of calcium oxalate crystals to injured renal epithelial cells in culture (Verkoelen et al, 1998). Whether the renal tubular cells or the interstitium constitutes the primary site of stone formation is unclear. Evidence of endocytosis of calcium oxalate crystals into renal tubular cells has been demonstrated in patients with disorders of oxalate metabolism (Saxon et al, 1974; Mandell et al, 1980; Lieske et al, 1992). Intracellular incorporation of these crystals could potentially lead to cell death and deposition of crystals in the interstitium, or transport of the crystals from the luminal to the basement membrane side could promote cell damage and subsequent erosion through to the papillary surface. Knoll and colleagues (2004) demonstrated in cell culture that oxalate-induced damage was more pronounced in renal nontubular compared with tubular cell lines and, further, that renal epithelial cells were more vulnerable to the toxic effects of oxalate on their basolateral side compared with their apical (luminal) side, implicating the interstitium as a possible site of primary stone formation.

In light of these recent findings, a number of investigators have revisited the role of Randall's plaques in the pathogenesis of stone formation. Low and Stoller (1997) mapped the papillae of patients undergoing endoscopic stone removal, as well as control subjects undergoing endoscopy for unrelated reasons, and found that papillary plaques occurred in 74% of stone formers compared with only 43% of control subjects. Stoller and colleagues (2004) hypothesized that the inciting event in the pathogenesis of stones may be vascular injury to the vasa recta near the renal papilla. Repair of damaged vessel walls could involve an atherosclerotic-like reaction that results in calcification of the endothelial wall, followed by erosion into the papillary interstitium and then into the collecting ducts, where it could serve as a nidus for stone formation.

Evan and coworkers presented an alternative view of the pathogenesis of stone formation based on extensive analysis of papillary plaques derived from biopsies obtained during percutaneous nephrolithotomy in idiopathic calcium oxalate stone formers. **They localized the origin of the plaque to the basement membrane of the thin limbs of the loops of Henle and demonstrated that the plaque subsequently extends through the medullary interstitium to a subepithelial location** (Fig. 42–3) (Evan et al, 2003). **Once these plaques, which are invariably composed of calcium apatite, erode through the urothelium, they constitute a stable, anchored surface on which calcium oxalate crystals can nucleate and grow as attached stones.** They further noted that among idiopathic calcium oxalate stone formers, the volume of papillary surface covered by plaque correlated negatively with urine volume and positively with hypercalciuria (Kuo et al, 2003a, 2003b) and the number of stones formed (Kim et al, 2005a), providing further corroborating clinical evidence for the sequence of events they proposed.

In contrast, **patients with enteric hyperoxaluria due to intestinal bypass for obesity demonstrated no plaque but did show apatite crystal deposits plugging the terminal collecting duct lumen and associated epithelial cell damage with inflammation and fibrosis of the interstitium** (Fig. 42–4) (Evan et al, 2003). Patients who form brushite stones were found to have intermediate pathology between the calcium oxalate stone formers and the intestinal bypass patients, demonstrating interstitial apatite plaque and apatite plugging of the terminal collecting ducts, along with associated collecting duct injury and interstitial fibrosis (Fig. 42–5) (Evan et al, 2005). The pathogenesis of brushite stones was postulated to occur by way of crystallization of apatite in the collecting duct, followed by collecting duct injury and cell death leading to enlarged collecting ducts, interstitial inflammation as a result of the injured cells, and, finally, progressive involvement of adjacent renal tissue.

The finding of distinct morphologic subtypes characterizing particular patient phenotypes is consistent with their divergent underlying pathophysiologic abnormalities and supports the role of both urine chemistry/state of saturation as well as local factors in the pathogenesis of stone formation.

Inhibitors and Promoters of Crystal Formation

At the concentrations that most stone-forming salt components are present in urine, including calcium, oxalate, and phosphate, urine is supersaturated, thereby favoring crystal formation. However, **the presence of molecules that raise the supersaturation needed to initiate crystal nucleation or reduce the rate of crystal growth or aggregation prevents stone formation from occurring on a routine basis.** Although inhibitors have been identified for calcium oxalate and calcium phosphate, no specific inhibitors are known that affect uric acid crystallization.

Whole urine, when added to a solution of calcium phosphate, raises the supersaturation level required to initiate calcium phosphate crystallization (formation product) (Fleisch et al, 1962). Inorganic pyrophosphate was found to be responsible for 25% to 50% of the inhibitory activity of whole urine against calcium phosphate crystallization. By using different methodology, however, citrate, magnesium, and pyrophosphate together were noted to account for

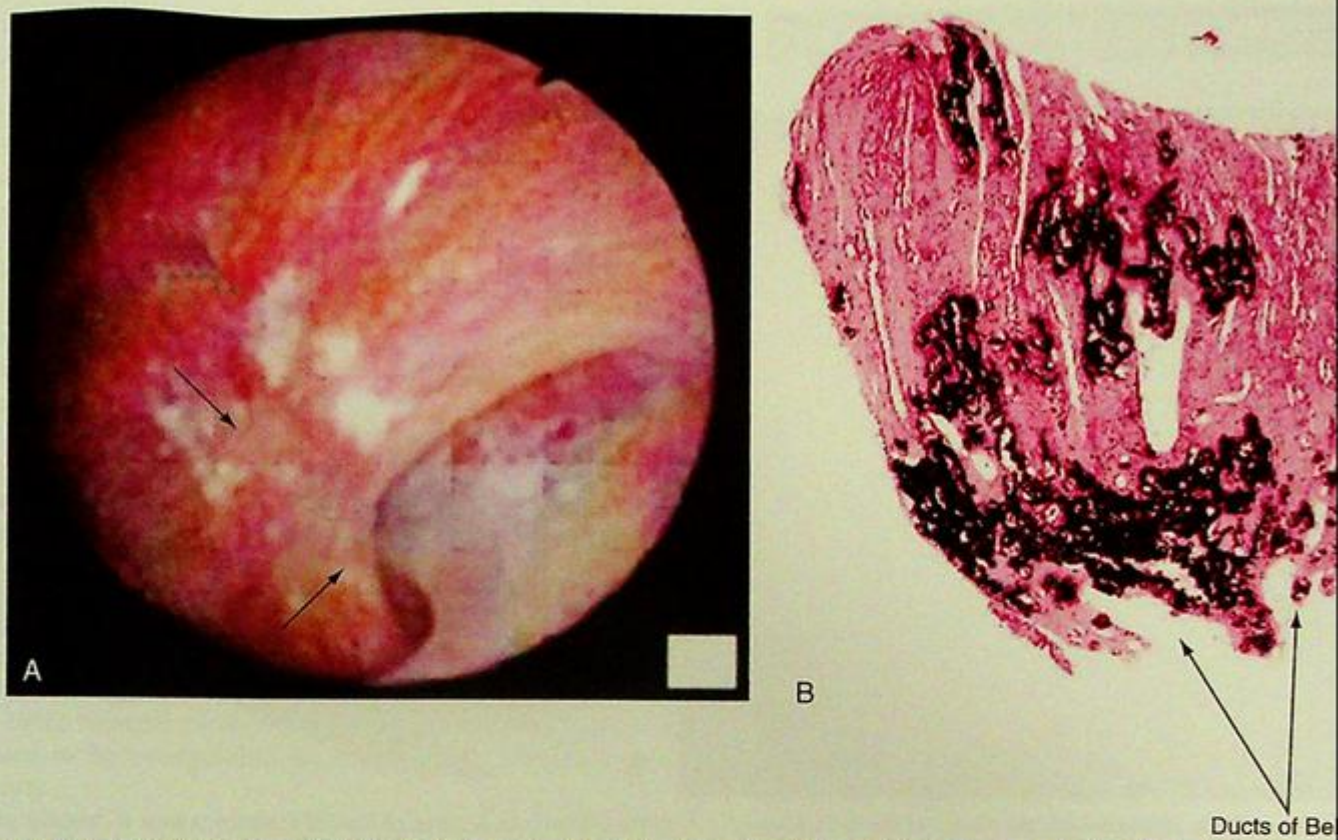

Figure 42–3. Endoscopic (**A**) and histologic (**B**) images of Randall's plaques in calcium oxalate patients. In **A**, sites of Randall's plaques as irregular white areas beneath the urothelium. In **B**, a low-magnification light-microscopic image of a papillary biopsy specimen is shown. deposits were stained black by the Yasue metal substitution method for calcium histochemistry. Figure 42–5. Endoscopic (**A**) and histologic (**B**) images of Randall's plaques in brushite patients. In **A**, sites of Randall's plaque appear as irregular white areas of crystalline deposit beneath the urothelium. In addition, a yellowish crystalline deposit is apparent at the opening of the ducts of Bellini. In **B**, a low-magnification light-microscopic image of a papillary biopsy specimen is shown. Sites of calcium deposits were stained black by the Yasue metal substitution method for calcium histochemistry. A large amount of Yasue-positive material is seen in the ducts of Bellini. (From Evan AP, et al: Kidney Int 2005;67:576-591.)

approximately 20% of the inhibitory activity of whole urine, with citrate comprising the most important factor of the three (Bisaz et al, 1978).

Citrate acts as an inhibitor of calcium oxalate and calcium phosphate stone formation by a variety of actions. First, it complexes with calcium, reducing the availability of ionic calcium to interact with oxalate or phosphate (Meyer et al, 1975; Pak et al, 1982). Second, it directly inhibits the spontaneous precipitation of calcium oxalate (Nicar et al, 1987) and prevents the agglomeration of calcium oxalate crystals (Kok et al, 1986). Although it has limited inhibitory effect on calcium oxalate crystal growth, it has more potent activity in reducing calcium phosphate growth (Meyer et al, 1975). Lastly, citrate prevents heterogeneous nucleation of calcium oxalate by monosodium urate (Pak and Peterson, 1986).

The inhibitory activity of magnesium is derived from its complexation with oxalate, which reduces ionic oxalate concentration and calcium oxalate supersaturation (Meyer et al, 1975). In addition, magnesium reduces the rate of calcium oxalate crystal growth in vitro (Desmars et al, 1973).

Polyanions, including glycosaminoglycans, acid mucopolysaccharides, and RNA have been shown to inhibit crystal nucleation and growth. Among the glycosaminoglycans, heparin sulfate interacts most strongly with calcium oxalate monohydrate crystals (Yamaguchi et al, 1993).

Two urinary glycoproteins, nephrocalcin and Tamm-Horsfall glycoprotein, are potent inhibitors of calcium oxalate monohydrate crystal aggregation (Nakagawa et al, 1987). Nephrocalcin is an acidic glycoprotein containing predominantly acidic amino acids that is synthesized in the proximal renal tubules and the thick ascending limb. In simple solution, nephrocalcin strongly inhibits the growth of calcium oxalate monohydrate crystals (Nakagawa et al, 1987). Nephrocalcin has been identified in four isoforms; non–stone formers excrete greater quantities of two isoforms associated with the most inhibitory activity, whereas stone formers excrete urine enriched for the two isoforms lacking inhibitory activity (Nakagawa, 1997). The isoforms with inhibitory activity were found to contain γ-carboxyglutamic acid residues that were lacking in the isoforms isolated from stone formers.

Tamm-Horsfall protein is expressed by renal epithelial cells in the thick ascending limb and the distal convoluted tubule as a membrane-anchored protein that is released into the urine after cleavage of the anchoring site by phospholipases or proteases. **Tamm-Horsfall is the most abundant protein found in the urine and a potent inhibitor of calcium oxalate monohydrate crystal aggregation, but not growth.** The role of Tamm-Horsfall as an inhibitor, promoter, or bystander is controversial and may depend on the state of the molecule itself, which can self-aggregate under certain conditions. A recent study using a Tamm-Horsfall (THP) knockout mouse model demonstrated spontaneous formation of calcium oxalate crystals in the kidneys of mice fed ethylene glycol and vitamin D, suggesting a protective role of Tamm-Horsfall protein against crystallization of calcium salts (Mo et al, 2004).

Osteopontin, or uropontin, is an acidic phosphorylated glycoprotein expressed in bone matrix and renal epithelial cells of the ascending limb of the loop of Henle and the distal tubule. **Osteopontin has been shown to inhibit nucleation, growth, and aggregation of calcium oxalate crystals as well as to reduce binding of crystals to renal epithelial cells in vitro** (Asplin et al, 1998; Wesson et al, 1998). In an osteopontin knockout mouse model, intratubular calcium oxalate crystals can be induced in mice exposed to high levels of oxalate by ethylene glycol feeding (Wesson et al, 2003). Interestingly, in a THP knockout mouse model, mice fed ethylene glycol and vitamin D exhibited a dramatic increase in osteopontin levels over baseline but still formed calcium oxalate crystals (Mo et al, 2004). The authors concluded that osteopontin may constitute an inducible inhibitor of calcium oxalate crystallization that works in conjunction with constitutively expressed Tamm-Horsfall protein to prevent crystallization.

Lastly, inter-α-trypsin is a glycoprotein synthesized in the liver that is composed of three polypeptides (two heavy chains and one light chain), of which bikunin comprises the light chain. Bikunin is a strong inhibitor of calcium oxalate crystallization, aggregation, and growth in vitro (Hochstrasser et al, 1984; Atmani et al, 1999), and its expression has been shown to be upregulated in a rat model when exposed to oxalate.

Matrix

Renal calculi consist of both crystalline and noncrystalline components. The noncrystalline component is termed *matrix*, which typically accounts for about 2.5% of the weight of the stone (Boyce and Garvey, 1956). In some cases, matrix comprises the majority of the stone (up to 65%), usually in association with chronic urinary tract infection (Boyce and Garvey, 1956; Allen and Spence, 1966). The exact composition of matrix is difficult to ascertain because only 25% of it is soluble (Ryall, 1993); however, chemical analysis reveals a heterogeneous mixture consisting of 65% protein, 9% non-amino sugars, 5% glucosamine, 10% bound water, and 12% organic ash (Boyce, 1968). Among the proteins incorporated into the matrix substance are Tamm-Horsfall protein, nephrocalcin, a γ-carboxyglutamic acid–rich protein, renal lithostathine, albumin, glycosaminoglycans, free carbohydrates, and a mucoprotein called matrix substance A (Hess et al, 1996). Boyce and associates (1962) found that substance A is immunologically unique and present in the matrix component of all stone formers. Moore and Gowland (1975) determined that substance A is composed of three or four distinct antigens unique to stones that were detected in the urine of 85% of stone formers but in no normal individuals. The exact role of matrix in stone formation, whether as a promoter, an inhibitor, or a passive bystander has yet to be elucidated.

KEY POINTS: PHYSICOCHEMISTRY
■ Urine must be supersaturated for stones to form.
■ Supersaturation alone is not sufficient for crystallization to occur in urine, owing to the presence of urinary inhibitors.
■ Nephrocalcin, uropontin, and Tamm-Horsfall protein are important inhibitors of crystal nucleation, growth, or aggregation.
■ Urinary calcium and oxalate are equal contributors to urinary saturation of calcium oxalate.
■ Calcium stones may originate from subepithelial plaques composed of calcium apatite that serve as an anchor on which calcium oxalate stones can grow.
■ The noncrystalline component of stones is matrix, which is composed of a combination of mucoproteins, proteins, carbohydrates, and urinary inhibitors.

MINERAL METABOLISM

Calcium

Thirty to 40 percent of dietary calcium is absorbed from the intestine, with most being absorbed in the small intestine and only approximately 10% absorbed in the colon (Bronner et al, 1999). By a process of intestinal adaptation, absorption of calcium varies with calcium intake. At times of low calcium intake, fractional calcium absorption is enhanced; during high calcium intake, fractional calcium absorption is reduced. With a calcium-rich diet, a nonsaturable, paracellular pathway for calcium absorption predominates. A saturable, vitamin D–dependent transcellular pathway constitutes the major pathway for intestinal calcium absorption when calcium intake is limited; this pathway is downregulated by a diet replete in calcium (Buckley et al, 1980; Bronner et al, 1986). Because of the saturable component of calcium transport, a larger portion of calcium is absorbed when it is divided into several doses taken hours apart compared with a large single dose (Phang et al, 1968). A small amount of calcium is secreted into the lumen of the intestine, thereby reducing net calcium absorption, such that, overall, 100 to 300 mg of a total average calcium intake of 600 to 1200 mg daily will be absorbed.

Calcium is absorbed in the ionic state, and incomplete calcium absorption is due in part to formation of soluble calcium complexes in the intestinal lumen. **As such, substances that complex calcium such as phosphate, citrate, oxalate, sulfate, and fatty acids reduce the availability of ionic calcium for absorption** (Allen, 1982). Calcium readily complexes with phosphate in the intestinal lumen, but because calcium phosphate formation is dependent on pH (pK = 6.1), high luminal pH favors calcium phosphate complexation, thereby reducing calcium availability. On the other hand, calcium oxalate complex formation displays less pH dependence and complex formation is less reversible. Consequently, an oxalate-rich diet reduces calcium absorption. Transcellular calcium absorption is mediated by $1,25(OH)_2D_3$ (calcitriol), which is reported to enhance calcium permeability at the brush border of the intestinal epithelial cells (Fontaine et al, 1981).

The active form of vitamin D, $1,25(OH)_2D_3$, is the most potent stimulator of intestinal calcium absorption. After

ate appropriate therapy. However, due to the multiple causes associated with calcium-based stones, an understanding of the underlying metabolic disorders and environmental factors that predispose to stone formation is required to implement a rational treatment plan (Wall et al, 1988; Wall and Tiselius, 1990). Recent investigation into the molecular and genetic causes of stone formation may ultimately translate into newer treatment strategies (Frick et al, 2003; Langman, 2004).

Calcium Stones

Hypercalciuria

Hypercalciuria is the most common abnormality identified in calcium stone formers (Pak et al, 1982; Coe et al, 1992; Bushinsky, 1998). However, the role of hypercalciuria in stone formation is controversial, owing to the overlap in urine calcium levels between stone formers and non–stone formers (Robertson and Morgan, 1972; Coe et al, 1992). There are several lines of evidence that support a pathogenetic role for hypercalciuria in stone formation. First, hypercalciuria is common in stone-forming patients, occurring in 35% to 65% of patients (Coe and Kavalach, 1974; Menon, 1986). Indeed, treatment strategies aimed at reducing urinary calcium levels are associated with a reduction in stone recurrence rates (Yendt and Cohanim, 1978), and medical therapy often fails in patients with persistent hypercalciuria (Strauss et al, 1982). Studies on genetic hypercalciuric stone-forming rats have suggested that hypercalciuria and subsequent calcium phosphate supersaturation play a critical role in stone formation (Bushinsky et al, 2000). Lastly, recent investigations of Randall's plaques as potential precursors to calcium stone formation have shown that plaques occur more commonly in stone formers and their number is directly correlated with urine calcium levels and number of stone episodes (Kuo et al, 2003a; Kim et al, 2005b).

High urinary calcium concentrations lead to increased urinary saturation of calcium salts (Pak et al, 1976b) and reduced urinary inhibitory activity by way of complexation with negatively charged inhibitors such as citrate and chondroitin sulfate (Zerwekh et al, 1988). The normal kidney filters approximately 270 mmol of calcium daily and reabsorbs all but 4 mmol (Bushinsky, 1998). However, a variety of conditions lead to elevated urinary calcium levels and increased urinary saturation of calcium salts. Criteria defining hypercalciuria are variable, but **the strictest definition classifies hypercalciuria as greater than 200 mg of urinary calcium/day after adherence to a 400-mg calcium, 100-mg sodium diet for 1 week** (Menon, 1986). **Parks and Coe** (1986) **defined hypercalciuria as excretion of calcium of greater than 4 mg/kg/day or greater than 7 mmol/day (men) or 6 mmol/day (women).**

Historically, the term *idiopathic hypercalciuria* was applied to stone formers for whom classification of their metabolic abnormality was difficult. Calcium transport is regulated at three sites: intestine, bone, and kidney. Dysregulation at any of these sites can lead to hypercalciuria. Furthermore, calcium transport pathways may be interrelated; studies in genetic hypercalciuric rats have demonstrated that hypercalciuria may involve the dysregulation of multiple calcium transport systems (Frick et al, 2003). In 1974, Pak and colleagues divided hypercalciuria into three distinct subtypes based on unique pathophysiologic abnormalities: absorptive hypercalciuria due to increased intestinal absorption of calcium, renal hypercalciuria due to primary renal leak of calcium, and resorptive hypercalciuria due to increased bone demineralization (Pak et al, 1974).

Although this classification system is still widely utilized due to its utility in simplifying the understanding and treatment of specific metabolic derangements, many have argued that hypercalciuria is associated with multiple, interrelated disturbances that cannot be readily separated into a specific organ system (Coe et al, 1992). Furthermore, studies into the molecular mechanisms of stone formation have identified gene mutations that can affect several organ systems, culminating in hypercalciuria (Frick et al, 2003; Langman, 2004). Improved understanding of the molecular and genetic causes of stone disease may well change the categorization and management of stones in the future.

Absorptive Hypercalciuria. Absorptive hypercalciuria (AH) is defined by increased urinary calcium excretion (>0.2 mg/mg creatinine) after an oral calcium load. Although fasting urinary calcium is usually normal in AH (<0.11 mg/dL glomerular filtration), severe forms of AH may occasionally be associated with fasting hypercalciuria as well. The underlying pathophysiologic abnormality in AH is increased intestinal absorption of calcium, which occurs in approximately 55% of stone formers (Menon, 1986). AH is classified as type I when urinary calcium remains high despite a low calcium diet (400 mg dietary calcium daily) and type II when urinary calcium normalizes with a restricted calcium intake. **The added systemic load of calcium due to intestinal calcium hyperabsorption results in a transient increase in serum calcium, which suppresses serum PTH and results in increased renal filtration of calcium, ultimately leading to hypercalciuria. Because the increase in intestinal absorption of calcium is matched by enhanced renal calcium excretion, serum calcium level remains normal.**

The cause of increased intestinal absorption of calcium has been variously ascribed to vitamin D–independent and dependent processes, as well as to upregulation of the vitamin D receptor (Breslau et al, 1992). However, no proposed mechanism completely accounts for all the findings associated with absorptive hypercalciuria, and there is no clear evidence that upregulation of intestinal calcium absorption is the primary cause. However, hypersensitivity to vitamin D has been shown to increase intestinal calcium absorption (Bushinsky and Monk, 1998). Moreover, several studies have linked hypercalciuria with the vitamin D receptor (VDR) gene. Jackman and coworkers (1999) identified a polymorphism in the VDR gene in 19 patients with a family history of nephrolithiasis and hypercalciuria, thereby establishing a potential link. Likewise, Scott and colleagues (1999) identified linkage between a microsatellite marker and the VDR locus on chromosome 12q12-14 in a cohort of 47 French Canadian pedigrees with idiopathic hypercalciuria and calcium nephrolithiasis.

Other studies, however, failed to confirm the association of VDR abnormalities with hypercalciuria (Zerwekh et al, 1995, 1998). Indeed, other genetic loci have been identified in association with AH. Reed and colleagues (1999, 2002) mapped the locus for an inherited form of AH to chromosome

1q23.3-q24 and found a putative gene (subsequently shown by others to be homologous with the rat soluble adenylate cyclase gene) in this region in 12 unrelated white AH patients.

Another proposed etiology of AH is renal phosphate wasting leading to a subsequent increase in active vitamin D. Patients with hereditary hypophosphatemic rickets with hypercalciuria (HHRH) manifest this abnormality (Tieder et al, 1987). These patients manifest decreased renal reabsorption of phosphate and a subsequent increase in vitamin D levels, leading to enhanced absorption of calcium in the intestine. The mutations associated with HHRH are thought to be inherited in an autosomal recessive pattern. Renal phosphate leak, however, is a rare cause of nephrolithiasis, affecting only at best 2% to 4% of patients (Levy et al, 1995).

Renal Hypercalciuria. The kidney filters approximately 270 mmol of calcium and must reabsorb more than 98% of it to maintain calcium homeostasis (Bushinsky, 1998). Approximately 70% of calcium reabsorption occurs in the proximal tubule, with paracellular pathways predominating (Frick et al, 2003). In renal hypercalciuria, impaired renal tubular reabsorption of calcium results in elevated urinary calcium levels leading to secondary hyperparathyroidism (Coe et al, 1973). Serum calcium level remains normal because the renal loss of calcium is compensated by enhanced intestinal absorption of calcium and bone resorption as a result of increased secretion of PTH and enhanced synthesis of $1,25(OH)_2D_3$. **High fasting urinary calcium levels (>0.11 mg/dL glomerular filtration) with a normal serum calcium value are characteristic of renal hypercalciuria.** The elevated fasting urinary calcium and serum PTH levels differentiate renal from absorptive hypercalciuria.

Several lines of evidence support the existence of primary renal calcium leak. First, a subset of patients with fasting hypercalciuria and elevated PTH levels show no improvement in urinary calcium levels with ingestion of sodium cellulose phosphate (which binds intraluminal cations, including calcium) despite reduced intestinal calcium absorption (Pak and Galosy, 1979). Second, patients with renal hypercalciuria and secondary elevation in serum PTH have an exaggerated response to hydrochlorothiazide (HCTZ), implying a renal tubular defect in solute reabsorption (Sakhaee et al, 1985). In addition, calcium excretion was higher at baseline and the calciuric response to an oral glucose load (100 g) was significantly higher 3 hours after glucose ingestion in patients with renal hypercalciuria compared with AH patients and normal subjects (Barilla et al, 1978b).

The actual cause of renal calcium leak is not known, although various theories have been proposed involving renal injury, structural abnormalities, and functional defects (Sutton et al, 1980; Yendt et al, 1981). Excessive dietary sodium intake may lead to changes similar to those seen in patients with renal hypercalciuria (Breslau et al, 1982). However, Pak found that restricting sodium alone does not correct biochemical changes seen in patients with renal hypercalciuria (Pak, 1990).

Another theory implicates urine prostaglandins in the pathogenesis of renal hypercalciuria. Patients with hyperprostaglandin E syndrome/antenatal Bartter's syndrome typically exhibit renal salt wasting, hypercalciuria, nephrocalcinosis, and secondary hyperaldosteronism (Nusing et al, 2001). Administration of the cyclooxygenase-2 specific inhibitor nimesulide to patients with hyperprostaglandin E syndrome/antenatal Bartter's syndrome was shown to block renal prostaglandin E_2 synthesis, thereby relieving the hyperprostaglandinuria and secondary hyperaldosteronism and correcting the hypercalciuria (Nusing et al, 2001). Other studies have also supported the association of prostaglandin elevation with hypercalciuria and shown correction of hypercalciuria with prostaglandin inhibitors (Buck et al, 1981; Houser et al, 1984; Hasanoglu et al, 1997). Baggio and associates (2000) noted that patients with nephrolithiasis had significantly higher levels of plasma phospholipid arachidonic acid content, prostaglandin E_2, vitamin D, and urinary calcium compared with controls. Institution of a 30-day fish oil diet resulted in a reduction in plasma phospholipid arachidonic acid levels, and, with the exception of serum 25-dihydroxyvitamin D_3 levels, baseline blood and urinary parameters normalized, as did intestinal calcium absorption. Calo and colleagues (1990) also found that HCTZ, which is typically used to treat renal hypercalciuria, promoted a significant decrease in urinary prostaglandin E_2 levels.

New insights into the abnormalities associated with renal hypercalciuria have come from studies of several genetic disorders. Dent's disease (X-linked recessive nephrolithiasis), characterized by hypercalciuria, proteinuria, nephrolithiasis, and nephrocalcinosis, and X-linked hypophosphatemic rickets/osteomalacia (XLR) are both linked to defects in the CLC-5 chloride channel (Pook et al, 1993; Fisher et al, 1994; Lloyd et al, 1996; Igarashi et al, 1998). The gene for CLC-5 is associated with nine known voltage-gated, transmembrane-spanning chloride channels found in renal tubule and bone cells that are associated with diverse cellular functions, such as transepithelial transport, intravesicular acidification, volume regulation, and transmembrane potential homeostasis (Gunther et al, 1998; Langman, 2004). Although the exact mechanism by which loss of CLC-5 chloride channels results in hypercalciuria is not understood, it may involve abnormal regulation of vitamin D and PTH (Frick et al, 2003; Langman, 2004). DNA screening analysis for common hot spots in the *CLCN5* gene is currently available commercially and may play a role in future genetic counseling if associated with one of the X-linked recessive disorders (Langman, 2004).

Bartter's syndrome is characterized by hypokalemic, hypochloremic metabolic alkalosis that arises from defects in one of three genes involving the thick ascending limb of the kidney: the Na^+-K^+-$2Cl^-$ gene *NKCC2*, the K^+ channel gene *ROMK*, or the chloride channel gene *CLCNKB*. Each of these mutations is associated with hypercalciuria and nephrolithiasis.

Resorptive Hypercalciuria. Resorptive hypercalciuria is an infrequent abnormality most commonly associated with primary hyperparathyroidism. Primary hyperparathyroidism is the cause of nephrolithiasis in about 5% of cases (Broadus, 1989). Excessive PTH secretion from a parathyroid adenoma leads to excessive bone resorption and increased renal synthesis of $1,25(OH)_2D_3$, which in turn enhances intestinal absorption of calcium; the net effect is elevated serum and urine calcium levels and reduced serum phosphorus levels. Although most patients with primary hyperparathyroidism demonstrate hypercalcemia and hypercalciuria, a normal

serum calcium level in the presence of an inappropriately high serum PTH value may be seen in some cases, making the diagnosis more difficult. Administration of a thiazide diuretic will enhance renal calcium reabsorption and exacerbate the hypercalcemia, thereby facilitating the diagnosis ("thiazide challenge") (Coffey et al, 1977). When diagnosing primary hyperparathyroidism, other causes of hypercalcemia should be excluded.

Primary hyperparathyroidism is associated with nephrolithiasis in less than 5% of affected individuals (Heath et al, 1980; Parks et al, 1980). However, the diagnosis should be suspected in patients with nephrolithiasis and serum calcium levels greater than 10.1 mg/dL (Broadus et al, 1980; Menon, 1986). Serum calcium levels can vary by up to 5%, and patients with mild hyperparathyroidism may exhibit relatively small increases of serum calcium (Yendt and Gagne, 1968). As such, repeated measurements of serum calcium may be necessary to make the diagnosis. Measurement of serum ionized calcium may help in equivocal cases, because it may be elevated in the setting of normal serum calcium (Yendt and Gagne, 1968). Urinary cyclic AMP levels have been used to diagnose primary hyperparathyroidism, because PTH promotes release of cyclic AMP from the kidney, leading to increased urinary cyclic AMP levels (Broadus et al, 1980). However, this test has been largely abandoned in favor of direct measurement of serum PTH. PTH also increases excretion of bicarbonate and phosphorus from the proximal renal tubule, resulting in phosphaturia and mild hyperchloremic acidosis. Aro and colleagues (1977) noted that a serum chloride:phosphate ratio greater than 33, along with a phosphate level below 2.5 mg/dL, should raise suspicion of hyperparathyroidism.

Sarcoid and Granulomatous Disease. Additional, rare causes of resorptive hypercalciuria include hypercalcemia of malignancy, sarcoidosis, thyrotoxicosis, and vitamin D toxicity. Many granulomatous diseases including tuberculosis, sarcoidosis, histoplasmosis, leprosy, and silicosis have been reported to produce hypercalcemia. Among these, sarcoidosis is most commonly associated with urolithiasis. **The sarcoid granuloma produces $1,25(OH)_2D_3$, causing increased intestinal absorption of calcium, hypercalcemia, and hypercalciuria** (Hendrix, 1966; Bell et al, 1979). Pulmonary alveolar cells and lymph node homogenates in patients with sarcoidosis are capable of synthesizing vitamin D, a function usually limited to the kidney. Most patients with sarcoidosis have a suppressed level of PTH secondary to hypercalcemia (Cushard et al, 1972). Sarcoidosis can also be differentiated from other diagnoses by the rapid resolution of hypercalcemia with initiation of corticosteroid therapy (Breslau et al, 1982).

Malignancy-Associated Hypercalcemia. **Whereas primary hyperparathyroidism is the most common cause of hypercalcemia in an outpatient setting, malignancy is the main cause of hypercalcemia in hospitalized patients** (Rizzoli and Bonjour, 1992). An assay for intact PTH can help distinguish patients with hyperparathyroidism from those with other causes of hypercalcemia (Table 42–3) (Burtis et al, 1990). Tumors in patients with humoral hypercalcemia produce a PTH-related protein (PTHrP) (Burtis et al, 1990). Lung and breast cancers account for about 60% of malignancy-associated hypercalcemia, whereas renal cell (10% to 15%), head and neck (10%), and hematologic cancers such as lymphoma and myeloma (10%) account for the rest. While direct mechanical destruction of bone constitutes one cause of hypercalcemia, many tumors secrete humoral factors, including PTHrP, transforming growth factor-α, and cytokines such as interleukin-1 and tumor necrosis factor, which activate osteoclasts and result in bone lysis and hypercalcemia (Burtis et al, 1990; Mundy, 1990; Edelson et al, 1995).

Glucocorticoid-Induced Hypercalcemia. Glucocorticoids can significantly alter calcium metabolism through their actions on bone, intestine, and parathyroid glands. Their most potent effect is related to calcium metabolism in bones, where

glucocorticoids promote bone resorption and reduce bone formation, ultimately leading to osteopenia with chronic use (Manelli and Giustina, 2000). Additionally, they stimulate release of PTH (Fucik et al, 1975). On the other hand, glucocorticoids inhibit intestinal absorption of calcium, which accounts for their effectiveness in preventing hypercalciuria induced by sarcoidosis (Manelli and Giustina, 2000). The net effect probably favors promotion of stone formation because nephrolithiasis is common in patients with Cushing's syndrome (Faggiano et al, 2003). In one study, stones were found in 50% of patients with active Cushing's syndrome, 27% of cured patients, and 6.5% of controls. Compared with controls, patients with active disease had a significantly higher prevalence of hypercalciuria, hypocitraturia, and hyperuricosuria, but these patients were also at greater risk of obesity and diabetes, which have been linked to stone formation (Faggiano et al, 2003).

Hyperoxaluria

Hyperoxaluria, defined as urinary oxalate greater than 40 mg/day, leads to increased urinary saturation of calcium oxalate and subsequent promotion of calcium oxalate stones. Additionally, oxalate has been implicated in crystal growth and retention by means of renal tubular cell injury mediated by lipid peroxidation and the generation of oxygen free radicals (Ravichandran and Selvam, 1990). Membrane injury facilitates the fixation of calcium oxalate crystals and subsequent crystal growth. Antioxidant therapy has been shown to prevent calcium oxalate precipitation in the rat kidney and to reduce oxalate excretion in stone patients (Selvam, 2002). Similarly, calcium oxalate crystal deposition on urothelium in vitro was prevented by free radical scavengers such as phytic acid and mannitol, purportedly by protecting the membrane from free radical–mediated damage (Thamilselvan and Selvam, 1997; Selvam, 2002). Recent human studies, however, failed to demonstrate increases in markers of oxidative stress or renal injury in normal subjects ingesting large doses of oxalate (up to 8 mmol), thus calling into question the importance of oxalate-induced cell membrane damage in calcium oxalate stone formation (Holmes and Assimos, 2004).

Causes of hyperoxaluria include disorders in biosynthetic pathways (primary hyperoxaluria); intestinal malabsorptive states associated with inflammatory bowel disease, celiac sprue, or intestinal resection (enteric hyperoxaluria); and excessive dietary intake or high substrate levels (vitamin C) (dietary hyperoxaluria).

Primary Hyperoxaluria. Primary hyperoxaluria is the result of a rare autosomal recessive disorder in glyoxylate metabolism by which the normal conversion of glyoxylate to glycine is prevented, leading to preferential oxidative conversion of glyoxylate to oxalate, an end product of metabolism (Fig. 42–6). Consequently, markedly high levels of urinary oxalate ensue (>100 mg/day), leading to increased saturation of calcium oxalate, aggressive stone formation, and marked nephrocalcinosis. The primary enzyme catalyzing glyoxylate conversion to glycine is alanine glyoxylate aminotransferase (AGT), which is synthesized in the liver. Mutations in this gene result in primary hyperoxaluria type 1. Elucidation of the

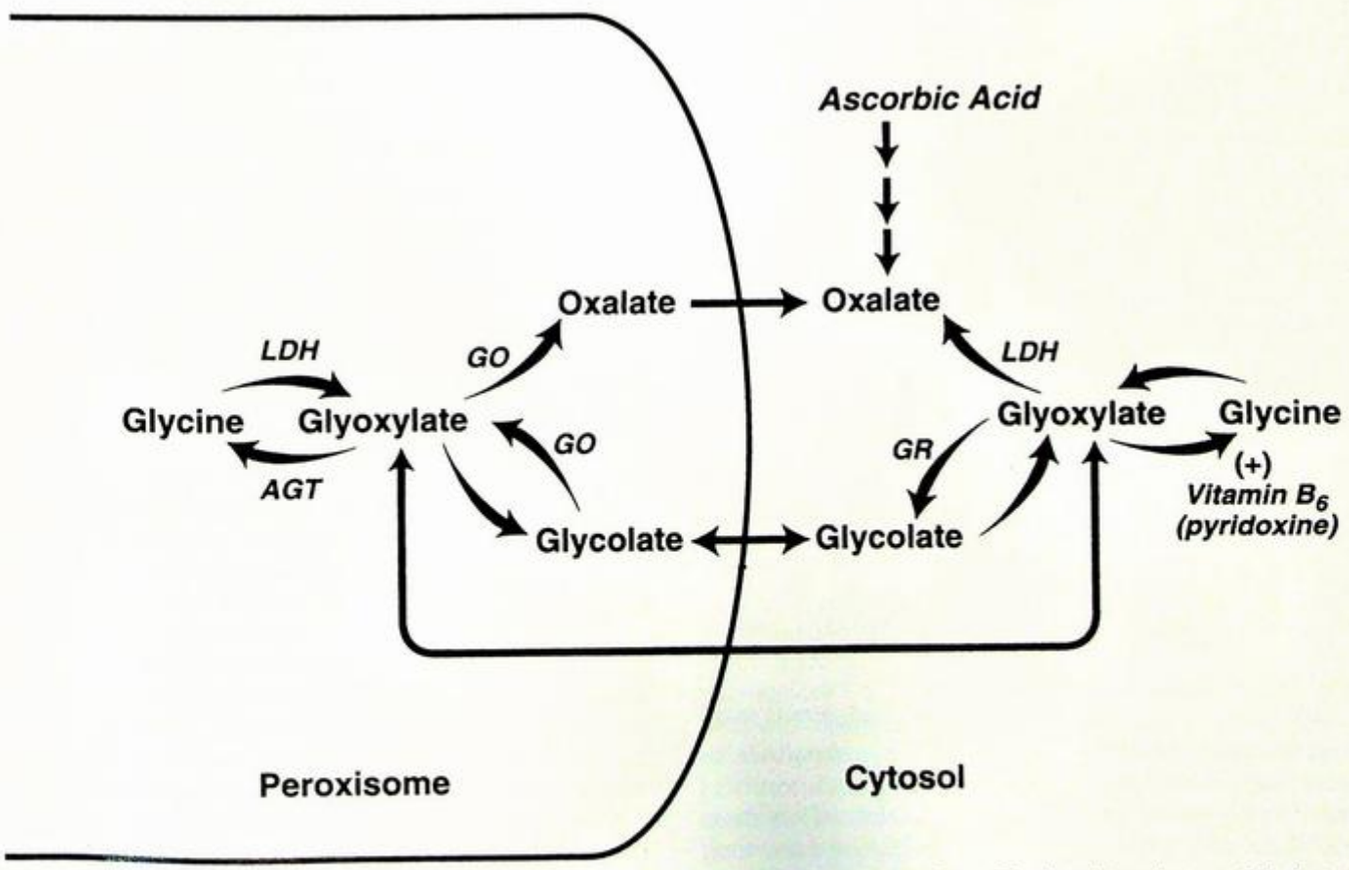

Figure 42–6. Pathway of oxalate metabolism. AGT, alanine:glyoxylate aminotransferase; GO, glycolate oxidase; GR, glyoxylate reductase; LDH, lactate dehydrogenase. (From Reed LA, Pearle MS, Pak CYC: Medical therapy—calcium oxalate-nephrolithiasis. Urol Clin North Am 1997;24:117-133.)

crystal structure of AGT to 2.5A° has improved our understanding of mutations of this protein (Zhang et al, 2003). The most common mutation of the AGT gene *(AGXT)* results in a substitution of glycine by arginine at position 170, which results in failure of the enzyme to dimerize, thereby causing the enzyme to inappropriately target the liver mitochondria rather than the liver peroxisomes (Danpure et al, 2003). In-vitro experiments have shown that by varying the temperature in the presence of glycerol, the enzyme can be induced to dimerize correctly, thus becoming completely functional (Lumb et al, 2003). Other mutations result in accelerated AGT proteolysis, intraperoxisomal aggregation, and loss of catalytic activity (Langman, 2004). Improved understanding of these mutations may allow for rational treatment strategies using small molecule chaperones or ribozyme-based therapeutics (Langman, 2004). Primary hyperoxaluria type 2 is associated with a mutation in glyoxylate reductase (*GRHPR* gene) in the liver, resulting in hyperoxaluric nephrolithiasis, but with a less aggressive course with regard to renal failure (Johnson et al, 2002).

If untreated, primary hyperoxaluria inevitably leads to end-stage renal failure, which occurs by age 15 in 50% of affected patients and is associated with an overall death rate of approximately 30% (Cochat et al, 1999). Because the liver is the only organ responsible for the detoxification of glyoxylate, combined liver-kidney transplant is accepted treatment for most patients with severe primary hyperoxaluria. Patient survival after transplantation approximates 80% at 5 years and 70% at 10 years. Furthermore, the renal function of survivors reportedly remains stable over time (Cochat et al, 1999; Hoppe and Langman, 2003).

Enteric Hyperoxaluria. The most common cause of acquired hyperoxaluria is enteric hyperoxaluria. This abnormality is associated with chronic diarrheal states, by which **fat malabsorption results in saponification of fatty acids with divalent cations such as calcium and magnesium, thereby reducing calcium oxalate complexation and increasing the pool of available oxalate for reabsorption** (Earnest et al, 1975). The poorly absorbed fatty acids and bile salts may increase colonic permeability to oxalate, further enhancing intestinal oxalate absorption (Dobbins et al, 1976). There is a strong relationship between fecal fat and urinary oxalate excretion, which has been demonstrated in patients with steatorrhea (Fig. 42–7) (Andersson, 1974; Dobbins et al, 1977; McDonald et al, 1977; Stauffer, 1977; Modigliani et al, 1978). Dehydration, hypokalemia, hypomagnesuria, hypocitraturia, and low urine pH also increase the risk of calcium oxalate stone formation in patients with chronic diarrheal syndrome. Malabsorption of any cause can lead to increased intestinal absorption of oxalate. As such, small bowel resection (Smith et al, 1972), intrinsic disease, and jejunoileal bypass (Cryer et al, 1975) have all been associated with hyperoxaluria.

Dietary Hyperoxaluria. Overindulgence in oxalate-rich foods such as nuts, chocolate, brewed tea, spinach, broccoli, strawberries, and rhubarb can result in hyperoxaluria in otherwise normal patients. Increased animal protein can also increase urinary levels of calcium and oxalate (Robertson et al, 1979). In addition, severe calcium restriction may result in reduced intestinal binding of oxalate and increased intestinal oxalate absorption. Ascorbic acid supplementation has been shown to increase urinary oxalate levels by in vivo conversion to oxalate (Traxer et al, 2003), although increased clinical rates of stone formation have not been unequivocally linked to ascorbic acid use (Curhan et al, 1996, 1999).

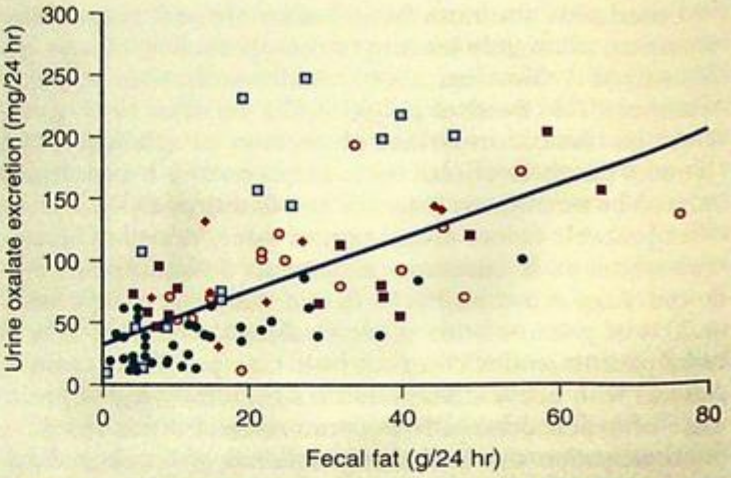

Figure 42–7. The relationship between fecal fat and urinary oxalate excretion in patients with steatorrhea. Diet oxalate was 300-500 mg/day in all but one study in which it was 55-90 mg/day; diet calcium 500-900 mg/day in all studies when reported. Normal urine citrate was less than 50 mg/day in all studies, except one in which it was <34 mg/day. Oxalate = 2.1 × fecal fat + 30.7 ($r^2 = 0.4$, n = 96, $P < .001$). (From Worcester EM: Stones due to bowel disease. In Coe F, Favus M, Pak C, et al [eds]: Kidney Stones: Medical and Surgical Management. New York, Lippincott-Raven, 1996, pp 883-903.)

Recent studies have also implicated *Oxalobacter formigenes*, an oxalate-degrading intestinal bacterium, as a potential modulator of intestinal oxalate levels and decreased oxalate absorption in some stone formers (Duncan et al, 2002). Several studies have linked the absence of *Oxalobacter formigenes* with increased stone formation (Sidhu et al, 2001; Mikami et al, 2003) and increased oxalate excretion in stone formers (Troxel et al, 2003).

Idiopathic Hyperoxaluria. Several studies have suggested that mild hyperoxaluria is as important a factor as hypercalciuria in the pathogenesis of idiopathic calcium oxalate stones (Menon, 1986; Robertson et al, 1993). In some populations such as those inhabiting the Arabian Peninsula, the prevalence of calcium-containing stones is considerably higher than in the West despite the almost complete absence of hypercalciuria (Robertson and Hughes, 1993). Hyperoxaluria is implicated as the predominant risk factor in this population.

Abnormalities in the metabolism and transport of oxalate may contribute to calcium oxalate nephrolithiasis. Baggio and associates (1986) detected a higher rate of oxalate flux across the red blood cell membrane at steady state in 114 patients with a history of calcium oxalate kidney stones compared with control subjects. Treatment with oral HCTZ (50 mg/day), amiloride (5 mg/ day), or both restored normal or nearly normal red blood cell oxalate exchange in all of the patients who initially demonstrated increased rates. Up to 50% of the time, however, the abnormality in red blood cell oxalate transport is not associated with hyperoxaluria. Furthermore, Motola and colleagues found high rates of oxalate flux in non–calcium oxalate stone formers as well, thus leading some to question the importance of this mechanism in calcium oxalate stone formation (Motola et al, 1992).

Hyperuricosuria

Hyperuricosuria is defined by urinary uric acid exceeding 600 mg/day. Up to 10% of calcium stone formers have high urinary uric acid levels as the only abnormality (Menon, 1986). Hyperuricosuria increases urinary levels of monosodium urate, which in turn promotes calcium oxalate stone formation. At pH less than 5.5, the undissociated form of uric acid predominates, leading to uric acid and/or calcium oxalate stone formation. **At pH greater than 5.5, sodium urate formation promotes calcium oxalate stone formation through heterologous nucleation** (Grover et al, 1994). Uric acid may reduce the effectiveness of naturally occurring inhibitors of crystallization (Robertson et al, 1976); **uric acid crystals can bind urinary glycosaminoglycans such as heparin that inhibit crystallization of calcium oxalate** (Finlayson et al, 1978a; Grover et al, 1994). Several studies have shown that patients with hyperuricosuria and calcium stones have higher rates of stone formation and more severe symptoms than those stone formers with normouricosuria (Coe and Kavalach, 1974; Favus et al, 1980; Fellstrom et al, 1982).

The most common cause of hyperuricosuria is increased dietary purine intake. However, acquired and hereditary diseases may also be accompanied by hyperuricosuria, including gout, myeloproliferative and lymphoproliferative disorders, multiple myeloma, secondary polycythemia, pernicious anemia, hemolytic disorders, hemoglobinopathies and thalassemia, complete or partial hypoxanthine-guanine phosphoribosyltransferase deficiency, superactivity of phosphoribosylpyrophosphate synthetase, and hereditary renal hypouricemia (Halabe and Sperling, 1994). The recent identification of a urate transporter in the proximal tubule, the anion exchanger URAT1, may provide new insight into the causes of hyperuricosuria (Enomoto et al, 2002; Ichida et al, 2004). Mutations in the gene coding for URAT1, *SLC22A12*, have been shown to cause hyperuricosuric hypouricemia, or renal uric acid leak (Enomoto et al, 2002; Ichida et al, 2004; Iwai et al, 2004).

Another potential gene abnormality, characterized by an increased prevalence of uric acid stones, has been identified in a small, isolated founder population in Sardinia. A susceptibility locus was identified on chromosome 10q21-q22 that codes for a protein with unknown function but that has a strong association with uric acid stones (Ombra et al, 2001; Gianfrancesco et al, 2003).

Hypocitraturia

Hypocitraturia is an important and correctable abnormality associated with nephrolithiasis that exists as an isolated abnormality in up to 10% of calcium stone formers and is associated with other abnormalities in 20% to 60% (Menon and Mahle, 1983; Pak and Fuller, 1986; Pak, 1994; Pak et al, 1985; Levy et al, 1995). Citrate is an important inhibitor that can reduce calcium stone formation by several mechanisms. First, citrate reduces urinary saturation of calcium salts by complexing with calcium (Pak et al, 1982). Second, citrate directly prevents spontaneous nucleation of calcium oxalate (Sakhaee et al, 1987). Third, citrate inhibits agglomeration and sedimentation of calcium oxalate crystals (Kok et al, 1986; Tiselius et al, 1993a, 1993b) as well as the growth of calcium oxalate and calcium phosphate crystals (Meyer and Smith, 1975). Finally, normal urinary citrate levels can enhance the inhibitory effect of Tamm-Horsfall glycoprotein (Hess et al, 1993).

Hypocitraturia is defined as a urinary citrate level less than 320 mg/day (Pak, 1987) or less than 0.6 mmol (men) or 1.03 mmol (women) daily (Menon and Mahle, 1983). **Acid-base state is the primary determinant of urinary citrate excretion. Metabolic acidosis reduces urinary citrate levels secondary to enhanced renal tubular reabsorption and decreased synthesis of citrate in peritubular cells** (Jenkins et al, 1985). A study comparing normal subjects and stone formers noted comparable mean serum citrate levels and filtered citrate loads in the two groups; however, 24-hour urinary citrate and fasting citrate:creatinine ratio were significantly reduced and mean tubular reabsorption of citrate was significantly increased in the stone formers compared with control subjects (Minisola et al, 1989).

Indirect evidence for a primarily renal etiology of hypocitraturia comes from a study comparing intestinal absorption of citrate in idiopathic hypocitraturic stone formers and normal subjects (Fegan et al, 1992). Oral ingestion of citrate was followed by rapid and efficient absorption in both groups, with 96% to 98% absorbed within 3 hours. As such, hypocitraturia is unlikely to arise from impaired gastrointestinal absorption of citrate in stone formers without overt bowel disease.

Low urinary citrate results from a variety of pathologic states associated with acidosis. Distal renal tubular acidosis (RTA) is characterized by high urine pH (>6.8), high serum chloride, and low serum bicarbonate and potassium (Preminger et al, 1985). The inability to acidify urine in response to an oral acid (ammonium chloride) load confirms the diagnosis of RTA. Chronic diarrheal states cause intestinal alkali loss in the stool with subsequent systemic acidosis and hypocitraturia (Rudman et al, 1980). Excessive animal protein can provide an acid load, reducing citrate levels (Breslau et al, 1988). Indeed, a recent metabolic study evaluating the effect of a high protein, low carbohydrate diet demonstrated a significant reduction in urinary citrate and pH, likely as a result of low citrus and high animal protein intake (Reddy et al, 2002). Diuretics such as thiazides induce hypokalemia and intracellular acidosis (Nicar et al, 1984). Enalapril can cause hypocitraturia independently of systemic acidosis or hypokalemia perhaps due to intracellular acidosis (Melnick et al, 1998). Finally, strenuous exercise may induce lactic acidosis (Sakhaee et al, 1987). However, hypocitraturia may also represent an isolated abnormality unrelated to an acidotic state.

Citrate levels in the urine increase in alkalotic states, as well as with elevated levels of PTH, estrogen, growth hormone, and vitamin D.

Low Urine pH

At low urine pH (<5.5), the undissociated form of uric acid predominates, leading to uric acid and/or calcium stone formation. Calcium oxalate stones form as a result of heterologous nucleation with uric acid crystals (Coe and Kavalach, 1974; Pak et al, 1976a). Any disorder leading to low urine pH may predispose to stone formation. Chronic metabolic

acidosis can lead to low urine pH, hypercalciuria, and hypocitraturia. Acidosis increases bone resorption and produces renal calcium leak (Lemann, 1999; Lemann et al, 2003). "Gouty diathesis" refers to a stone-forming propensity characterized by low urine pH of unknown etiology with or without associated gouty arthritis (Levy et al, 1995).

Renal Tubular Acidosis

RTA is a clinical syndrome characterized by metabolic acidosis resulting from defects in renal tubular hydrogen ion secretion and urinary acidification. There are three types of RTA: 1, 2, and 4. Type 1 (distal) RTA is of particular significance to urologists not only because it is the most common form of RTA but also because it is the form of RTA most frequently associated with stone formation, which occurs in up to 70% of affected individuals (Van den Berg et al, 1983; Caruana et al, 1988). Indeed, symptoms associated with nephrolithiasis lead to the initial diagnosis of RTA in upward of 50% of cases (Van den Berg et al, 1983).

Acid-base balance is maintained by the kidney through several mechanisms involving both the proximal and distal nephron. Because bicarbonate is freely filtered at the glomerulus, the **kidney must reabsorb or regenerate nearly all of the filtered bicarbonate each day** (approximately 4500 mmol) to maintain its buffering capacity (Pohlman et al, 1984). **Furthermore, the kidney must excrete excess acid,** which accumulates from the breakdown of carbohydrates, fats, and proteins and as a result of bicarbonate loss in the stool (Kinkead et al, 1995). A defect in either bicarbonate reabsorption or acid excretion will lead to metabolic acidosis.

Filtered bicarbonate (HCO_3^-) is almost completely reabsorbed in the proximal renal tubule through an indirect mechanism (Laing et al, 2005). As sodium (Na^+) is pumped out of the proximal tubule cell by the Na^+/K^+-ATPase exchanger located in the basolateral membrane, intracellular sodium decreases, driving the Na^+/H^+ exchanger in the apical membrane. Carbonic anhydrase in the tubular cells generates H^+ and HCO_3^-, thereby providing H^+ ions that are secreted into the tubular lumen. HCO_3^- is then transferred via a basolateral Na^+/HCO_3^- co-transporter (Unwin et al, 2002). **The proximal nephron is a high-capacity, low-gradient transport system that allows reabsorption of filtered HCO_3^- without causing net H^+ secretion or significant changes in urinary pH** (Rocher and Tannen, 1986; Kinkead et al, 1995).

In the distal nephron, 10% to 20% of the filtered bicarbonate is reabsorbed in a similar manner as in the proximal nephron. Net elimination of H^+ occurs through several mechanisms. **Hydrogen binds with urinary buffers such as phosphate and ammonia, allowing net elimination of hydrogen in the form of NH_4^+. Net H^+ excretion occurs through active secretion from α-intercalated cells.** These cells secrete H^+ using an H^+ ATPase and an H^+/K^+ ATPase exchanger (Laing et al, 2005). The intercalated cells also have a Cl^-/HCO_3^- anion exchanger that transports HCO_3^- into the blood and is homologous to the red cell anion exchanger known as "band 3" (eAE1) (Alper, 1991; Shayakul et al, 2004a, 2004b). **These active pumps generate a 1000:1 hydrogen ion gradient between the cell and the tubular lumen, allowing reduction of urine pH to as low as 4.5** (Kinkead et al, 1995). Another contributing factor is the lack of luminal carbonic anhydrase that prevents the rapid dissociation of carbonic acid catalyzed by the enzyme.

RTA occurs as a result of impairment of net excretion of acid into the urine (type 1) or of reabsorption of bicarbonate (type 2) (Kinkead et al, 1995). Distinction between these abnormalities provides the means for classification of RTA into proximal or distal, although both share the characteristic findings of hyperchloremic metabolic acidosis associated with inappropriately high urinary pH.

Type 1 (Distal) RTA. Type 1 RTA comprises a syndrome of abnormal collecting duct function characterized by inability to acidify the urine in the presence of systemic acidosis. The classic findings include hypokalemic, hyperchloremic, non–anion gap metabolic acidosis along with nephrolithiasis, nephrocalcinosis, and elevated urine pH (>6.0) (Pohlman et al, 1984). Patients with incomplete RTA have normal serum electrolytes but demonstrate defective renal acid excretion manifest as failure to lower urine pH below 5.5 after an acid load (Osther et al, 1989).

Patients with distal RTA commonly present as adults with symptoms of nephrolithiasis (Caruana et al, 1988). However, children comprise a third of affected individuals, and they often present with vomiting or diarrhea, failure to thrive, or growth retardation. The most common type of stone associated with distal RTA is calcium phosphate as a result of **hypercalciuria, hypocitraturia, and increased urinary pH** (Fig. 42–8) (Van den Berg et al, 1983; Pohlman et al, 1984). The metabolic acidosis promotes bone demineralization, which leads to secondary hyperparathyroidism and hypercalciuria. **Profound hypocitraturia, perhaps the most important factor in stone formation, is due to impaired citrate excretion as a result of metabolic acidosis,** but may also be related to abnormal renal tubular citrate transport or migration of citrate into the mitochondria due to intracellular acidosis (Kinkead et al, 1995; Osther et al, 1989).

Type 1 RTA is a heterogeneous disorder that may be hereditary, idiopathic, or acquired. Most cases of distal RTA are sporadic, but both autosomal dominant (AD) and autosomal recessive (AR) genetic defects have been identified. Most mutations associated with distal RTA occur in either the Cl^-/HCO_3^- anion exchanger (*SLC4A1* gene) or the H^+ ATPase (gene *ATP6V0A4*) (Laing et al, 2005). RTA is endemic in Southeast Asia, where it has been associated with sudden unexplained nocturnal death, hypokalemic periodic paralysis, and renal stones (Nimmannit et al, 1991, 1996). RTA in this population was found to be associated with *SLC4A1* AR mutations (Sritippayawan et al, 2004).

The molecular defects associated with distal RTA include abnormalities in the H^+ ATPase that are responsible for excretion of excess acid into the distal tubule (Karet et al, 1999). Early childhood features of autosomal recessive distal RTA include severe metabolic acidosis with inappropriately alkaline urine, poor growth, rickets, and renal calcification. Secondary distal RTA in sporadic cases is commonly associated with autoimmune diseases, such as Sjögren's syndrome and systemic lupus erythematosus, and it occurs more frequently in women than men (Buckalew, 1989). Secondary RTA is also associated with obstructive uropathy, pyelonephritis, acute tubular necrosis, hyperparathyroidism, and idiopathic hypercalciuria.

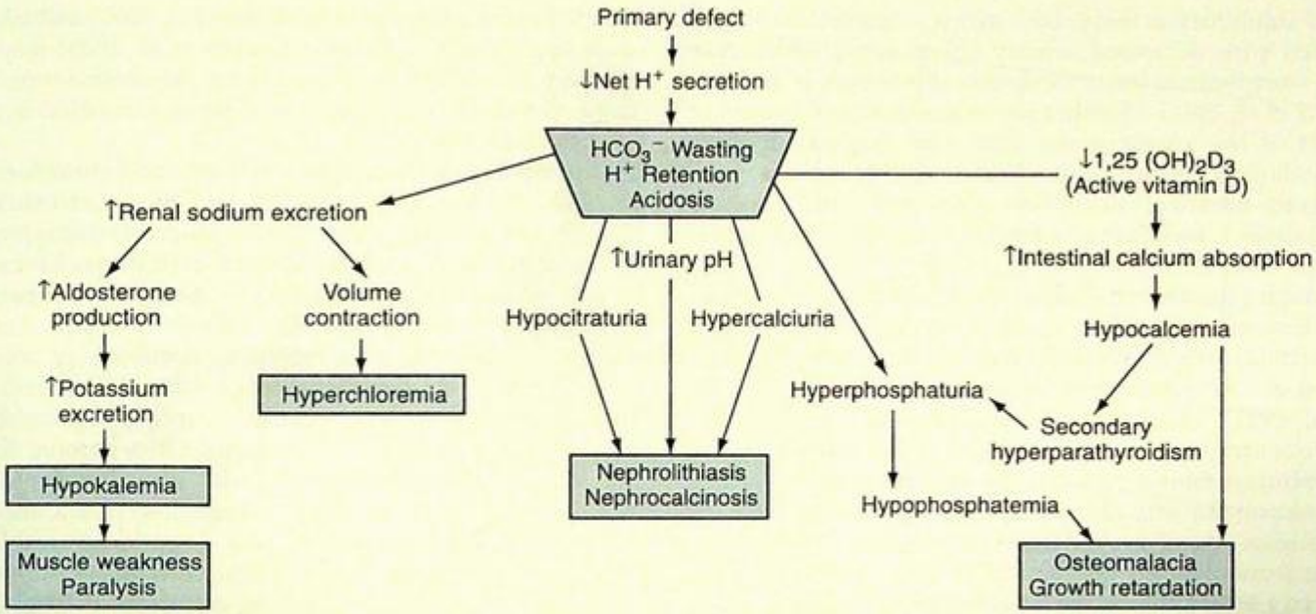

Figure 42–8. Pathophysiologic mechanisms for clinical features seen in type 1 (distal) renal tubular acidosis. Primary defects in renal acid excretion lead directly and through hormonally mediated pathways to metabolic abnormalities that produce the clinical syndromes seen in renal tubular acidosis. (From Kinkead TM, Menon M: Renal tubular acidosis. AUA Update 1995;14:54.)

Type 2 (Proximal) RTA. Proximal RTA is characterized by a defect in HCO_3^- reabsorption associated with initial high urine pH that normalizes as plasma HCO_3^- decreases and the amount of filtered HCO_3^- falls (Laing et al, 2005). Initially, when serum HCO_3^- levels are normal, more than 15% of filtered HCO_3^- is lost. This syndrome is usually associated with generalized defects in proximal tubule function similar to Fanconi's syndrome, with loss of glycogen, protein, uric acid, and phosphate (Rocher and Tannen, 1986). **Nephrolithiasis is uncommon in this disorder owing to relatively normal urinary citrate excretion** (Laing et al, 2005). The clinical manifestations of proximal RTA include growth retardation and hypokalemia in children due to metabolic acidosis. Metabolic bone disease is seen more frequently with proximal RTA due to associated abnormalities in vitamin D metabolism and hypophosphatemia (Kinkead et al, 1995).

Most cases of proximal RTA are sporadic, but inherited diseases associated with proximal RTA have been described. In humans and terrestrial vertebrates, the kidneys control systemic pH in part by absorbing filtered HCO_3^- in the proximal tubule via an electrogenic Na^+/HCO_3^- co-transporter (NBCe1/SLC4A4). Homozygous point mutations in NBCe1 cause proximal renal tubular acidosis (pRTA), glaucoma, and cataracts (Igarashi et al, 1999). Other mutations in this gene have been identified that cause voltage- and Na^+-dependent transport reabnormalities, thereby causing both insufficient HCO_3^- reabsorption by the kidney (proximal RTA) and inappropriate anterior chamber fluid transport (glaucoma) (Dinour et al, 2004).

Carbonic anhydrase II catalyzes the hydration/dehydration of CO_2 and H_2CO_3 and is expressed in the renal proximal tubule, loop of Henle, and intercalating cells of the collecting duct as well as in brain glial cells and bone osteoclasts (Laing et al, 2005). Deficiency of carbonic anhydrase II (carbonate hydrolyase, EC 4.2.1.1) is the primary defect in the syndrome of osteopetrosis, proximal renal tubular acidosis, and cerebral calcification. Fortunately, this is a rare abnormality (Sly et al, 1985; Roth et al, 1992).

Type 4 (Distal) RTA. Type 4 RTA is associated with chronic renal damage, usually seen in patients with interstitial renal disease and diabetic nephropathy. Reduction in glomerular filtration results in hyperkalemic, hyperchloremic metabolic acidosis due to loss of HCO_3^- in the urine and decreased excretion of ammonium (Pohlman et al, 1984). Aldosterone resistance is commonly associated with type 4 RTA (Davidman et al, 1988). Because aldosterone contributes to stimulation of distal acidification and H^+/K^+ exchange, aldosterone resistance results in decreased ammonia generation and further exacerbates hyperkalemia (Davidman et al, 1988). Patients with type 4 RTA can still generate acidic urine in response to an acid challenge.

Renal stone formation is uncommon in patients with type 4 RTA. A study comparing patients with type 4 RTA and matched subjects with a similar degree of renal impairment found that patients with type 4 RTA had significantly lower urinary pH and decreased urinary calcium excretion compared with controls (Uribarri et al, 1994). **The protection against renal stone formation in these patients may be attributed to reduced renal excretion of stone-forming substances, such as calcium and uric acid, owing to impaired renal function.**

Hypomagnesuria

Hypomagnesuria is a rare cause of nephrolithiasis, affecting less than 1% of stone formers as an isolated abnormality, although it can be found in conjunction with other abnormalities in 6% to 11% of cases (Levy et al, 1995; Schwartz et al, 2001). Magnesium complexes with oxalate and calcium salts, and therefore such low magnesium levels result in

reduced inhibitory activity. Low urinary magnesium is also associated with decreased urinary citrate levels, which may further contribute to stone formation (Preminger et al, 1989; Schwartz et al, 2001). Whether low magnesium is the cause or an effect of low citrate is not clear. Low magnesium levels occur with poor dietary intake (Pfab et al, 1985) or as a result of reduced intestinal absorption associated with intestinal abnormalities producing chronic diarrheal syndrome (Rudman et al, 1980).

Although a number of studies in rats have implicated hypomagnesuria as a factor in stone formation (Rushton and Spector, 1982), others (Faragalla et al, 1963; Borden et al, 1969; Rattan et al, 1993) have questioned the impact of magnesium (Su et al, 1991). Clinical studies regarding the role of magnesium are contradictory. Schwartz and colleagues (2001) found that hypomagnesiuric patients had higher stone recurrence rates than patients with normal urinary magnesium. However, other studies found no difference in magnesium excretion between stone patients and controls (Johansson et al, 1980; Esen et al, 1991). Of note, the lack of difference in mean magnesium levels may be a result of the small fraction of stone formers with low urinary magnesium levels.

Although magnesium has been shown to increase urinary pH, citrate, and magnesium and therefore to decrease urinary saturation of calcium oxalate in vitro (Khan et al, 1993) and in vivo (Curhan et al, 2001), two randomized trials comparing magnesium oxide with placebo or no treatment in stone formers have failed to demonstrate clinical benefit (Wilson et al, 1984; Ettinger et al, 1988).

Uric Acid Stones

All mammals, except humans and Dalmatians, synthesize the enzyme uricase, which catalyzes the conversion of uric acid to allantoin, the end product of purine metabolism (Yu, 1981; Bannasch et al, 2004). Consequently, humans accumulate significantly higher levels of uric acid in their blood and urine (Watts, 1976; Yu, 1981). Because allantoin is 10 to 100 times more soluble in urine than uric acid, humans are prone to uric acid stone formation.

Uric acid is a weak acid with a pKa of 5.35 at 37°C. At that pH, half of the uric acid is present as the urate salt and half as free uric acid. Because sodium urate is approximately 20 times more soluble than the free acid, the relative proportion present as free uric acid strongly determines the risk of stone formation. **Urine pH is a critical factor in determining uric acid solubility;** at pH 5, even modest amounts of uric acid exceed uric acid solubility, whereas at pH 6.5, concentrations of uric acid exceeding 1200 mg/L remain soluble (Fig. 42–9) (Asplin, 1996). Because daily uric acid excretion averages 500 to 600 mg/L, urine may reach supersaturation at pH less than 6. Consequently, low urine pH increases concentrations of sparingly soluble undissociated uric acid, which leads to direct precipitation of uric acid. Of note, uric acid and sodium urate can also serve as a nidus for calcium oxalate stones through heterologous nucleation, and, thus, low urine pH is a risk factor for both uric acid and calcium oxalate stones (Coe and Kavalach, 1974; Levy et al, 1995).

The process of uric acid stone formation once uric acid crystals precipitate has not been fully elucidated. Although some investigators have suggested that uric acid crystal adhesion to kidney epithelial cells (Koka et al, 2000) and inhibitors such as glycosaminoglycans (Ombra et al, 2003) may play a role in uric acid stone formation, the involvement or importance of these factors in uric acid stone formation is unclear (Pak et al, 1976a).

The three main determinants of uric acid stone formation are low pH, low urine volume, and hyperuricosuria (Fig. 42–10). **The most important pathogenetic factor is low urine pH, because most patients with uric acid stones have normal uric acid excretion but invariably demonstrate persistent low urine pH** (Pak et al, 1985, 2003a). Uric acid stones can develop as a result of congenital, acquired, or idiopathic causes. Congenital disorders associated with uric acid stones involve renal tubular urate transport or uric acid metabolism. Acquired causes of uric acid stones, such as chronic diarrhea, volume depletion, myeloproliferative disorders, high animal protein intake, and uricosuric drugs, may affect any of the three factors determining uric acid stone formation. Patients with "gouty diathesis" or idiopathic low urine pH typically demonstrate decreased fractional excretion of urate and do not have gout (Maalouf et al, 2004a). Patients with gouty diathesis differ from those with hyperuricosuric calcium nephrolithiasis in that the former generally have normal urinary uric acid levels and acidic urine, whereas the latter have hyperuricosuria and normal urine pH. Patients with hyperuricosuria frequently have high urinary sodium and calcium levels leading to increased urinary saturation of sodium urate and calcium oxalate, placing them at risk for calcium oxalate stones (Sorensen and Chandhoke, 2002). Most patients with uric acid stones, however, have normal urinary uric acid levels and low urinary pH (Pak et al, 2003a).

Pathogenesis of Low Urine pH

Although the pathogenesis of low urine pH in idiopathic uric acid stone formers is not known with certainty and may be multifactorial, several potential mechanisms have been proposed. Sakhaee and colleagues (2002) first observed that normouricosuric individuals with pure uric acid stones were more likely to have diabetes mellitus or to demonstrate glucose intolerance than normal individuals or those with mixed uric acid/calcium oxalate or pure calcium oxalate stones. Furthermore, when a group of normouricosuric uric acid stone formers were placed on a controlled metabolic diet, their urinary pH was lower than that of either normal volunteers or other stone formers (mixed uric acid/calcium oxalate or calcium oxalate). Further investigation revealed that the uric acid stone formers excreted less acid into the urine as ammonium and proportionately more titratable acid and less citrate in order to maintain normal overall acid-base balance. This apparent impairment in ammonium excretion in uric acid stone formers has been putatively linked to an insulin-resistant state.

Supporting this hypothesis, Pak and colleagues (2003b) noted a higher prevalence of uric acid stones and low urinary pH among patients with non–insulin-dependent diabetes (34%) than among nondiabetic stone formers. Furthermore, uric acid stone formers have been found to share many of the characteristic features of the metabolic syndrome (a condition defined by insulin resistance), including hypertriglyceridemia, hyperglycemia, obesity, and hypertension (Sakhaee et al, 2002;

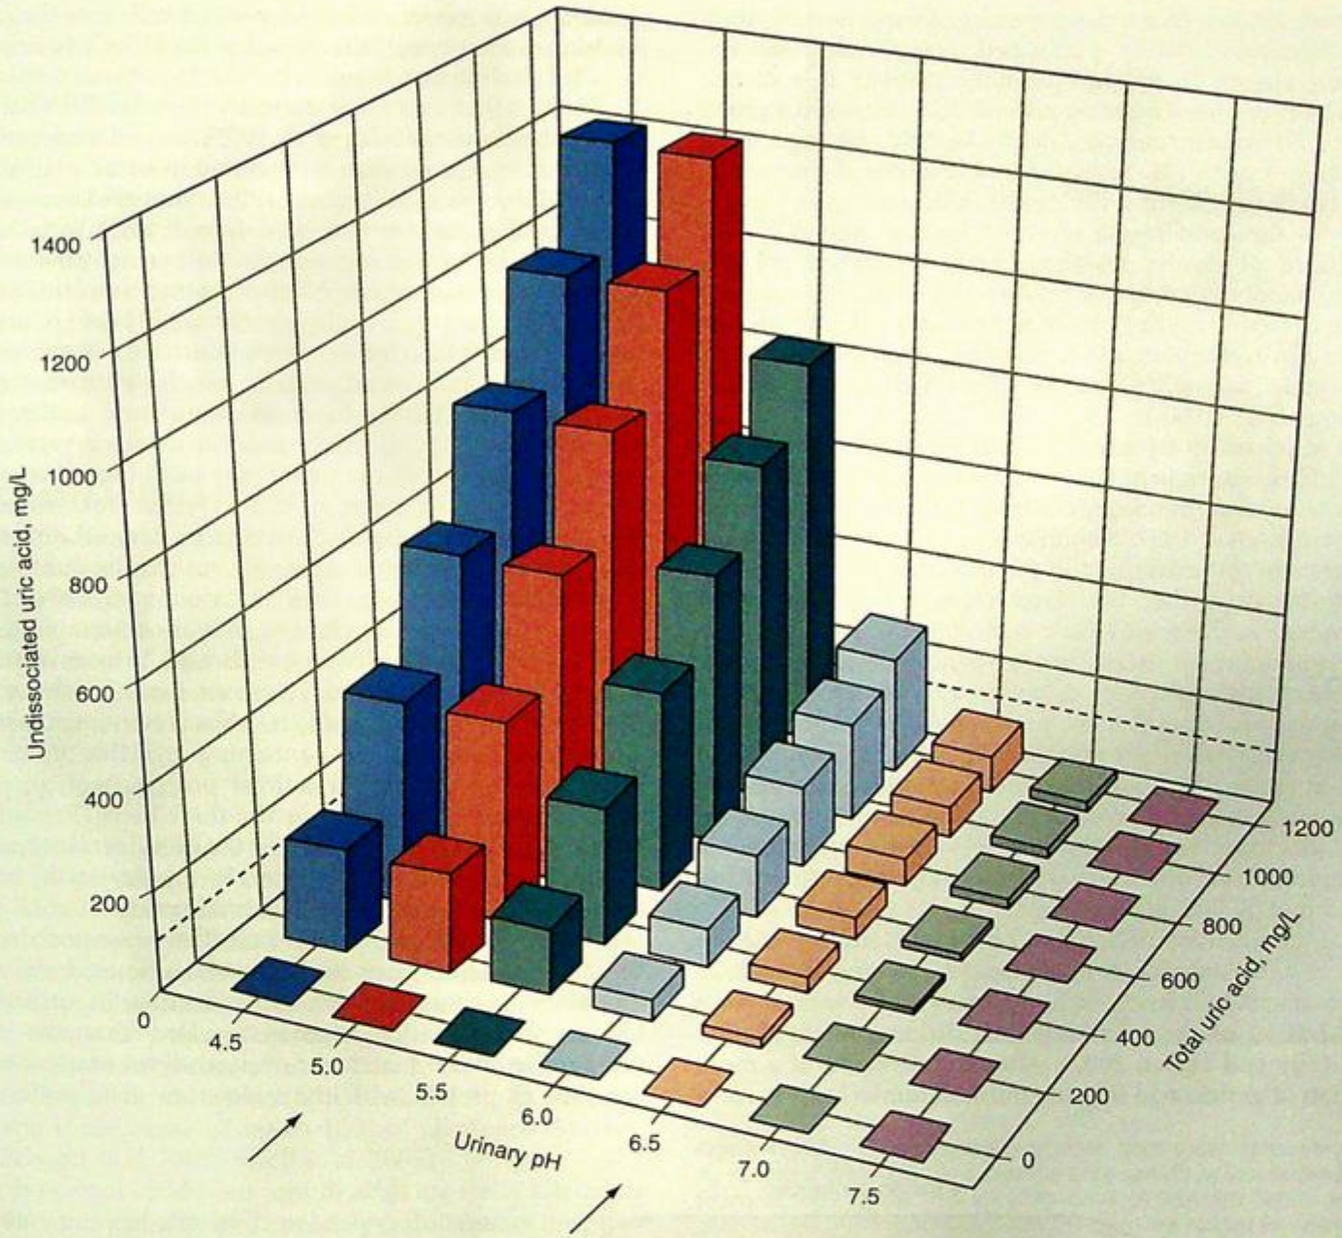

Figure 42–9. Relationship between undissociated uric acid, total uric acid, and urinary pH. The limit of solubility of undissociated uric acid is depicted by the *dotted line* (approximately 100 mg/L). Two hypothetical urine pH values are considered *(arrows)*. At low pH (e.g., 5.0), even a modest amount of total urinary uric acid will exceed its solubility. At high pH (e.g., 6.5), even massive hyperuricosuria is well tolerated. (From Maalouf NM, Cameron MA, Moe OW, Sakhaee K: Novel insights into the pathogenesis of uric acid nephrolithiasis. Curr Opin Nephrol Hypertens 2004a;13:181-189.)

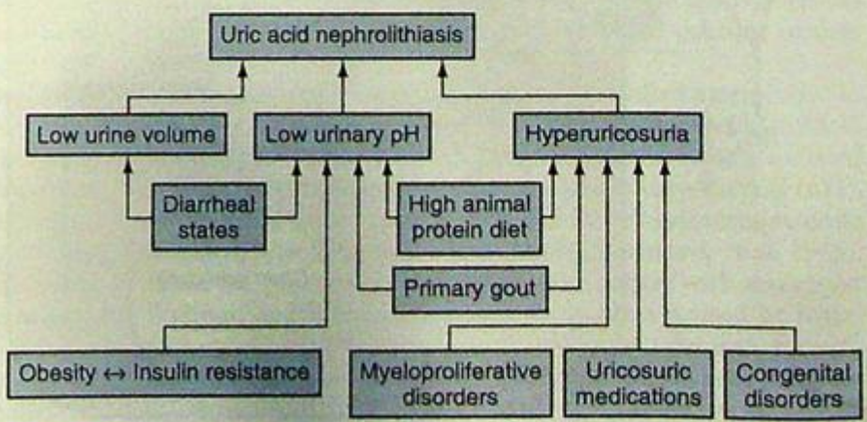

Figure 42–10. Pathophysiology and etiology of uric acid nephrolithiasis. The three major pathophysiologic mechanisms that contribute to uric acid nephrolithiasis are low urine volume, low urinary pH, and hyperuricosuria. Each of these mechanisms can result from diverse etiologies. The most important pathogenetic factor is low urinary pH. (From Maalouf NM, Cameron MA, Moe OW, Sakhaee K: Novel insights into the pathogenesis of uric acid nephrolithiasis. Curr Opin Nephrol Hypertens 2004a;13:181-189.)

Pak et al, 2003b). In an elegant series of experiments, Abate and colleagues (2004) performed hyperinsulinemic euglycemic clamps to measure insulin sensitivity in a diverse group of non–stone-forming normal volunteers and a group of uric acid stone formers and determined that among normal subjects, low urine pH correlated with low rates of glucose disposal (indicating insulin resistance). Uric acid stone formers displayed the most severe levels of insulin resistance. This association of insulin resistance and low urinary pH was further corroborated by the finding of a strong inverse association of body weight (known to be associated with peripheral insulin resistance) and urinary pH, even after adjusting for urinary sulfate (a marker of animal protein intake) (Maalouf et al, 2004b).

The mechanism by which insulin resistance leads to low urine pH is not known. However, insulin has been shown to promote renal ammoniagenesis from the substrate glutamine (Chobanian et al, 1987; Nissim et al, 1995) and also to stimulate the Na^+/H^+ exchanger in the proximal tubule, which is responsible for either the direct transport or trapping of ammonium in the urine (Klisic et al, 2002). Impaired ammonium production or excretion as a result of insulin resistance could leave hydrogen ions unbuffered in the urine, thereby leading to reduction in urine pH (Fig. 42–11). Alternatively, free fatty acids, which are present in increased amounts in the blood in states of insulin resistance, could compete with α-ketoglutarate, the end product of glutamine metabolism, for entry into the Krebs cycle, thereby reducing ammonia production that normally results from glutamine deamination (Maalouf et al, 2004a).

Another potential mechanism for uric acid stone formation is loss of diurnal variation in urinary pH. In most individuals there is diurnal variation in both serum and urine pH, with alkalinization of the urine noted in the morning and after meals (Niv and Fraser, 2002). After consumption of a meal, secretion of gastric acid into the stomach lumen leads to compensatory base excretion by the parietal cells into the serum, resulting in transient alkalinization of the blood and urine, the so-called alkaline tide. Support for this hypothesis comes from the findings that vagotomy prevents postprandial alkalinization of the urine (Gibaldi et al, 1975) and administration of antacids is associated with an increase in urine pH (Ahmad, 1986). Bilobrov and colleagues (1990) compared normal individuals and stone formers and found wide variations in urinary pH in normal individuals but persistently low urine pH among stone formers. Murayama and coworkers (1993, 2001) also found consistently low urinary pH (<6) in uric acid stone formers evaluated on both controlled metabolic and random diets and found absence of the postprandial and morning alkaline tides. In contrast, calcium oxalate stone formers maintained diurnal variation in urinary pH. Transient alkalinization of the urine may be sufficient to protect normal individuals from uric acid stone formation. The underlying cause of the absence of a urinary alkaline tide in uric acid stone formers is unknown but may be due to a renal defect rather than a gastric one (Maalouf et al, 2004a).

Dietary content also plays a role in determining urine acidity. Breslau and colleagues evaluated 15 normal subjects in a three-way randomized, crossover study involving three, 12-day phases of study in which subjects were maintained on a controlled metabolic diet containing vegetable protein, vegetable and egg protein, or animal protein, with increasing sulfate content, respectively, in the three diets (Breslau et al, 1988). As the fixed acid content of the diets increased, urinary calcium excretion increased from 103 mg/day on the vegetarian diet to 150 mg/day on the animal protein diet ($P < .02$). Moreover, the animal protein–rich diet was associated with the highest excretion of undissociated uric acid and lowest excretion of citrate due to the reduction in urinary pH. Urinary crystallization studies revealed that the animal protein diet, when matched for electrolyte composition and quantity of protein with the vegetarian diet, conferred an

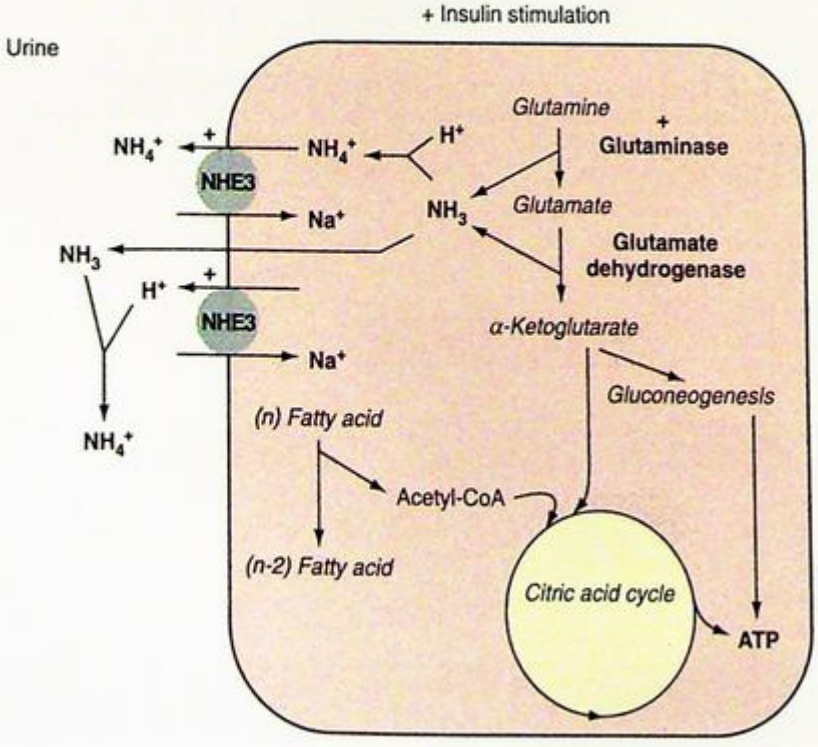

Figure 42–11. Potential effects of the insulin-resistant state on the generation and secretion of ammonium in the proximal tubule. The deamination of glutamine and glutamate provide ammonia. Insulin stimulates glutamine metabolism as well as the sodium/hydrogen exchanger NHE3. NHE3 mediates ammonium transport by either directly carrying the ammonium ion or providing the luminal hydrogen ion to trap ammonia. The end-product of glutamine metabolism is α-ketoglutarate, which can enter the Krebs cycle or gluconeogenesis to generate adenosine triphosphate (ATP). Alternatively, the metabolism of free fatty acids may generate acetyl-coenzymeA (CoA), which may compete with α-ketoglutarate to enter the Krebs cycle, thus providing energy to the cell but diminishing ammonia production. (n)-Fatty acid and (n-2)-Fatty acid represent fatty acids made of a skeleton of n and n-2 carbon atoms, respectively. (From Maalouf NM, Cameron MA, Moe OW, Sakhaee K: Novel insights into the pathogenesis of uric acid nephrolithiasis. Curr Opin Nephrol Hypertens 2004a;13:181-189.)

increased risk of uric acid stones, but, because of opposing factors, not of calcium oxalate or calcium phosphate stones.

Hyperuricosuria

Hyperuricosuria is defined as urinary uric acid less than 600 mg/day (Menon, 1986). Hyperuricosuria predisposes to calcium oxalate or uric acid stone formation by causing supersaturation of the urine with respect to monosodium urate. Patients with gout and urinary uric acid levels less than 600 mg/day had significantly fewer stones than those with uric acid levels greater than 1000 mg/day (Hall et al, 1967; Yu and Gutman, 1967). The causes of hyperuricosuria have been discussed previously but include dietary factors as well as acquired and hereditary diseases and defects in the urate transporter.

Low Urinary Volume

All conditions that contribute to low urinary volume increase the risk of uric acid supersaturation. Borghi and colleagues (1993) noted high uric acid relative supersaturation in workers exposed to hot temperatures compared with those working in normal temperatures. Likewise, high rates of uric acid stone formation have been found in populations living in warmer climates such as Israel (Shekarriz and Stoller, 2002).

Cystine Stones

Cystinuria is an autosomal recessive disorder characterized by a defect in intestinal and renal tubular transport of dibasic amino acids, resulting in excessive urinary excretion of cystine (Ng and Streem, 1999, 2001). Although the defect results in high urinary concentrations of lysine, ornithine, and arginine as well, the poor solubility of cystine leads to stone formation. Cystine stones are rare, occurring in the United States and Europe with an incidence of only 1 in 1,000 to 1 in 17,000 (Cabello-Tomas et al, 1999; Knoll et al, 2005). In children, cystinuria is the cause of up to 10% of all stones (Faerber, 2001; Erbagci et al, 2003; Knoll et al, 2005).

Under normal conditions amino acids are freely filtered by the glomerulus and almost completely reabsorbed in the proximal tubules. In cystinuria, the defect in transport of cystine results in high urinary levels. There are several factors that determine the solubility of cystine, including cystine concentration, pH, ionic strength, and urinary macromolecules. The main contributor to cystine crystallization is supersaturation because there is no specific inhibitor of cystine crystallization in the urine (Pak and Fuller, 1983). Because of the poor solubility of cystine in urine, precipitation of cystine and subsequent stone formation occur at physiologic urine conditions (Joly et al, 1999). The solubility of cystine is highly pH dependent, with solubilities of 300 mg/L, 400 mg/L, and 1000 mg/L at pH levels of 5, 7, and 9, respectively (Dent et al, 1955). Ionic strength also influences solubility, and as much as 70 mg of additional cystine can be dissolved in each liter of solution as ionic strength increases from 0.005 to 0.3 (Pak and Fuller, 1983). Macromolecules such as colloid also increase cystine solubility, although the mechanism is unclear (Pak and Fuller, 1983). Therefore, cystine is more soluble in urine than in synthetic solution (Fig. 42–12).

Other factors may contribute to stone formation in cystinuric patients as well. Sakhaee and colleagues evaluated 27

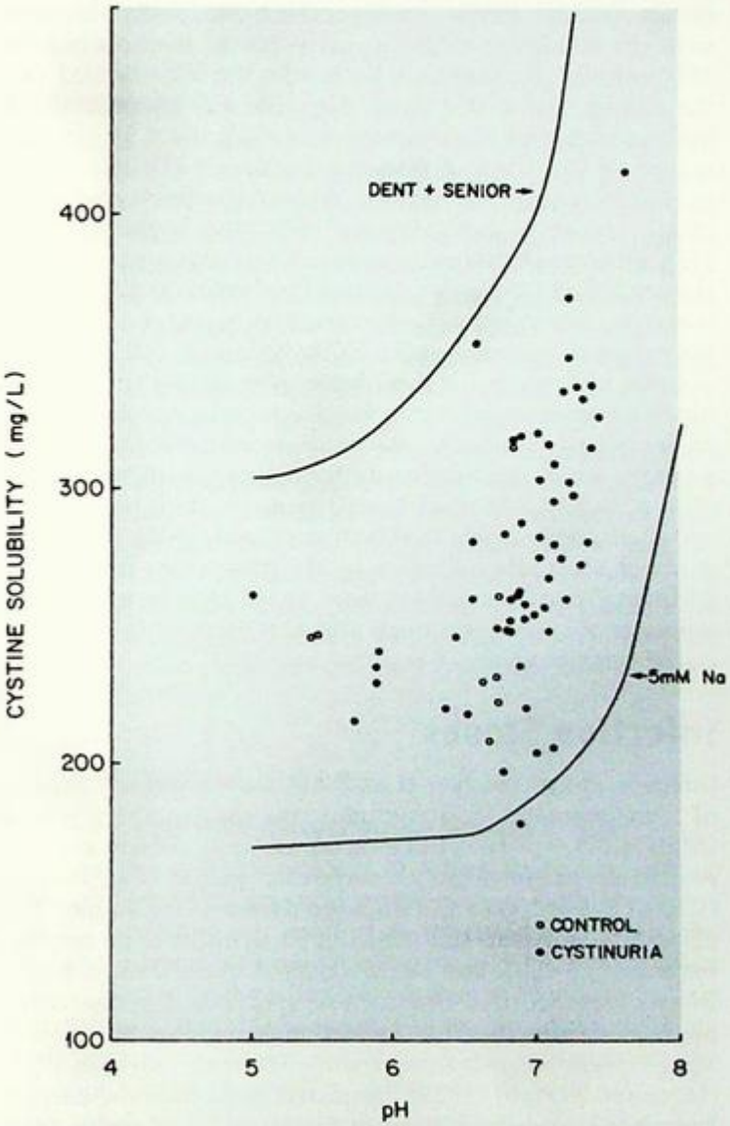

Figure 42–12. Cystine solubility in urine. Each point represents solubility of cystine determined in a separate urine sample by incubation with an excess of solid cystine. The solubility curve of Dent and Senior and that obtained in a 5-mM sodium cacodylate solution are plotted for comparison. (From Pak CY, Fuller CJ: Assessment of cystine solubility in urine and of heterogeneous nucleation. J Urol 1983;129:1066-1070.)

patients with documented cystine nephrolithiasis and identified hypercalciuria in 19%, hyperuricosuria in 22%, and hypocitraturia in 44% of patients, which could contribute to formation of not only cystine stones but also to stones composed of a combination of cystine and calcium oxalate (Sakhaee et al, 1989).

The genetics of cystinuria have been studied extensively. To date, two genes involved in the disease have been identified, *SLC3A1* and *SLC7A9*, which have been found to be associated with defects in heteromeric amino acid transporters (HATs). Historically, three types of cystinuria have been recognized in humans: type I, type II, and type III (Rosenberg et al, 1966). However, this classification correlates poorly with molecular findings, and therefore it has recently been revised by International Cystinuria Consortium (ICC) to take into account the chromosomal localization of the mutation: type A (chromosome 2), type B (chromosome 19), and type AB (both

chromosomes) (Dello Strologo et al, 2002). Homozygotes with the condition exhibit urinary cystine levels as high as 2000 µmol/g of creatinine. Review by the ICC revealed that the average age at first stone diagnosis was 12.2 years, with mean number of stone episodes of 0.42 and 0.21 per year occurring in men and women, respectively (Dello Strologo et al, 2002). Although mean urinary cystine levels are significantly higher in heterozygotes with type B abnormalities (475 µmol/g creatinine) compared with those with type A abnormalities (70 µmol/g creatinine), there is no difference in stone formation between the two groups, and, in fact, stone formation is uncommon (Dello Strologo et al, 2002).

Little information is available on the relative distribution of the types of cystinuria in specific populations. In 97 well-characterized families in the database of the ICC cohort of patients, which hail primarily from Italy, Spain, and Israel, 38%, 47%, and 14% transmitted type I, non–type I, and mixed cystinuria, respectively (Dello Strologo et al, 2002). In another study of 85 family members of 24 cystine stone formers, 24 additional family members were found to excrete excessive amounts of cystine, although only 5 of them (21%) had produced cystine calculi (Trinchieri et al, 2004).

Infection Stones

Infection stones (Bichler et al, 2002) are composed primarily of magnesium ammonium phosphate hexahydrate ($MgNH_4PO_4 \cdot 6H_2O$) but may in addition contain calcium phosphate in the form of carbonate apatite ($Ca_{10}[PO_4]_6 \cdot CO_3$). A Swedish geologist discovered magnesium ammonium phosphate in guano and named it "struvite" after his mentor, naturalist H. C. G. von Struve (Griffith and Osborne, 1987). Brown first theorized that bacteria split urea, thereby setting up the condition for stone formation, and indeed he later isolated *Proteus vulgaris* from a stone (Brown, 1901). In 1925, Hager and Magath (1925) postulated that a bacterial enzyme hydrolyzed urea, and Sumner (1926) isolated urease from *Canavalia ensiformis*. It is now well established that struvite stones (magnesium ammonium phosphate) occur only in association with urinary infection by urea-splitting bacteria (Griffith and Musher, 1973).

Pathogenesis

The process of urealysis provides an alkaline urinary environment and sufficient concentrations of carbonate and ammonia to induce the formation of infection stones. Because urease is not present in sterile human urine, **infection with urease-producing bacteria is a prerequisite for the formation of infection stones.** A cascade of chemical reactions generates the conditions conducive to the formation of infection stones. Urinary urea, a constituent of normal urine, is first hydrolyzed to ammonia and carbon dioxide in the presence of bacterial urease:

$$(NH_2)_2CO + H_2O \rightarrow 2NH_3 + CO_2$$

The alkaline urine that results from this reaction (pH 7.2 to 8.0) favors the formation of ammonium:

$$NH_3 + H_2O \rightarrow NH_4^+ + OH^- \quad pK = 9.0$$

Under physiologic conditions, the alkaline urine would prevent further generation of further ammonium. However, in the presence of urease, ammonia continues to be produced despite alkaline urine, further increasing urinary pH. The alkaline environment also promotes the hydration of carbon dioxide to carbonic acid, which then dissociates into HCO_3^- and H^+. Further dissociation of HCO_3^- yields carbonate and two hydrogen ions:

$$CO_2 + H_2O \rightarrow H_2CO_3 \quad pK = 4.5$$

$$H_2CO_3 \rightarrow H^+ + HCO_3^- \quad pK = 6.3$$

$$HCO_3^- \rightarrow H^+ + CO_3^{2-} \quad pK = 10.2$$

The dissociation of hydrogen phosphate under alkaline conditions provides phosphate, thereby completing the generating of constituent ions for infection stone formation:

$$H_2PO_4^- \rightarrow H^+ + HPO_4^{2-} \quad pK = 7.2$$

$$HPO_4^{2-} \rightarrow H^+ + PO_4^{3-} \quad pK = 12.4$$

This chemical cascade, along with physiologic concentrations of magnesium, provides the constituents necessary for precipitation of struvite. In addition, the concentrations of calcium, phosphate, and carbonate allow precipitation of carbonate apatite and hydroxyapatite, thereby comprising the components of infection stones (Fig. 42–13).

Although infection stones are a direct result of persistent or recurrent infection with urease-producing bacteria, they may also be associated with or exacerbated by urinary obstruction or stasis (Bichler et al, 2002). As such, growth of infection stones can progress at a very rapid rate (Hinman, 1979).

Bacteriology

Although the family Enterobacteriaceae comprise the majority of urease-producing pathogens, a variety of gram-positive

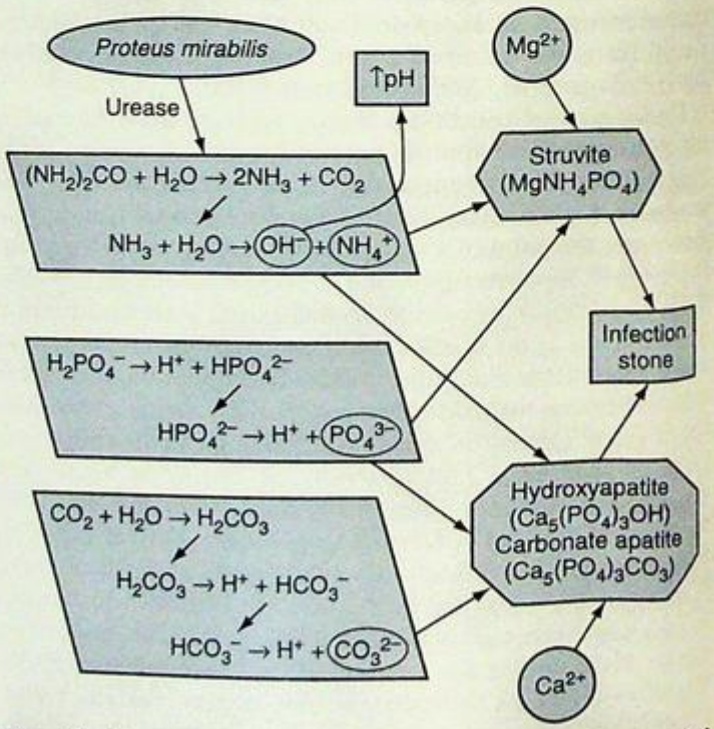

Figure 42–13. Schematic depicting concurrent events leading to struvite stone formation. (From Johnson DB, Pearle MS: Struvite stones. In Stoller ML, Meng MV [eds]: Urinary Stone Disease: The Practical Guide to Medical and Surgical Management. Totowa, NJ, Humana Press, in press.)

and gram-negative bacteria and some yeasts and *Mycoplasma* species have the capacity to synthesize urease (Table 42–4). **The most common urease-producing pathogens are *Proteus, Klebsiella, Pseudomonas,* and *Staphylococcus* species** (Griffith and Osborne, 1987), **with *Proteus mirabilis* the most common organism associated with infection stones** (Silverman and Stamey, 1983). Although *Escherichia coli* is a common cause of urinary tract infections, rare species of *E. coli* produce urease (Bichler et al, 2002). Bacterial urease can be detected by the Urea-Rapid Test, a urea-indole medium from Bio-Merieux, Inc. (Durham, NC) (Bichler et al, 2002).

Bacteria may be involved in stone formation by damaging the mucosal layer of the urinary tract, resulting in both increased bacterial colonization and crystal adherence (Parsons et al, 1984; Grenabo et al, 1988). It has been proposed that ammonium, generated as a result of urealysis, may alter the glycosaminoglycan layer present on the surface of the transitional cell layer and significantly increase bacterial adherence to normal bladder mucosa, further exacerbating infection risk (Parsons et al, 1984). In addition, a study in rats found that injury to the bladder mucosa increased crystal adherence to the bladder wall, a process that was potentiated by the presence of common bacteria such as *Proteus, E. coli, Enterococcus,* and *Ureaplasma urealyticum* (Grenabo et al, 1988). Another potential mechanism for increased stone formation in the presence of bacteria is the finding that particular bacteria, such as *E. coli* and *Proteus,* may alter the activity of urokinase and sialidase, whereas organisms not typically associated with infection stones do not (du Toit et al, 1992). This altered enzymatic activity may explain the frequent association of *E. coli* with stone formation despite lacking urease activity (Holmgren et al, 1989).

Epidemiology

Infection stones comprise 5% to 15% of all stones (Levy et al, 1995). However, struvite/carbonate apatite was the most common stone composition among a population of African American stone formers in Ohio, accounting for a third of stones in males and nearly half the females in this population (Sarmina et al, 1987). **Because infection stones occur most commonly in those prone to frequent urinary tract infections, struvite stones occur more often in women than men by a ratio of 2:1** (Resnick, 1981). Other populations at risk of recurrent infection include the elderly (Kohri et al, 1991), premature infants or infants born with congenital urinary tract malformation, diabetics, and those with urinary stasis as a result of urinary tract obstruction, urinary diversion, or neurologic disorders. Spinal cord–injured patients are at particular risk for both infection and metabolic stones owing to neurogenic urinary tract dysfunction and hypercalciuria related to immobility. Patients with a functionally complete cord transection are at highest risk of developing a staghorn calculus (DeVivo et al, 1984).

Miscellaneous Stones

Xanthine and Dihydroxyadenine Stones

Xanthine stones are comprised of a rare stone type that is often confused with uric acid stones because both are radiolucent. They form as a result of an inherited disorder in the catabolic enzyme xanthine dehydrogenase (XDH) or xanthine oxidase, which catalyzes the conversion of xanthine to uric acid. Because xanthine is poorly soluble in urine, the high levels of xanthine that accumulate in XDH deficiency lead to xanthine stones (Seegmiller, 1968; de Vries et al, 1977; Cameron et al, 1993).

Allopurinol, which inhibits XDH and consequently is used to treat hyperuricemia and hyperuricosuria, can, at very high levels, predispose to xanthine stones. This side effect is distinctly uncommon, because the drug causes only partial inhibition of the enzyme and rarely reduces serum uric acid to levels lower than 3 mg/dL. Patients with Lesch-Nyhan syndrome who suffer from an inherited deficiency of the purine salvage enzyme hypoxanthine-guanine phosphoribosyltransferase (HPRT) are occasionally treated with high enough doses of allopurinol to place them at risk for xanthine stones (Cameron et al, 1993).

Children with inherited deficiencies of adenine phosphoribosyltransferase (APRT) can also present in infancy with renal complications and stones (Cameron et al, 1993). Children with APRT deficiency may be difficult to distinguish from those with HPRT deficiency because the insoluble product excreted, 2,8-dihydroxyadenine (2,8-DHA), is chemically similar to uric acid. Like xanthine stones, 2,8-DHA stones are extremely insoluble at any pH, but stone formation can be averted by the administration of allopurinol.

Ammonium Acid Urate Stones

Ammonium acid urate stones represent less than 1% of all stones (Herring, 1962; Klohn et al, 1986). In developing coun-

tries, however, endemic ammonium acid urate urolithiasis is still observed because they comprise bladder calculi in children (Minon Cifuentes and Pourmand, 1983; Vanwaeyenbergh et al, 1995). **Conditions associated with ammonium acid urate crystallization include laxative abuse, recurrent urinary tract infection, recurrent uric acid stone formation, and inflammatory bowel disease** (Borden and Dean, 1979; Klohn et al, 1986; Dick et al, 1990; Pichette et al, 1997; Soble et al, 1999). Soble and associates (1999) reviewed their experience with 44 patients identified as having stones composed of ammonium acid urate, although the ammonium acid urate contribution varied from 2% to 60%. Among these patients, 25% had a history of inflammatory bowel disease, 14% had a history of significant laxative abuse, 41% were morbidly obese, 36% had history of recurrent urinary tract infections, and 21% had a history of recurrent uric acid stones. The subgroup of patients with inflammatory bowel disease and ileostomy as the sole clinical risk factor had the highest mean ammonium acid urate content (39%), and ammonium acid urate constituted the predominant stone type in 7 of 8 such patients.

Patients with ileostomy after colectomy have markedly reduced urinary volume, pH, and sodium and are not prone to hyperoxaluria like other individuals with bowel disease because the colon is the main site of dietary oxalate absorption (Kennedy et al, 1982). As such, these patients are prone to ammonium acid urate and uric acid stones rather than calcium oxalate stones. **The underlying pathophysiologic mechanism of ammonium acid urate stone formation due to laxative abuse has been postulated to be the result of dehydration due to gastrointestinal fluid loss causing intracellular acidosis and enhanced ammonia excretion. Because urinary sodium is very low with laxative use, urate complexes with abundant ammonia, thereby leading to urinary supersaturation of ammonium acid urate.**

Bowyer and colleagues (1979) demonstrated that ammonium acid urate precipitation is favored at pH 6.2 to 6.3. The association of recurrent uric acid stones with ammonium acid urate stones is likely related to the shared risk factors of low urine volume and pH. Soble and colleagues (1999) identified 9 patients with stones of mixed composition, containing both uric acid and ammonium acid urate (mean ammonium acid urate content 27%), although 8 of the 9 patients had uric acid as the predominant constituent (range: 40% to 95%). They theorized that transient fluctuations in urinary acidity and ammonium and sodium levels may shift the balance between uric acid and sodium- or ammonium-bound urate excretion.

Among the ammonium acid urate stone producers in Sobel and colleagues' study, obesity (body mass index greater than 30) was the most prevalent characteristic in 41% of patients, after excluding patients with inflammatory bowel disease and ileostomy (none of whom was obese). Indeed, a statistically significant correlation was found between body mass index and ammonium acid urate content. This is consistent with recent evidence suggesting a correlation between stone risk and obesity (Powell et al, 2000) and between obesity and low urine pH (Maalouf et al, 2004b).

Matrix Stones

The association between urinary proteins and stone formation has long been recognized. Early experiments demonstrated that protein suspensions could promote calcium stone formation (Kimura et al, 1976). Both osteopontin and calprotectin have been shown to play a role in forming the matrix structure of urinary calcium stones (Tawada et al, 1999; Kleinman et al, 2004). However, stones composed predominantly of matrix are rare; these "stones" are typically radiolucent and may be mistaken for tumor or uric acid stones depending on the imaging study obtained (Bani-Hani et al, 2005). The literature regarding matrix stones is sparse, consisting mostly of anecdotal case reports (Boyce and King, 1963; Allen and Spence, 1966; Bani-Hani et al, 2005). The matrix component of calcium-based stones comprises only 2.5% of the dry weight of the stone, whereas pure matrix stones may contain upward of 65% protein (Allen and Spence, 1966). Boyce and Garvey (1956) determined that the composition of matrix stones was approximately two thirds mucoprotein and one third mucopolysaccharide by weight. Furthermore, they found that the matrix substance in crystalline calculi is closely related to the matrix substance found in matrix calculi. However, it is unclear why some matrix calculi fail to fully calcify. While some have theorized that reduced urinary calcium levels may account for the preferential formation of matrix stones (Boyce and King, 1959; Allen and Spence, 1966), a recent metabolic evaluation of 5 patients with matrix stones revealed normal urinary calcium excretion (Bani-Hani et al, 2005). In renal failure patients undergoing dialysis, proteinuria may contribute to an increased risk of matrix stone formation. In these patients, matrix stones have been shown to include both microfibrillar protein (Bommer et al, 1979) and β_2-microglobulin (Linke et al, 1986).

Medication-Related Stones

Drug-induced stones form either directly due to precipitation and crystallization of a drug or its metabolite or indirectly by altering the urinary environment, making it favorable for metabolic stone formation (Daudon, 1999). Drugs such as loop diuretics (furosemide, bumetanide), acetazolamide, topiramate, and zonisamide contribute to calcium stone formation (Matlaga et al, 2003). Ephedrine (Powell et al, 1998; Assimos et al, 1999), triamterene (Ettinger et al, 1980; Carr et al, 1990), guaifenesin (Assimos et al, 1999), silicate (Farrer and Rajfer, 1984), indinavir (Bruce et al, 1997; Gentle et al, 1997), and ciprofloxacin (Matlaga et al, 2003) have all been associated with stones composed of the drug itself in patients who consumed excessive amounts.

Medications That Directly Promote Stone Formation

Indinavir Stones. Indinavir sulfate is a protease inhibitor that has been shown to be effective in increasing CD4+ cell counts and decreasing HIV-RNA titers in patients infected with human immunodeficiency virus (HIV) or who have the acquired immunodeficiency syndrome (Wu and Stoller, 2000). However, indinavir poses a risk for indinavir stone formation in treated patients, leading to an estimated incidence of 4% to 13% (Wu and Stoller, 2000). Indinavir is rapidly absorbed from the intestine, achieving peak plasma concentrations in less than 1 hour. The drug is metabolized in the liver and eliminated primarily in the stool, but about half of the ingested dose of indinavir is excreted essentially

unchanged in the urine (Sutherland et al, 1997). In pure form, indinavir is relatively insoluble in aqueous solution, although the solubility is pH dependent. With a pKa of 5.5, indinavir has a solubility of 0.300 mg/mL at pH 5, 0.035 mg/mL at pH 6.0, and 0.020 mg/mL at pH 7.0 (Daudon et al, 1997; Hermieu et al, 1999). Although indinavir solubility increases significantly at pH levels below 5.5, the standard dose of indinavir in an individual with an average urine volume and pH would produce a urinary concentration of indinavir near the limit of solubility 3 hours after ingestion (Daudon et al, 1997). As such, **individuals taking indinavir on a regular basis are at high risk of producing indinavir stones due to the high urinary excretion and poor solubility of the drug at physiologic urinary pH.** Initiation of indinavir in 54 asymptomatic indinavir-naive HIV-positive individuals led to indinavir crystalluria in 67% of subjects (Gagnon et al, 2000). After the first 2 weeks, indinavir crystalluria remained constant at a frequency of approximately 25% of urine sediments examined at each test point.

Triamterene Stones. Triamterene is a potassium-sparing diuretic commonly used for the treatment of hypertension. It is a very uncommon stone composition, accounting for only 0.4% of 50,000 calculi in one report, with only one third of the stones composed largely or entirely of triamterene (Ettinger et al, 1980). An evaluation of triamterene stone formers revealed no significant differences between patients and matched control subjects with respect to total recovery of the drug, hourly excretion patterns, and urinary concentrations of triamterene and its sulfate metabolite (Ettinger, 1985). Approximately half of all subjects tested demonstrated urine concentrations of the sulfate metabolite that exceeded the observed solubility limit. One investigation determined that triamterene is more likely to become incorporated into existing stones or stone nidi than to promote stone formation independently (Werness et al, 1982). This may account for the rarity of this stone in non–stone formers as well as the finding that hospitalization rate for urinary stones did not differ between patients prescribed triameterene and HCTZ (Jick et al, 1982).

Guaifenesin and Ephedrine. Consumption of large quantities of guaifenesin and ephedrine can lead to stones composed of their metabolites (Powell et al, 1998; Assimos et al, 1999). Most of the patients reported to have these stones are found to have consumed large quantities of over-the-counter preparations of cold medicine for the stimulatory properties of the ephedrine component, and a history of drug abuse is not uncommon (Assimos et al, 1999). Herbal ecstasy and Ma Huang are also popular ephedrine-containing preparations that are abused for stimulatory properties (Mack, 1997). Unfortunately, chronic ephedrine use leads to tachyphylaxis and prompts the use of increasing doses to achieve a comparable effect. Serious toxicity may result from ephedrine abuse, including death, cardiomyopathy, stroke, hypertension, and seizures.

Silicate Stones. Silica is a common element seen in vegetables, whole grains, seafood, and even drinking water that is easily excreted in the urine (Matlaga et al, 2003). Silicate stones are extremely rare and have been associated with consumption of large amounts of silicate-containing antacids, such as magnesium trisilicate (Daudon, 1999; Haddad and Kouyoumdjian, 1986).

Medications That Indirectly Promote Stone Formation. Other medications indirectly promote stone formation by increasing urinary stone risk factors. Corticosteroids, vitamin D, and phosphate-binding antacids can induce hypercalciuria. Thiazides cause intracellular acidosis and subsequent hypocitraturia (Nicar et al, 1984). Loop diuretics such as furosemide and bumetanide inhibit sodium and calcium resorption in the thick ascending loop of Henle, which in addition to a diuretic effect results in hypercalciuria (Matlaga et al, 2003). Renal calculi have been identified in up to 64% of low-birth-weight infants receiving furosemide therapy, and stones are consistently composed of calcium oxalate (Hufnagle et al, 1982; Shukla et al, 2001). Carbonic anhydrase inhibitors such as acetazolamide block resorption of sodium bicarbonate in the proximal tubule, leading to urinary alkalinization (Parfitt, 1969). Chronic use results in a hyperchloremic metabolic acidosis with subsequent hypocitraturia and increased risk for calcium phosphate stones (Matlaga et al, 2003). Topiramate is a widely used antiepileptic agent that inhibits certain isoenzymes of carbonic anhydrase with subsequent stone-potentiating effects (Matlaga et al, 2003). Zonisamide is a sulfonamide agent that also exerts an antiepileptic effect and has a weak carbonic anhydrase activity (Peters and Sorkin, 1993). Laxatives can lead to persistent diarrhea and increase the risk of ammonium acid urate stones. Patients abusing laxatives excrete large amounts of ammonia in the urine to eliminate excess acid, resulting in low urine pH. In the setting of low urine volume due to dehydration, the urine of these patients can be highly supersaturated with respect to ammonium urate (Matlaga et al, 2003). Lastly, cytotoxic agents promote a high cell turnover, resulting in urinary excretion of large amounts of uric acid.

Anatomic Predisposition to Stones

Patients with anatomic anomalies associated with urinary obstruction and/or stasis have been noted to have a high incidence of associated stones. It has long been debated whether the predisposition to stone disease is a result of urinary stasis and delayed transit time through the nephron, leading to higher likelihood of crystal formation and retention, or if these patients form stones as a result of the same or unique metabolic abnormalities associated with stone formation.

Ureteropelvic Junction Obstruction

The incidence of renal calculi in patients with ureteropelvic junction (UPJ) obstruction is nearly 20% (David and Lavengood, 1975; Lowe and Marshall, 1984; Clark and Malek, 1987). However, **Husmann and colleagues** (1995) **provided several lines of evidence to suggest that patients with UPJ obstruction and concurrent renal calculi carry the same metabolic risks as other stone formers in the general population.** First, among 111 adult patients with UPJ obstruction and stones for whom long-term follow-up was available, 62% developed recurrent stones after treatment of the UPJ obstruction and 43% of the recurrences occurred in the contralateral kidney. These findings suggest that a metabolic predisposition persisted despite correction of the obstruction. Second, 76% of 42 patients with noninfectious stones who underwent a metabolic evaluation demonstrated an underlying metabolic abnormality that could account for the stones, a rate compa-

rable to that of other stone formers (Pak, 1982; Yagisawa et al, 1999). Finally, the type and distribution of metabolic abnormalities identified in these patients were similar to that of the general stone-forming population: hypercalciuria in 46% of patients, hyperuricosuria in 11%, hypocitraturia in 13%, primary hyperparathyroidism in 13%, and RTA in 3% (Pak et al, 1980). Treatment of patients with identifiable abnormalities significantly reduced their rate of recurrence, from 55% in patients managed conservatively to 17% in treated patients.

Matin and Streem also performed metabolic evaluations before definitive repair in 47 patients with UPJ obstruction with or without associated stones (Matin and Streem, 2000). An identifiable abnormality was found in 67% of the stone patients compared with only 33% of the control group; urinary calcium and the incidence of hypercalciuria and hyperuricosuria were significantly higher in the patients with stones compared with the controls, further underscoring the contribution of pathophysiologic background to stone-forming risk in patients with anatomic abnormalities.

Similar findings in two series of children with UPJ obstruction and concurrent renal calculi further support a metabolic contribution to stone formation in the presence of renal obstruction. Tekin and associates (2001) prospectively compared children with UPJ obstruction with and without stones to a control group of calcium stone formers without UPJ obstruction. Both groups of stone formers, those with and without UPJ obstruction, exhibited significantly higher urinary levels of citrate and lower levels of oxalate compared with the non–stone-forming children with UPJ obstruction. Husmann and coworkers (1996) reported a 70-fold increased risk of stone formation in the pediatric population with UPJ obstruction compared with normal children. Among 22 children who underwent treatment of their stones and UPJ obstruction, 68% of patients with nonstruvite stones developed a recurrence after surgical treatment and a metabolic abnormality was identified in 68%. Among the 7 patients with nonstruvite renal calculi who did not experience a recurrence, only 29% had an identifiable metabolic abnormality. As such, correction of the UPJ obstruction did not prevent recurrent stones in most patients, further emphasizing the role of underlying metabolic abnormalities in the etiology of renal calculi in patients with UPJ obstruction.

Horseshoe Kidneys

Horseshoe kidneys occur with a prevalence of 0.25% but have an associated rate of renal calculi of 20% (Janetschek et al, 1988; Cussenot et al, 1992). Because of the high insertion of the ureter into the renal pelvis, there is a relative impairment of renal drainage, predisposing to UPJ obstruction. As such, the risk of stone formation has been attributed to urinary stasis rather than to metabolic derangements. Raj and colleagues (2004) reviewed 37 patients with horseshoe kidneys and stones and identified at least one metabolic abnormality in all 11 patients in whom 24-hour urine collections were available. Compared with a group of stone formers with normal renal anatomy, the patients with horseshoe kidneys exhibited a similar distribution of metabolic derangements, with the exception that hypocitraturia was overrepresented (55% in the patients with horseshoe kidneys vs. 31% in controls). It seems clear that **although urinary stasis likely contributes to a propensity toward stone formation in patients with horseshoe kidneys, an underlying metabolic abnormality is required for stone formation to occur.**

Caliceal Diverticula

Caliceal diverticula are associated with stones in up to 40% of patients (Middleton and Pfister, 1974). Like stones in horseshoe kidneys, it is unclear whether the stones are caused by local anatomic obstruction and urinary stasis or are due to underlying metabolic factors. Two groups of investigators addressed the issue. Hsu and Streem (1998) identified metabolic abnormalities, including hypercalciuria, hyperoxaluria and hyperuricosuria, in 50% of 14 patients with stone-bearing caliceal diverticula. Notably, 64% of patients reported a history of synchronous or metachronous stones at a site distinct from the diverticulum, supporting the idea of an underlying metabolic risk as a contributing cause of the stones. In contrast, Liatsikos and coworkers (2000) compared 49 patients with caliceal diverticula and stones with 44 stone formers without diverticula and found a low rate of metabolic abnormalities in both groups (25% in patients with diverticula and 23% in the control patients). Of note, however, the metabolic evaluation in this study involved measurement of only urinary volume, creatinine, calcium, phosphorus, oxalate, and uric acid. As it has been shown that low urinary pH and hypocitraturia are identified in approximately 10% and 28% of recurrent stone formers, respectively (Levy et al, 1995), the number of metabolic abnormalities reported in this series is likely underrepresented.

Medullary Sponge Kidney

Medullary sponge kidney (MSK) is a disorder characterized by ectasia of the renal collecting ducts. Nephrocalcinosis and renal calculi are frequent complications of MSK (Lavan et al, 1971; Parks et al, 1982; Sage et al, 1982; Ginalski et al, 1990), but the exact risk factors for stone formation are not clearly understood. Although recurrent infection and urinary stasis within the ectatic tubules pose a risk for stone formation (Ginalski et al, 1990), renal tubular defects, including hypercalciuria, impaired renal concentrating ability, and defective urinary acidification after an ammonium chloride load have been detected in some MSK patients (Granberg et al, 1971), further potentiating the risk of stone formation. Deck (1965) reported three cases of MSK associated with RTA, which led him to suggest that the acidification defect may constitute the primary event leading to MSK. Osther and colleagues (1988) performed ammonium chloride load tests in 13 patients with MSK and found renal acidification defects in 9 patients: 8 with distal RTA and 1 with proximal RTA. Likewise, Higashihara and associates (1984) reported renal acidification defects in 80% of patients (36% with distal RTA) and impaired concentrating ability in 90% of 11 MSK patients.

Despite these findings, three studies performed specifically on MSK patients with nephrolithiasis revealed no case of associated RTA (O'Neill et al, 1981; Parks et al, 1982; Yagisawa et al, 2001). O'Neill and associates (1981) identified hypercalciuria as the most common metabolic abnormality in 17 patients with MSK and nephrolithiasis, occurring in 88% of patients and attributed to absorptive hypercalciuria in most cases (59%). The spectrum of abnormalities in these patients was judged to be comparable to that of the general stone-

forming population. Other investigators identified hypercalciuria less frequently, in only 9% to 44% of MSK patients with nephrolithiasis. In some cases, the cause of the hypercalciuria was attributed to renal calcium leak by which renal calcium reabsorption was presumed to be impaired by damaged renal tubules (Yendt, 1981; Parks et al, 1982; Yagisawa et al, 2001). Yagisawa identified hypocitraturia as the most common metabolic abnormality, occurring in 77% of 22 MSK patients (Yagisawa et al, 2001). Kinoshita (1990) likewise reported hypocitraturia in 58% of MSK patients. **Thus, it appears that although renal tubular defects may be associated with MSK, RTA has not been firmly established as a major cause of stone formation in patients with MSK, and hypercalciuria and hypocitraturia are likely the primary risk factors.**

Stones in Pregnancy

Symptomatic stones during pregnancy occur at a rate of 1 in 250 (Lewis et al, 2003) to 1 in 3000 (Butler et al, 2000) pregnant women. Like stones in nonpregnant women, they occur more commonly in white than African American women (Lewis et al, 2003). The majority of symptomatic stones occur in the second and third trimester of pregnancy, heralded by symptoms of flank pain or hematuria (Stothers and Lee, 1992; Butler et al, 2000; Biyani et al, 2002; Lewis et al, 2003). The diagnosis can be difficult in this patient population; up to 28% of women are misdiagnosed with appendicitis, diverticulitis, or placental abruption (Stothers and Lee, 1992).

Although most stones pass spontaneously and complications are rare, one report identified an increased risk of premature rupture of the membranes in association with stone passage (Lewis et al, 2003). Although ultrasound constitutes the first-line imaging modality when renal colic is suspected, ultrasound has been reported to miss up to 40% of stones, and a limited, or one-shot intravenous urogram, was found to be more reliable (Butler et al, 2000).

A number of physiologic changes occur during pregnancy. Physiologic hydronephrosis occurs in up to 90% of pregnant women and persists up to 4 to 6 weeks post partum (Swanson et al, 1995). Although hydronephrosis may be in part due to the effects of progesterone, compression of the ureters by the gravid uterus is at least a contributory, if not the primary, factor (Gorton and Whitfield, 1997; McAleer and Loughlin, 2004). Dilation is typically greater on the right ureter as a result of the engorged uterine vein and derotation of the enlarged uterus (Biyani et al, 2002). The physiologic dilatation may promote crystallization due to urinary stasis (Swanson et al, 1995), and the increased renal pelvic pressure has been suggested to increase the likelihood of stone movement and symptoms.

Important physiologic changes in the kidney occur during pregnancy that modulate urinary stone risk factors. Renal blood flow increases, leading to a 30% to 50% rise in glomerular filtration rate, which subsequently increases the filtered loads of calcium, sodium, and uric acid. (McAleer et al, 2004). Hypercalciuria is further enhanced by placental production of $1,25(OH)_2D_3$, which increases intestinal calcium absorption and secondarily suppresses PTH (Gertner et al, 1986; Biyani et al, 2002). Hyperuricosuria has also been reported as a result of increased filtered load of uric acid (Swanson et al, 1995).

Despite increases in a number of stone-inducing analytes, pregnant women have been shown to excrete increased amount of inhibitors such as citrate, magnesium, and glycoproteins (Maikranz et al, 1987; Smith et al, 2001). As such, the overall stone risk of stone formation has been reported to be similar in gravid and nongravid women, and stone composition is similar between the two groups (Coe et al, 1978; Drago et al, 1982).

KEY POINTS: PATHOGENESIS

- Absorptive hypercalciuria is characterized by normal serum calcium, normal or suppressed PTH, normal fasting urinary calcium, and elevated urinary calcium.
- Renal hypercalciuria is due to impaired renal calcium reabsorption, which stimulates PTH secretion and leads to fasting hypercalciuria.
- Resorptive hypercalciuria is primarily due to primary hyperparathyroidism but may be seen with granulomatous diseases that elaborate $1,25(OH)_2D_3$.
- The most important determinant of uric acid stone formation is low urinary pH.
- Low urine pH seen in uric acid stone formers is likely due to impaired ammoniagenesis as a result of insulin resistance.
- In distal renal tubular acidosis, a defective H^+ ATPase accounts for excretion of excess acid into the distal tubule.
- Formation of infection stones requires alkaline urine that can be achieved only with infection with urease-producing bacteria.

SUMMARY

DIAGNOSTIC EVALUATION OF NEPHROLITHIASIS

There is no doubt that a symptomatic urinary calculus can cause considerable discomfort to the patient. Although many stones pass spontaneously, the methods used to treat calculi may also cause significant morbidity. In addition to physical consequences, patients may suffer financial pain because of the expense of emergency department visits, office visits, surgical procedures, or time lost from work. It follows, then, that most patients are interested in learning how to prevent a recurrence of such an episode. **Through even a rudimentary understanding of the physiologic causes of urinary calculus formation, physicians may offer a straightforward approach to elucidation of the metabolic basis of nephrolithiasis for any given patient. This evaluation should be simple to perform; it must be economically viable, and it should provide information that can be applied toward a selective, rational therapy for stone disease** (Pak et al, 1980a).

Any evaluation should be able to identify associated metabolic disorders responsible for recurrent stone disease. These metabolic problems include distal renal tubular acidosis, primary hyperparathyroidism, enteric hyperoxaluria, cystinuria, and gouty diathesis. In many of these relatively uncommon conditions, it is generally agreed that selective medical therapy is indicated not only to prevent further stone formation but also to correct the underlying physiologic disturbance that may lead to nonrenal complications (Pak et al, 2002a, 2003a).

Selection of Patients for Metabolic Evaluation

Debate continues regarding which patients merit the performance of a metabolic evaluation. First-time stone formers have often been estimated to have a 50% risk of recurrence within the subsequent 10 years (Uribarri et al, 1989). In two separate studies, Ljunghall and colleagues attempted to measure the incidence of a stone recurrence in a northern European population. A retrospective review estimated the chance of recurrence as nearly 50% at 5 years, whereas a prospective evaluation noted a lower overall rate of 53% within 8 years (Ljunghall and Danielson, 1984; Ljunghall, 1987). Males had a higher incidence of calculi overall as well as a higher recurrence rate. Patients had a higher risk for recurrent stones in the years immediately after the first episode. It is not completely apparent whether these were preexisting stones that passed later or represented the formation of new calculi. **In fact, recent evidence suggests that the incidence of stone disease may be increasing, along with a higher percentage of female stone formers** (Scales et al, 2005).

Conversely, Ahlstrand noted that only 26% of patients observed for 10 years had a recurrence, significantly below previously quoted rates (Ahlstrand and Tiselius, 1990). With

this in mind, it may not be financially sound to perform a complete diagnostic panel for every patient since it is unclear what percentage will not be bothered by recurrent episodes. Perhaps new stone formers should simply be given empirical fluid and dietary recommendations and asked to return if they suffer a recurrence. Indeed, a study of single stone formers prescribed a conservative program of high fluid intake and avoidance of dietary excess revealed a low incidence of recurrent stone disease (Hosking et al, 1983). Calling this finding the "stone clinic effect," Hosking and colleagues noted metabolic inactivity in nearly 60% of all patients observed for more than 5 years.

The debate continues, however, as Pak has found that single stone formers have just as high an incidence of metabolic abnormalities as recurrent stone formers do (Pak, 1982). In addition, these derangements are just as severe, leading the author to conclude that single stone formers should undergo the same evaluation as recurrent stone formers do. Similar findings were reported in a series of 182 patients; half of the patients had hypercalciuria or hyperuricosuria, whereas approximately 20% had a systemic disorder that predisposed the patients to the formation of calculi (Strauss et al, 1982). The remainder, 29.1%, had no metabolic disorder. Surprisingly, the incidence of hypercalciuria was actually lower in the patients with multiple stones, although not dramatically so. Patients with single stones tended to be older when they passed their stones and required a greater rate of intervention for treatment of the calculus. The recurrence for both groups of patients was similar (around 10% at 3 years). Since the authors did not note substantial differences between solitary and recurrent stone disease, they recommended that first-time stone formers be evaluated like patients with recurrent stone disease.

However, this approach has been partially refuted by Yagisawa and coworkers (1998), who noted that men with recurrent calculi had a higher rate of metabolic derangements than did first-time stone formers. Whereas women had a trend toward the same pattern, this achieved statistical significance only with regard to decreased levels of urinary citrate (hypocitraturia) (Yagisawa et al, 1998). A more complete discussion of the economic aspects surrounding the decision to perform a metabolic evaluation is found later in this chapter.

Importantly, the formation of a first stone may be the harbinger of a more severe underlying systemic disorder, such as renal tubular acidosis, bone disease, or hypercalcemia due to hyperparathyroidism. In such patients, metabolic evaluation is justified solely to make the correct diagnosis to prevent extrarenal complications. With the development of reliable parathyroid hormone assays, it is unacceptable to wait for bone loss before embarking on curative therapy. Whereas the clinical significance of normocalcemic hyperparathyroidism has been questioned and it is frequently simply observed, current practice favors the treatment of those with symptoms that can be attributed to the disorder (such as nephrolithiasis and osteoporosis) (Bilezikian and Silverberg, 2004).

The decision to thoroughly investigate a first-time stone former should ideally be shared by the physician and the patient. Some first-time stone formers will readily accept and follow conservative therapy; others may elect to undergo a thorough evaluation. It is reasonable to determine the extent of evaluation according to the estimation of potential or risk for recurrent stone formation (Smith, 1984). **Patients at higher risk for repeated episodes are those with a family history of stones and those with intestinal disease (particularly when it is causing chronic diarrheal states), pathologic skeletal fractures, osteoporosis, urinary tract infection, or gout.** In these patients, an extensive evaluation is recommended. Any patients with stones composed of cystine, uric acid, or struvite should undergo a complete metabolic workup.

All children should be required to undergo a complete investigation because they have been found to have a significant risk of underlying metabolic disturbances (Polito et al, 2000; Tekin et al, 2001; Pietrow et al, 2002; Coward et al, 2003; Bartosh, 2004). In addition, these young patients have more at stake; early, repeated episodes of urinary obstruction with a threat of urinary tract infection could put their developing kidneys at significant risk. To complicate matters, there is a lack of consensus regarding the safety of surgical intervention in these patients (Lottmann et al, 1995, 2000; Gough and Baillie, 2000; Brinkmann et al, 2001; Villanyi et al, 2001). It is no surprise that the performance of an open anatrophic pyelolithotomy can have a deleterious effect on a child's future renal function, causing a decline of 6% to 16% on nuclear scintigraphy (Gough and Baillie, 2000). It is additionally disconcerting that 20 years after its introduction, authors do not agree on the risks associated with exposure of developing renal parenchyma to shockwave energy.

African Americans have been observed to have a significantly lower incidence of nephrolithiasis than their white counterparts. Indeed, in a study by Sarmina and colleagues (1987), white patients had urinary calculi three to four times as often as black subjects did. However, the male-to-female prevalence is not as drastic as it is for white subjects (1 to 1.55 compared with 2.3 to 1, respectively). This finding is taken one step further in a study by Michaels and colleagues (1994), in which the women made up approximately 60% of the African American patients, thereby reversing the expected gender ratio. However, Sarmina found a higher incidence of infection calculi in the African American population in his study, and these stone types were excluded from analysis in the study by Michaels. Following the assumption that a lower incidence of calculi might imply a significant risk of a metabolic or anatomic abnormality in those patients who still manage to make calculi, it seems reasonable to advocate the performance of a metabolic evaluation for all patients of African American descent. This suggestion is supported by a study that assessed the underlying metabolic abnormalities of nonwhite stone formers. **African Americans, Asians, and Hispanics have a surprisingly similar incidence of underlying metabolic disturbances compared with white stone formers. These results suggest that dietary and environmental factors may be as important as ethnicity in the etiology of stone disease** (Beukes et al, 1987; Maloney et al, 2005).

Regardless of whether a particular, individual patient requires a full metabolic evaluation, it is prudent to perform at least a screening evaluation to assess for underlying systemic syndromes that may cause recurrent calculi and extrarenal complications. This assessment should also screen for those patients at an increased risk for stone recurrence as outlined in the preceding paragraphs (Table 43–1).

Table 43–1. Indications for a Metabolic Stone Evaluation

Recurrent stone formers
Strong family history of stones
Intestinal disease (particularly chronic diarrhea)
Pathologic skeletal fractures
Osteoporosis
History of urinary tract infection with calculi
Personal history of gout
Infirm health (unable to tolerate repeated stone episodes)
Solitary kidney
Anatomic abnormalities
Renal insufficiency
Stones composed of cystine, uric acid, or struvite

Table 43–2. Abbreviated Evaluation of Single Stone Formers

History
Underlying predisposing conditions (as in Table 43–1)
Medications (calcium, vitamin C, vitamin D, acetazolamide, steroids)
Dietary excesses; inadequate fluid intake or excessive fluid loss
Multichannel blood screen
Basic metabolic panel (sodium, potassium, chloride, carbon dioxide, blood urea nitrogen, creatinine)
Calcium
Intact parathyroid hormone
Uric acid
Urine
Urinalysis
pH > 7.5: infection lithiasis
pH < 5.5: uric acid lithiasis
Sediment for crystalluria
Urine culture
Urea-splitting organisms: suggestive of infection lithiasis
Qualitative cystine
Radiography
Radiopaque stones: calcium oxalate, calcium phosphate, magnesium ammonium phosphate (struvite), cystine
Radiolucent stones: uric acid, xanthine, triamterene
Intravenous pyelography: radiolucent stones, anatomic abnormalities
Stone analysis

KEY POINTS: SELECTION OF PATIENTS FOR METABOLIC EVALUATION

- The incidence of nephrolithiasis is increasing.
- The historic male predominance of stone formers is disappearing.
- Racial protection may be overcome by dietary indiscretions.
- Children are generally evaluated because of concerns about renal damage and long-term sequelae of stone recurrence.

Abbreviated Protocol for Low-Risk Single Stone Formers

In single stone formers without increased risk, the following abbreviated protocol may be applied (Table 43–2). A thorough medical history should be obtained for any underlying conditions that may have contributed to the stone disease. Because of the association between bowel disease and calcium oxalate nephrolithiasis (enteric hyperoxaluria), a careful history of bowel habits and bowel disease should be sought (Smith et al, 1972; Bohles et al, 1988; Lindsjo et al, 1989; McConnell et al, 2002; Worcester, 2002; Parks et al, 2003b). This includes questions about chronic diarrhea that could be caused by inflammatory bowel disease (Crohn's disease, ulcerative colitis) or irritable bowel syndrome. A history of gout should be sought as this finding may predispose the patient to hyperuricosuria or gouty diathesis with either uric acid calculi or calcium oxalate stone formation (Grover and Ryall, 1994; Khatchadourian et al, 1995; Kramer and Curhan, 2002). As described by Pak and colleagues, patients with a history of diabetes mellitus may be at an increased risk for development of a gouty diathesis, with altered ammonium management, acidic urine, and a predisposition for a mixture of calcium oxalate and uric acid stones (Pak et al, 2003c).

In addition, information should be gleaned about the patient's dietary habits, including fluid consumption and excessive intake of certain foods as well as all medications taken. A social history may provide obvious clues about the hydration status of these patients. Do they have access to fluids on a regular basis or are they sequestered in an environment that does not allow easy access to fluids (such as along an assembly line or in the operating suite)? Do they perform daily tasks that would increase the insensible loss of fluids (manual labor, prolonged outdoor exposure)? Some have suggested that a sedentary lifestyle may actually increase the risk of stone formation above that of those who perform manual labor. Even a brief family history will reveal a potential genetic predisposition to urinary calculi if there is a history of close relatives affected by nephrolithiasis. Age at onset of the patient or of affected relatives may give clues about genetic disorders, such as autosomal recessive cystinuria.

A multichannel blood screen can be helpful in identifying certain systemic problems. These include primary hyperparathyroidism (high serum calcium and low serum phosphorus levels), renal phosphate leak (hypophosphatemia), uric acid lithiasis (hyperuricemia), and distal renal tubular acidosis (hypokalemia, decreased carbon dioxide).

Voided urine specimens should be obtained for comprehensive urinalysis and culture. The urinalysis should include pH determination (preferably with an electrode). A pH above 7.0 is suggestive of infection lithiasis or of renal tubular acidosis; a pH below 5.5 suggests uric acid lithiasis secondary to gouty diathesis.

The urine sediment should be examined for crystalluria since particular crystal types may give a clue as to the composition of stones the patient is forming (Fig. 43–1). Tetrahedral "envelopes" are seen in calcium oxalate lithiasis; rectangular "coffin-lid" crystals are often seen in patients with struvite calculi. Hexagonal crystals confirm cystinuria; uric acid crystals may be seen as amorphous fibers or as irregular plates. The microscopic appearances of common calculi are summarized in Table 43–3.

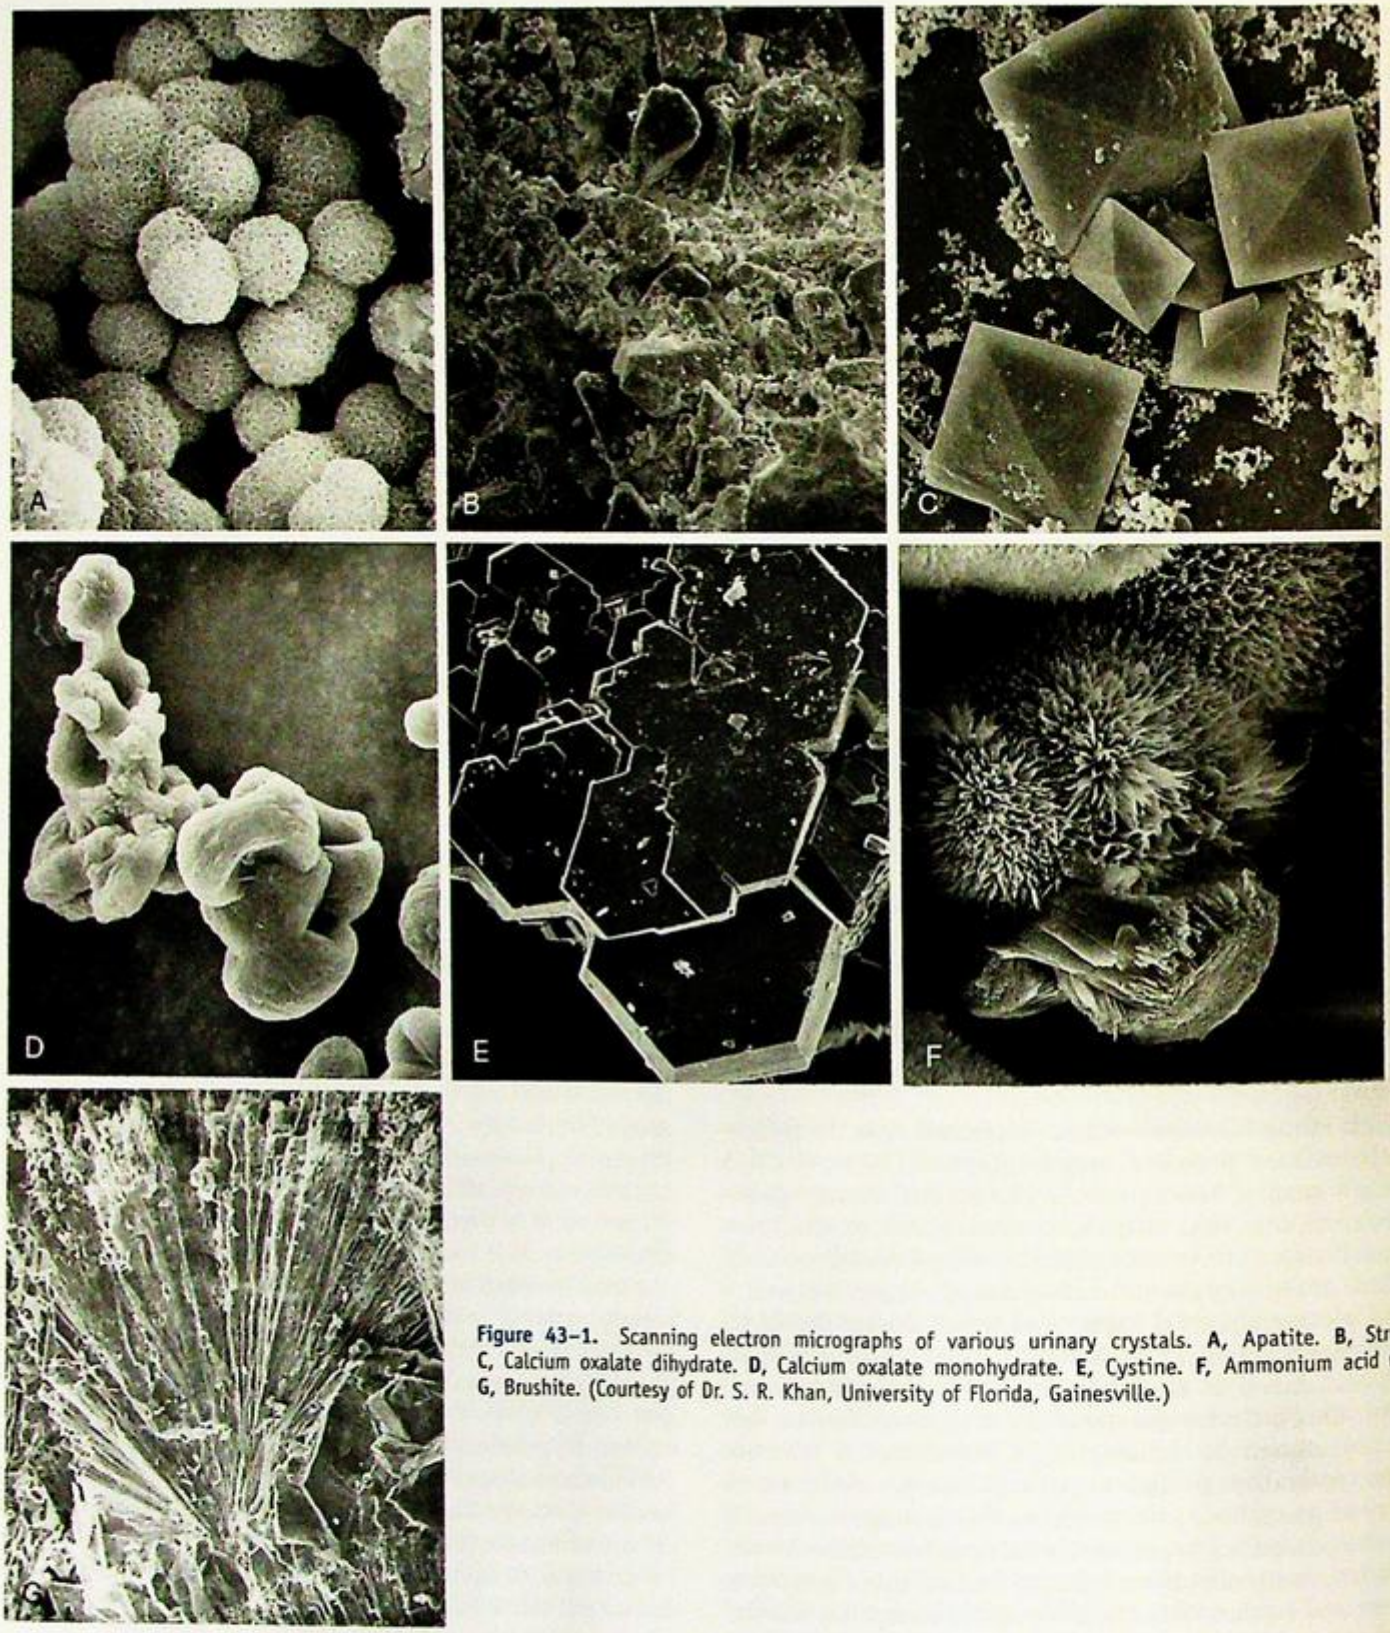

Figure 43–1. Scanning electron micrographs of various urinary crystals. **A,** Apatite. **B,** Struvite. **C,** Calcium oxalate dihydrate. **D,** Calcium oxalate monohydrate. **E,** Cystine. **F,** Ammonium acid urate. **G,** Brushite. (Courtesy of Dr. S. R. Khan, University of Florida, Gainesville.)

Urine cultures are performed if there is a suspicion of infection-related calculi or if there are signs or symptoms of a urinary tract infection. A culture that is positive for urea-splitting organisms such as *Proteus, Pseudomonas,* and *Klebsiella* would help explain the formation of a struvite calculus. A positive culture will also warrant therapy with appropriate antibiotics before the initiation of any surgical procedure to remove the stone. The surgical management of a calculus during an active infection will place the patient at great risk for bacteremia or sepsis. **Unfortunately, many infected calculi will harbor bacteria even after treatment with broad-spectrum antibiotics.** Indeed, Rocha and Santos (1969)

Table 43–3. Microscopic Appearance of Common Urinary Calculi

Chemical Type	*Appearance*
Calcium oxalate monohydrate	Hourglass
Calcium oxalate dihydrate	Envelope, tetrahedral
Calcium phosphate–apatite	Amorphous
Brushite	Needle shaped
Magnesium ammonium phosphate (struvite)	Rectangular, coffin-lid
Cystine	Hexagonal
Uric acid	Amorphous shards, plates

demonstrated that bacteria can still be cultured from the interior of a calculus despite its being soaked in iodine and alcohol for 6 hours. Furthermore, McAleer and associates (2003) have shown that infection calculi contain large quantities of endotoxin after disintegration. In a comparison of infected and noninfected calculi, infected stones contained 36 times more endotoxin. Half of the infected calculi grew bacteria on culture that were different from those of the preoperative urine specimens. The same investigators have described how endotoxin can cause a vascular collapse as it induces physiologic changes consistent with septic shock (McAleer et al, 2002).

Abdominal radiographs should be obtained to document the existence of any residual stones within the urinary tract. The radiopacity of any existing stones may suggest the type of stones that are present. Whereas magnesium ammonium phosphate and cystine stones are often radiopaque, they are not as dense as calcium oxalate or calcium phosphate stones. A plain abdominal film is also useful in identifying nephrocalcinosis (suggestive of renal tubular acidosis) and staghorn calculi (likely due to infection lithiasis). An intravenous pyelogram may be obtained to confirm the presence of radiolucent stones and also to identify any anatomic abnormalities that may predispose the patient to stone formation. The radiographic evaluation of a patient during a metabolic workup for stone disease will differ from an approach taken during an episode of acute renal colic. In these instances, patients are frequently examined with multislice, non–contrast-enhanced computed tomography (CT), which is able to quickly image the entire collecting system in a rapid sequence (Fig. 43–2) (Smith et al, 1995; Sommer et al, 1995; Katz et al, 1996; Fielding et al, 1997).

Available stones should be analyzed to determine their crystalline composition. The presence of uric acid or cystine suggests gouty diathesis or cystinuria, respectively. The finding of struvite, carbonate apatite, and magnesium ammonium phosphate suggests infection lithiasis. A predominance of a hydroxyapatite component suggests renal tubular acidosis or primary hyperparathyroidism and warrants an assessment of basic electrolytes. Stones composed of pure calcium oxalate or mixed calcium oxalate and hydroxyapatite are less useful diagnostically since they may occur in several entities, including absorptive and renal hypercalciuria, hyperuricosuric calcium nephrolithiasis, enteric hyperoxaluria, hypocitraturic calcium nephrolithiasis, and low urine volume (Kourambas et al, 2001; Pak et al, 2004).

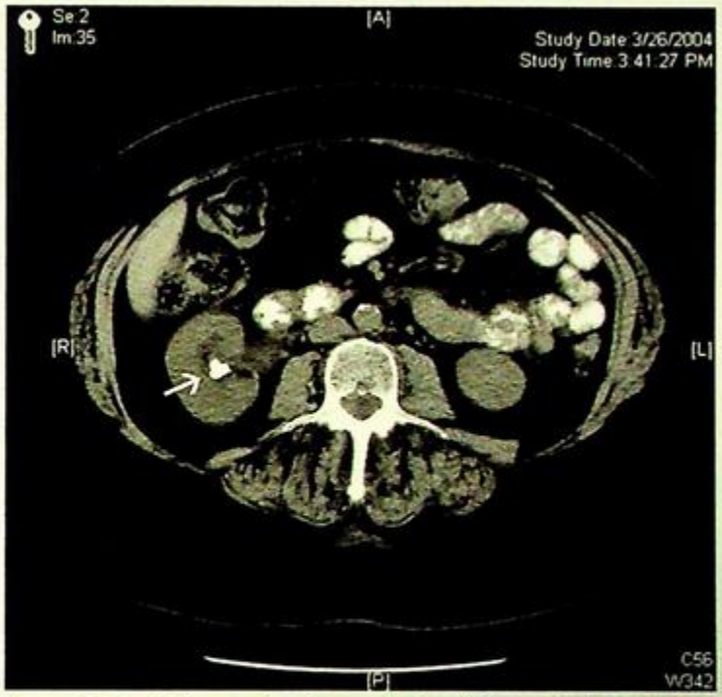

Figure 43–2. CT image of a urinary calculus. All stones (with the exception of some medication calculi) appear as dense, white objects within the urinary collecting system.

KEY POINTS: ABBREVIATED PROTOCOL FOR LOW-RISK SINGLE STONE FORMERS

- A complete history should be obtained from all stone formers.
- Patients should be screened for medical diseases that predispose to calculi.
- Serum metabolic panel and urinalysis are performed.
- Urine microscopy for crystals may provide clues to diagnosis.
- Stone analysis can remove the need for further evaluation.
- Basic radiography (plain films) screens for remaining calculi.

Extensive Diagnostic Evaluation

A more extensive evaluation, directed at the identification of underlying physiologic derangements, should be performed in patients with recurrent nephrolithiasis as well as in stone formers at increased risk for further stone formation.

Pak initially described an extensive outpatient (ambulatory) evaluation in 1980 and subsequently made minor revisions to help simplify the process (Pak et al, 1980a; Levy et al, 1995). The basic strategy involves two outpatient visits, and most of the required laboratory analyses can be performed in a routine clinical laboratory; only a few of the

specialized techniques are performed in a more sophisticated laboratory. **The entire schedule of visits and tests is outlined in Table 43–4.**

Before and throughout the period of evaluation, the patient is instructed to discontinue any medication that is known to interfere with the metabolism of calcium, uric acid, or oxalate. These medications include vitamin D, calcium supplements, antacids, diuretics, acetazolamide, and vitamin C. Any current medication for stone treatment (thiazides, phosphate, allopurinol, or magnesium) should be discontinued as well to better understand the patient's baseline physiology (and pathophysiology). Three 24-hour urine samples are collected. The first two 24-hour specimens are obtained with the patient on a random diet, which is reflective of the usual dietary intake. It is important to stress to the patients that they are not to "perform" during the urine collections. An attempt on the patient's part to suddenly eat well or to increase fluid consumption for the sake of the test will only mask the underlying cause of the stone disease.

Most patients will require detailed instructions on the proper collection of a complete 24-hour urine specimen. The patient should choose a day when all voids can be completely captured and when the specimen will represent a "typical" day. The first morning void is discarded, since this represents urine from the previous night and may not have had a predictable starting point. From that point on, all urine must be collected in the appropriate laboratory-provided container. The canister may need to be kept on ice or preservatives should have been added according to the requirements of the specific laboratory. When the patient awakens the next morning, the first morning void is collected with the rest of the specimen, thereby completing a full 24 hours. Total urinary creatinine should be measured to provide an internal check. Males will be expected to have produced approximately 15 to 20 mg of creatinine for every kilogram of body weight during the 24-hour period. Females generally have less muscle mass and therefore will typically produce 10 to 15 mg of creatinine for every kilogram of body weight in 24 hours. Significant aberrations in total creatinine excretion from these estimated values imply incomplete collection, overcollection, greater than expected muscle mass, or less than expected muscle mass.

A third 24-hour sample may be collected after 1 week with the patient on a calcium-, sodium-, and oxalate-restricted diet. This dietary restriction is imposed to standardize the diagnostic tests, to better assess the cause of hypercalciuria, and to prepare for the "fast and calcium load" test, which is performed on the second visit. Blood samples are obtained on both visits as outlined in Table 43–4.

Fast and Calcium Load Test

A fast and calcium load study is performed on the morning of the second visit (Pak et al, 1975). The purpose of this exercise is to help delineate various causes of hypercalciuria. As explained in Chapter 42 in greater detail, some patients are too efficient at absorbing calcium from the alimentary canal (absorptive hypercalciuria, types 1 and 2), whereas others suffer from a constant loss of calcium from the renal tubules (renal calcium leak). A third subset of patients has an overabundance of circulating parathyroid hormone, usually from a single parathyroid adenoma, with a constant loss of calcium and phosphate (resorptive hypercalciuria or primary hyperthyroidism).

To differentiate between these three hypercalciuric subtypes, it is essential that the patients have adhered to the restricted diet for at least 7 days before this testing to eliminate the effects of absorbed calcium on fasting calcium excretion. To ensure adequate hydration, distilled water (300 mL) is taken 12 hours and 9 hours before the calcium loading. Other than water ingestion at these times, the patients are to be fasting. Two hours before the scheduled calcium loading, patients empty the bladder completely, discard this urine, and drink an additional 600 mL of distilled water. All urine produced during the next 2 hours is collected as a pooled sample before an oral calcium load is taken (fasting urine). After the 2-hour fasting urine collection has been completed, a 1-g oral calcium load is administered by 250 mL of a liquid synthetic diet (Calcitest) as a carrier solution. This synthetic "meal" is prepared by adding 500 mL of water to a can of Calcitest. Since 250 mL of the synthetic meal contains only 100 mg of calcium, 39 mL of Neocalglucon (900 mg of calcium) must be added to bring the total calcium up to 1 g. The final mixture should be taken slowly during a 5- to 10-minute period.

For the next 4 hours, urine is again collected as a pooled sample (post-load urine). Both fasting and post-load samples are then assayed for calcium and creatinine. Fasting urinary calcium excretion is expressed as milligrams per deciliter of glomerular filtrate since it is reflective of renal function. To obtain this unit of measurement, the urinary calcium concentration (in milligrams per milligram of creatinine) is multiplied by the serum creatinine concentration (in milligrams per deciliter). Normal fasting urinary calcium excretion is less

than 0.11 mg per deciliter of glomerular filtrate. The post-load urinary calcium excretion is best expressed as milligrams per milligram of creatinine as it is a function of a fixed oral calcium load. The normal value for this measurement is less than 0.2 mg calcium per milligram of creatinine.

Most clinicians have moved away from the performance of a comprehensive metabolic evaluation that entails a calcium loading test. As explained later, the treatment of both absorptive hypercalciuria and renal leak hypercalciuria is now similar. With little therapeutic distinction, there is no longer as much of an incentive to discriminate between either type of hypercalciuria. **However, differentiation between absorptive and renal hypercalciuria is essential if one plans to prescribe a calcium-binding resin to a patient with absorptive hypercalciuria** (see "Selective Medical Therapy for Nephrolithiasis" later in this chapter).

KEY POINTS: EXTENSIVE DIAGNOSTIC EVALUATION

- A complete metabolic evaluation may be obtained on an outpatient basis.
- Calcium fast and load tests can discriminate between the various forms of hypercalciuria.
- Routine performance of calcium fast and load tests is not required to complete a metabolic evaluation.

Simplified Metabolic Evaluation

The extensive ambulatory protocol affords the physician a high diagnostic yield and is reliable. Unfortunately, many practicing physicians have found this protocol to be time-consuming and difficult to perform because of the inability to find a reliable local laboratory or perceived complexities of the evaluation protocol. Indeed, the full evaluation does entail several office visits and requires strict adherence to fluid protocols during the calcium fast and load tests.

Several authors have suggested a more simplified approach that uses the same standard principles and procedures as the full outpatient evaluation. These simplified protocols typically do not include the calcium fast and loading tests and can often be performed in one office visit. Rivers and colleagues (2000) have recommended the collection of two separate 24-hour urine specimens. One is collected while the patient is on a restricted diet; the other allows a random (typical) diet. Such manipulation is well tolerated by the patient and may allow identification of the various types of hypercalciuria with reasonable certainty.

Pak has also recognized the cumbersome nature of a full evaluation and has made similar recommendations (Pak, 1997). On the basis of the findings of a single 24-hour urine collection, patients are evaluated and treated without all steps of fasting and loading calcium challenges. Separation into complicated and uncomplicated calcium stone disease is made on the basis of the presence or absence of normocalcemia, normouricemia, or calcium stones and the absence of urinary tract infection, bowel disease, or marked hyperoxaluria. Uncomplicated calcium stone disease, represented by the majority of patients, is further separated into a hypercalciuric group and a normocalciuric group. Medical therapy is then based on this distinction.

Lifshitz and colleagues (1999) have also advocated a less complex approach. All patients undergo a basic metabolic screening in search of systemic disorders that could pose a long-term health risk. They suggest that all patients should be advised about conservative nonspecific preventive measures. High-risk patients should have a more extensive metabolic evaluation based on two 24-hour urine samples.

The cornerstone of these simplified protocols has been the development of a urine preservation method that allows collection of urine without refrigeration. The patient is then able to submit an aliquot to a central laboratory for the analysis of various stone-forming substances (Nicar et al, 1987). The urine constituents most commonly assayed include calcium, oxalate, citrate, total volume, sodium, magnesium, potassium, pH, uric acid, and sulfate. Whereas most of these parameters are self-evident, sulfate is added to the list to assess the volume of protein loading from animal meat. From such determinations, the urine saturation with respect to stone-forming salts can be calculated.

At present, there are two private companies that offer laboratory services focused on simplified, accurate 24-hour urine assessment for stone-forming risk factors—Mission Pharmacal (San Antonio, Texas) and LithoLink (Chicago, Illinois). Both provide collection containers with chemical preservatives (obviating iced storage and transport), and both laboratories extrapolate 24-hour cumulative data from the submission of a small aliquot of the entire collection. After the values of all urine constituents and saturations have been determined, the physician receives a computerized printout that provides a numeric display of the test results (Fig. 43–3). A graphic display of this information may also be generated, highlighting the increased or reduced risk for each environmental, metabolic, or physicochemical factor (Fig. 43–4). These results should aid the physician in formulating a metabolic and physiologic diagnosis. However, it is usually not possible to make a definitive diagnosis of a particular metabolic derangement without further testing. For example, it is desirable to confirm hypocitraturia or hyperuricosuria by repeated measurements. In addition, whereas this graphic analysis will demonstrate hypercalciuria, routine 24-hour urine analysis is not able to differentiate between the different forms of hypercalciuria.

There is controversy about the necessity of collecting two separate 24-hour urine specimens. As noted earlier, Rivers has advocated the collection of two samples on different diets (random and restricted) (Rivers et al, 2000). Assuming that the patient complies, these data may be able to discern between type 2 absorptive hypercalciuria and renal leak (hypercalciuria disappears on the restricted diet in type 2 absorptive hypercalciuria). Researchers from Dallas have suggested that only one single 24-hour collection is required (Pak et al, 2001). Their study retrospectively reviewed and compared the results of two 24-hour urine samples that were collected on random diets. They noted no significant difference in the excretion of urinary calcium, oxalate, uric acid, citrate, pH, total volume, sodium, potassium, sulfate, or phosphorus. They concluded that the reproducibility of urinary stone risk

factors was adequate in repeated samples, enough so that therapy would not have been altered.

Conversely, Parks and colleagues from Chicago have noted significant disparities between two separate collections (Parks et al, 2002). More than 1000 patients were examined from both private practice and academic settings. They noted that within nearly 70% of the comparisons, there were large enough differences such that the standard deviation would contain clinically relevant disparities. The authors therefore concluded that relying on one specimen alone could easily lead to misdiagnosis and, consequently, mismanagement.

The "normal limits" cited on commercially available urine analysis packages may not be the same as those normal values that have been quoted previously. Therefore, one should pay close attention to those patients who may fall in the "gray zone" when a commercially available urine analysis package is used.

KEY POINTS: SIMPLIFIED METABOLIC EVALUATION

- A simplified metabolic evaluation has been established.
- Commercial laboratories may facilitate the collection of 24-hour urine studies.
- There is no consensus regarding the need for one versus two 24-hour urine collections during an initial evaluation (although the authors prefer two collections).

CLASSIFICATION OF NEPHROLITHIASIS AND DIAGNOSTIC CRITERIA

With use of an ambulatory protocol, the etiology of nephrolithiasis can be classified into 12 separate categories reflecting specific physiologic derangements. The details regarding the physiology and pathophysiology of these distinct entities are included in Chapter 42. These categories are listed in Table 43–5 along with the relative frequency of their occurrence as noted by Pak and colleagues at a dedicated stone clinic in an academic medical center (Levy et al, 1995). An argument can be made that these relative incidences may not be representative of the general population for two reasons. First, referral to an academic center may imply a more serious version of stone disease and may therefore represent a selection bias. Second, recognizing that there are at least some regional variations of stone incidence (Harvey et al, 1990), this particular population of patients may be distinctly different from those populations in different regions of the United States and other regions of the world.

Calcium-Based Calculi

Hypercalciuria (>200 mg/day)

The classification of nephrolithiasis recognizes three broad categories of hypercalciuria.

Absorptive Hypercalciuria. Absorptive hypercalciuria involves an increase in the amount of calcium that is absorbed by the intestinal tract. In absorptive hypercalciuria type 1, this increased absorption will occur regardless of the amount of calcium in the patient's diet. Therefore, these subjects will demonstrate an increased urinary excretion of calcium on both the fasting and the loading specimens. In contrast, patients with absorptive hypercalciuria type 2 will have a normal amount of urinary calcium excretion during calcium restriction but will show elevations during their regular diet. Patients with both subtypes of absorptive hypercalciuria will have normal serum calcium concentration and a normal level of circulating intact parathyroid hormone (iPTH). In fact, **these patients often demonstrate a low iPTH**

Table 43–5. Classification of Nephrolithiasis

	Percentage	
	Sole Occurrence	*Combined Occurrence*

Table 43–6. Differential Diagnosis of Hypercalciuria

	Absorptive	*Renal*	*Resorptive*
Serum calcium	Normal	Normal	Elevated
Parathyroid function	Suppressed	Stimulated (secondarily)	Stimulated (primarily)
Fasting urinary calcium	Normal	Elevated	Elevated
Intestinal calcium absorption	Elevated (primarily)	Elevated (secondarily)	Elevated (secondarily)

level as a result of suppression from a constant abundance of available serum calcium.

Renal Hypercalciuria. Renal hypercalciuria (also known as renal leak) is thought to be due to a wasting of calcium by the functioning nephron. The details of this process and various hypotheses are outlined in Chapter 42. As a result of constant loss of calcium from the distal tubules, these patients will demonstrate hypercalciuria during all phases of fasting, loading, or restriction of dietary calcium. **Most patients with renal hypercalciuria will have a normal serum calcium concentration but may exhibit a mild elevation of iPTH as the regulatory systems attempt to "keep up" with the constant loss of calcium.**

Resorptive Hypercalciuria (Primary Hyperparathyroidism). Patients with this disorder suffer from an overproduction of parathyroid hormone from either one dominant adenoma or diffuse hyperplasia of all four glands. The hallmark of this disorder is the persistence of increased urinary calcium during all parts of the dietary calcium manipulations. In addition, these patients frequently demonstrate hypercalcemia and elevations of parathyroid hormone. The measurement of only the intact portion of the hormone (iPTH) has avoided confusion from the measurement of fragments of the same molecule (Kao et al, 1982; Nussbaum et al, 1987) and has greatly enhanced the ability to make this diagnosis.

Unfortunately, some patients may have normocalcemic hyperparathyroidism. These patients may be difficult to distinguish from those with renal leak hypercalciuria, during which serum calcium concentration will be normal but a mild elevation of the iPTH can occur, causing a secondary hyperparathyroidism. In these instances, the patients can be treated with a 2-week course of a thiazide diuretic, such as chlorthalidone (25 mg daily). If the patient actually suffers from renal leak, the calcium loss should be suppressed and the iPTH level should return to normal (Aroldi et al, 1979; Barilla and Pak, 1979; Zechner et al, 1981). Those with true primary hyperparathyroidism will continue to circulate elevated levels of iPTH and may become mildly hypercalcemic, although this feature has been debated in the literature (Klimiuk et al, 1981; Farquhar et al, 1990; Strong et al, 1991).

Idiopathic Hypercalciuria. Idiopathic hypercalciuria can be found both in normal people and among stone formers (Coe et al, 1979). These patients may demonstrate elevated amounts of urine calcium in all phases of the dietary calcium manipulation but will not demonstrate serum abnormalities. **On a cautionary note, this term does not always enjoy a strict definition and is sometimes substituted to describe those patients with hypercalciuria who have not undergone further evaluation to discriminate between the various subcategories.** Although this diagnosis is not as "clean" as possible, it represents a more pragmatic approach to hypercalciuria, since the treatment for absorptive and renal hypercalciuria is often the same (as outlined later in this chapter). Table 43–6 summarizes the laboratory parameters that help delineate the various types of hypercalciuria.

KEY POINTS: HYPERCALCIURIA

- Hypercalciuria can be divided into three causes: excessive gastrointestinal absorption, renal tubular leak, hyperparathyroidism.
- Idiopathic hypercalciuria refers to unknown etiology or unevaluated etiology.

Hyperuricosuric Calcium Nephrolithiasis

Patients with hyperuricosuria may be prone to the formation of calcium oxalate calculi through a process called heterogeneous nucleation (also referred to as epitaxy) (Coe and Kavalach, 1974; Pak and Arnold, 1975; Coe, 1980). The details of this process are outlined in Chapter 42. These patients give a history of calcium oxalate nephrolithiasis and may have a history of hyperuricemia with symptomatic gout. On metabolic evaluation, they will demonstrate hyperuricosuria (>800 mg/day).

Hyperoxaluria (>40 mg/day)

Enteric Hyperoxaluria. This entity is often one of the most striking findings during a metabolic evaluation because it involves multiple anomalies, all a result of chronic diarrhea with its attendant dehydration and bicarbonate losses (Worcester, 2002). The main hallmark is, of course, hyperoxaluria with values that can be quite high (i.e., >50 mg/day). As a result of intestinal fluid loss, patients will often exhibit low urine volumes. The bicarbonate loss (and the consumption of citrate as an acid-base buffer) can also cause a low urine pH and hypocitraturia (Rudman et al, 1980). Urine calcium excretion is often low because of the saponification of oral calcium with poorly absorbed fats in the intestinal tract.

Primary Hyperoxaluria. This disorder is caused by an inborn error of metabolism. The more common variant, type 1, is due to a defect of the enzyme alanine-glyoxylate transaminase through an autosomal recessive inheritance. Type 2 is a less common variant thought secondary to a defect in D-glycerate dehydrogenase and glyoxylate reductase. Both of these types usually present during childhood with early stone formation, tissue deposition of oxalate (oxalosis), and renal failure due to nephrocalcinosis. Death often occurs before the age of 20 years in untreated patients (Williams and Smith, 1968; Leumann and Hoppe, 1999). Metabolic evaluation reveals high urine oxalate excretion as well as high serum levels of this molecule.

Mild Metabolic Hyperoxaluria (Dietary). The importance of dietary oxalate and the possibility of an inheritable sensitivity to oral oxalate loads are debated and have already been discussed in the preceding chapter. Just as interesting is the possibility that a deficiency of a bacterium found within intestinal flora *(Oxalobacter formigenes)* could be a factor in the formation of calcium oxalate calculi (Allison et al, 1986; Sidhu et al, 1999; Troxel et al, 2003). Regardless of the underlying etiology, some patients without primary hyperoxaluria or without a history of bowel disorders will demonstrate an elevation of oxalate in the 24-hour urine collection. A review of the patient's dietary habits may reveal a predisposition for those foods that are particularly high in oxalate. **Whereas this molecule is ubiquitous and cannot be avoided, certain foods can deliver substantial amounts of oxalate in one serving.** An abbreviated list of foods that are particularly high in oxalate is contained in Table 43–7 (Assimos and Holmes, 2000; Holmes and Assimo, 2004).

Hypocitraturic Calcium Nephrolithiasis (<550 mg, female; <450 mg, male)

There is some controversy about the definition of normal urinary citrate excretion. Women tend to have higher urinary citrate measurements than men do, particularly before menopause (Pak, 1990). Menon and Mahle (1983) define hypocitraturia as citrate excretion of less than 110 mg for men and 200 mg for women. Despite noting gender differences, Pak (1990) defined normal urinary citrate as more than 320 mg for both genders. In some of the earlier studies from Dallas, hypocitraturia was found in up to 50% of all patients evaluated, frequently in association with other abnormalities (Nicar et al, 1983). Parks and Coe (1986) have also noted the importance of urinary citrate for the prevention of calcareous stones and have set the limits of normal at higher values (men, >450 mg daily; women, >550 mg daily). Nevertheless, hypocitraturia is considered one of the more common metabolic diagnoses, probably second only to hypercalciuria. There are four causes of hypocitraturia:

Distal Renal Tubular Acidosis (Type 1). Patients may have either an acquired or an inheritable version of renal tubular acidosis, with the incomplete version representing a less serious clinical pattern. Regardless of the actual cause, the laboratory hallmark of this disease is a low urine citrate concentration (hypocitraturia) with an inappropriately high urine pH. Often, the measured 24-hour urine citrate will be quite diminished with values below 100 mg/day. The urine pH will be elevated to 6.5 or above. Hypokalemia is often evident on the serum studies, as is hyperchloremia. A non–anion gap acidosis may be present as well with carbon dioxide values in the mid teens (Preminger et al, 1985). First-void urine specimens can be evaluated to assess the urine pH and to screen for a renal tubular acidosis. Patients with renal tubular acidosis will be unable to acidify the urine overnight and should have a urine pH no lower than 5.5.

Distal renal tubular acidosis may present as an isolated entity or may be the secondary manifestation of a variety of systemic and renal disorders. More than two thirds of patients with distal renal tubular acidosis are adults, but children will occasionally be identified with this disorder. Infants generally present with vomiting or diarrhea, failure to thrive, and growth retardation. Children often present with metabolic bone disease and renal stones; adults frequently present with symptoms attributable to nephrolithiasis and nephrocalcinosis.

Up to 70% of adults with distal renal tubular acidosis have kidney stones (Caruana and Buckalew, 1988). Those patients with onset at an early age or with severe forms of the disorder may develop nephrocalcinosis and eventual renal insufficiency (Fig. 43–5). Renal tubular acidosis is more common in women, accounting for nearly 80% of all cases. Secondary renal tubular acidosis can be induced by many common urologic disorders that may also be sought after a diagnosis of acquired renal tubular acidosis. These include obstructive uropathy, pyelonephritis, acute tubular necrosis, renal transplantation, analgesic nephropathy, sarcoidosis, idiopathic

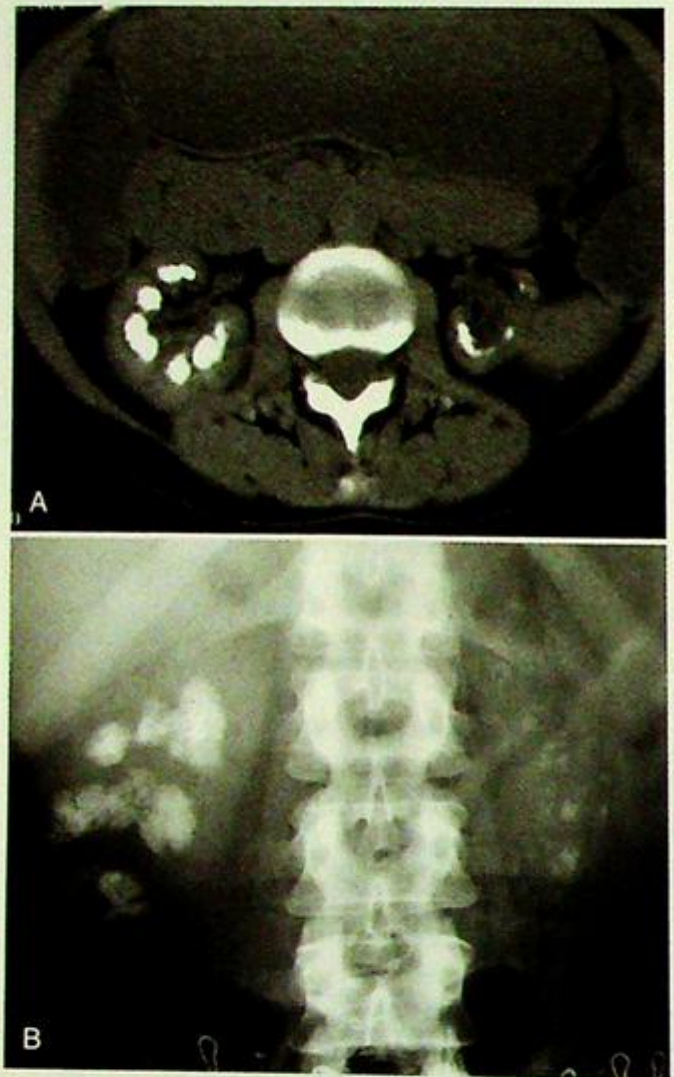

Figure 43–5. CT image (**A**) and plain film (**B**) of a patient with renal tubular acidosis and renal failure. Both kidneys demonstrate severe calcification of the medullary pyramids consistent with nephrocalcinosis. Notice the atrophic left kidney on the CT image.

hypercalciuria, and primary hyperparathyroidism (Buckalew, 1989) (Table 43–8).

Some patients will have an incomplete variant of the disease with less marked hypocitraturia and a more normal urine pH. Incomplete variants can be diagnosed with an ammonium chloride loading challenge. In this evaluation, the fasting patient is given 0.1 g of ammonium chloride per kilogram of body weight in crushed granules mixed with a soft drink. Subsequently, hourly measurements of urine pH and bihourly measurements of serum pH or bicarbonate are taken during 4 to 6 hours (Pohlman et al, 1984). If the serum pH falls below 7.32 or the bicarbonate level falls below 16 mmol/L but urine pH remains at or above 5.5, the diagnosis of incomplete distal renal tubular acidosis is confirmed. If at any time the urine pH falls below 5.5, the diagnosis of incomplete distal renal tubular acidosis is excluded (Preminger et al, 1985, 1987, 1988).

Chronic Diarrheal States. The laboratory findings in a patient with a chronic diarrheal disorder are similar to those in patients described with enteric hyperoxaluria. However, these patients do not tend to suffer from the bowel inflammation and subsequent heightened permeability to oxalate. Therefore, urinary oxalate may be mildly elevated, but usually not to the extent found in those patients with bowel resection or inflammatory disorders. These patients are likely to demonstrate moderate decreases in urinary citrate excretion with associated low urine volumes (Fegan et al, 1992; Caudarella et al, 1993; Worcester, 2002; Parks et al, 2003b).

Idiopathic hypercalciuria
Primary hyperparathyroidism

Thiazide-Induced Hypocitraturia. One of the side effects of thiazide therapy is hypocitraturia. This defect is presumably secondary to the hypokalemia and resultant intracellular acidosis that may develop after prolonged therapy with thiazides (Pak et al, 1985a). Such patients will demonstrate the effects of this medication. That is, they often have mild to moderate hypocitraturia and mild to moderate hypokalemia. Since thiazides are still widely used as a diuretic and for the management of hypertension, some patients may present with a stone episode after prolonged therapy with this medication. Patients with stone disease who are treated with thiazides for the control of hypercalciuria should be screened for these metabolic disturbances (Pak et al, 1985b).

Idiopathic Hypocitraturia. Patients with idiopathic hypocitraturia include all those with 24-hour urine citrate measurements less than 550 mg (males) or 450 mg (females) in the absence of any of the noted disease states. It is important to consider unrecognized incomplete renal tubular acidosis as a potential diagnosis, since this disorder carries with it a significant risk of long-term morbidity. In addition, a careful history should be taken to screen for bowel dysfunction.

KEY POINTS: HYPOCITRATURIA

- The definition of hypocitraturia may vary greatly.
- Severe hypocitraturia should immediately suggest renal tubular acidosis.
- Hypocitraturia frequently accompanies other diagnostic categories.

Hypomagnesiuric Calcium Nephrolithiasis (<80 mg)

Hypomagnesiuric calcium nephrolithiasis is characterized by low urinary magnesium concentration, hypocitraturia, and low urine volume. It is frequently associated with chronic thiazide therapy (Ljunghall et al, 1981; Preminger et

al, 1989). More commonly, inflammatory bowel disorders, particularly those that cause malabsorption, have been implicated in this process (Preminger et al, 1989). Excessive dependence on laxatives may also induce a pattern similar to a chronic diarrheal state (Dick et al, 1990; Soble et al, 1999). The importance of this disorder has been questioned, however, with the suggestion that the stone-risk association of hypomagnesiuria may actually be due to its effect on urinary citrate (Schwartz et al, 2001).

Uric Acid–Based Calculi

Gouty Diathesis

The pathophysiologic mechanism of uric acid nephrolithiasis is explained in detail in Chapter 42, but it does deserve some mention to better understand its diagnosis. Since there are no known inhibitors of uric acid crystallization, undissociated uric acid will precipitate when the urine becomes supersaturated. The sigmoidal solubility curve will predict that at a pH of 6.5, more than 90% of all uric acid is ionized and therefore soluble; 50% of uric acid will be soluble at a pH of approximately 5.5 (pKa) (Gutman and Yu, 1968). By definition, patients with gouty diathesis have a urine pH below 5.5.

It follows, then, that patients with gouty diathesis and uric acid calculi will tend to have lower urine pH than in normal subjects (Gutman and Yu, 1968). The 24-hour measurements of this molecule will often be more than 800 mg. Up to 20% of patients with gout will develop uric acid calculi, prompting examination of serum for hyperuricemia. Oftentimes, 24-hour urine collections can underestimate the total amount of uric acid if the specimen pH drops lower than 5.5. In this scenario, the uric acid forms precipitates and settles to the bottom of the collection container.

It should not be difficult to distinguish between those patients with hyperuricosuric calcium nephrolithiasis, who form calcium oxalate stones, and those with gouty diathesis, who can form either uric acid or calcium oxalate calculi. Patients with hyperuricosuric calcium nephrolithiasis present with normal urine pH and hyperuricosuria, accompanied sometimes by hypercalciuria. In contrast, those with gouty diathesis have a low fractional excretion of urate (that contributes to hyperuricemia) and low urine pH (that leads to increased amount of undissociated uric acid) (Khatchadourian et al, 1995; Pak et al, 2003c). The varying biochemical and physicochemical presentations of the two conditions can be ascribed to overindulgence with purine-rich foods in those with hyperuricosuric calcium nephrolithiasis and underlying primary gout in those with gouty diathesis (Pak et al, 2002b).

A dietary history should be obtained from all patients with uric acid calculi because they may have a tendency to purine gluttony (high intake of animal protein, specifically red meat). An astute clinician will at least give a brief consideration to the possibility of a neoplastic or myeloproliferative disorder. Patients with diabetes mellitus may also form uric acid calculi as a result of disorders in ammonium handling with subsequent low urine pH (Pak et al, 2003c).

Uric acid calculi can be notoriously radiolucent. Tomography may overcome this difficulty (Fig. 43–6), as can the acquisition of a non–contrast-enhanced renal CT. These stones frequently have an orange appearance, especially when they are viewed endoscopically. Uric acid stone formers can have a propensity to produce large volumes of very small calculi that may cause obstruction as they pass down the ureter.

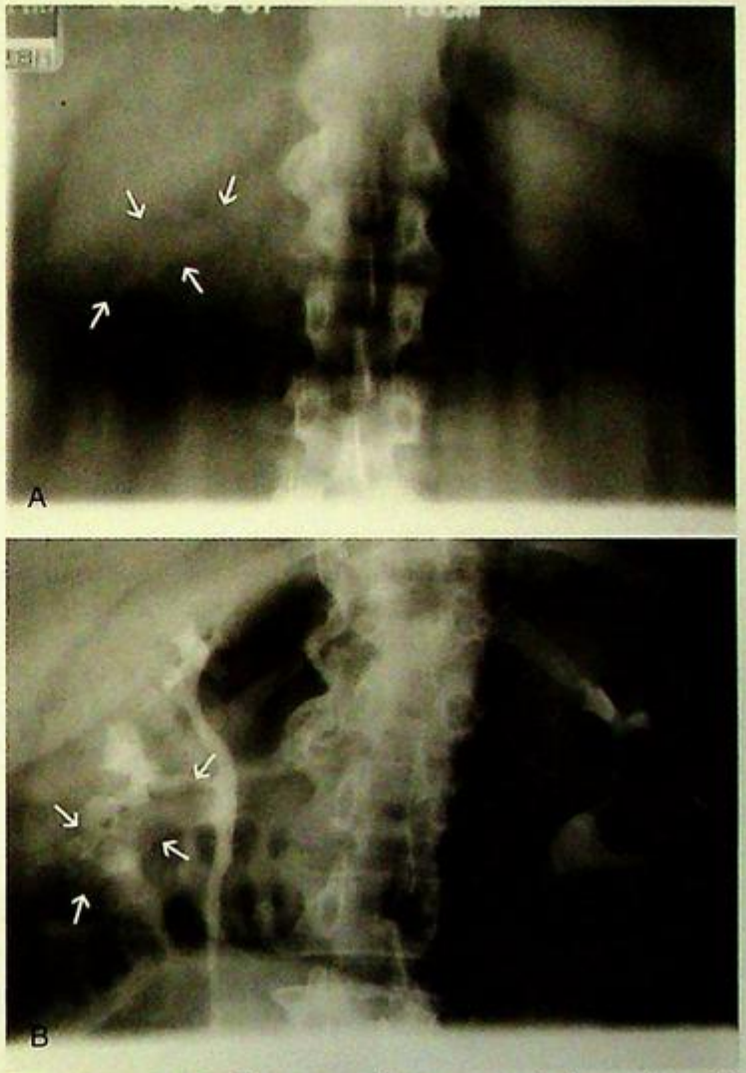

Figure 43–6. **A,** Plain film tomographic appearance of a lower pole partial staghorn uric acid calculus. **B,** The addition of intravenous contrast material demonstrates the stone as a filling defect during the excretory portion of the intravenous pyelogram.

KEY POINTS: URIC ACID–BASED CALCULI

- Hyperuricosuria may be associated with pure uric acid calculi or calcium oxalate calculi.
- Patients with gout may be predisposed to uric acid stones.
- Dietary indiscretion (purine gluttony) should always be suspected.

Cystinuria

Cystinuria is caused by an autosomal recessive error of transepithelial transport involving the intestine and the kidneys (Thier et al, 1965; Pak and Fuller, 1983). In this disease, patients are unable to reabsorb the dibasic amino acids cystine, ornithine, lysine, and arginine. The resultant **accumulation of cystine causes crystallization when concentrations rise above the saturation point (approximately 250 mg cystine per liter of urine)** (Pak and Fuller, 1983).

Patients with this disorder may present at a young age and may have affected first-degree relatives. The stones are often yellow and waxy in appearance and are relatively faint on plain radiography. Staghorn calculi or multiple, filled calyces are common (Fig. 43–7).

Historically, a diagnosis of cystinuria was made with a sodium nitroprusside spot test, which turned purple in the presence of cystine (Smith, 1977). Although this test is a helpful screening adjunct, quantitative measurements of cystine can be difficult to perform owing to interference from other sulfhydryl-containing compounds (such as medications used to treat this disorder) or significant variances with minor changes in urine pH or creatinine content (Pak and Fuller, 1983). Coe and colleagues have developed a more reliable method of cystine supersaturation measurement that may greatly aid in the diagnosis and especially the management of cystinuria (Nakagawa et al, 2000; Coe et al, 2001).

Cystinurics may also demonstrate additional metabolic anomalies on 24-hour urine studies (Sakhaee et al, 1989). In controlled dietary assessment of 27 patients with cystinuria, hypercalciuria was noted in 18.5% of patients, hyperuricosuria in 22.2%. Hypocitraturia was identified in 44.4% and was associated with defective renal acidification in 80% of the patients in whom it was tested. The authors noted that hypercalciuria, hyperuricosuria, and hypocitraturia frequently accompany cystinuria and speculated that these conditions might be renal in origin rather than a result of dietary or environmental aberrations. They further concluded that these unrelated anomalies may contribute to the formation of calcium and uric acid stones, which sometimes complicate cystine nephrolithiasis.

KEY POINTS: CYSTINURIA

- Cystinuria is manifested when concentrations exceed 250 mg/L.
- Cystinuria may be accompanied by other metabolic abnormalities.

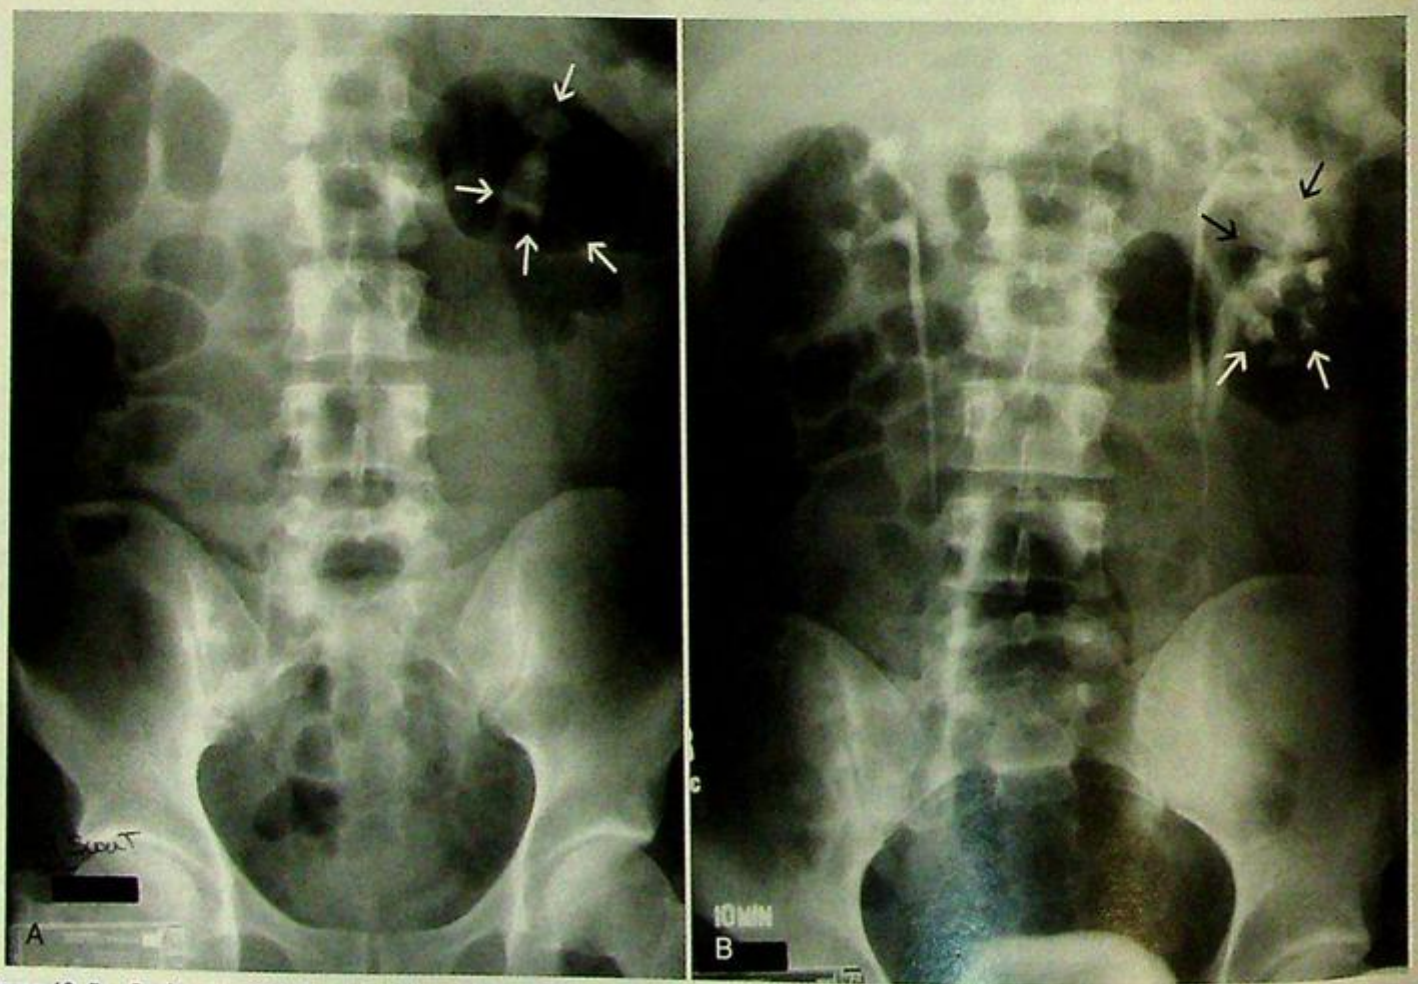

Figure 43–7. Cystine calculi are radiopaque on plain film but are less dense than other calcium-based calculi. Notice the stone within the lower pole of this duplicated system (**A**). Similar to uric acid stones, the cystine calculus is more clearly distinguished during the excretory phase of the intravenous pyelogram (**B**).

Infection Calculi (Struvite)

Struvite calculi form in the presence of alkaline urine (pH above 7.2) and in an environment rich in ammonia (Nemoy and Stamey, 1971). **The ammonia is thought to be produced through the splitting of urea by colonization with bacteria that produce urease.** The details of this process are presented in Chapter 42. Many bacterial organisms are able to produce this enzyme (Table 43–9), the most notorious of which is *Proteus mirabilis*. Although *Escherichia coli* is not able to spilt urea, it may be associated with struvite calculi in up to 13% of infections (perhaps through a metachronous infection).

Patients with these calculi may present with the symptoms of acute pyelonephritis, including fevers, chills, flank pain, dysuria, frequency, urgency, and malodorous, cloudy urine. Some patients may exhibit more chronic symptoms of malaise, fatigue, loss of appetite, and generalized weakness. Rarely, infections and obstruction have lasted long enough to produce a xanthogranulomatous pyelonephritis. Xanthogranulomatous pyelonephritis may cause the failure of an entire kidney or may affect just a portion. Spontaneous fistulas may develop to external surfaces or to peritoneal contents (Fig. 43–8).

Women are more often affected with struvite calculi than are men, probably because of an increased susceptibility to urinary tract colonization. A history of a foreign body (e.g., forgotten stent, suture material, staple) or of a neurogenic bladder may be noted. Struvite calculi can be quite large and often fill multiple calyces or even the entire collecting system (Fig. 43–9). **This stone type accounts for the majority of all staghorn calculi.** Urine cultures will often reveal a bacterial

Table 43–9. Organisms That May Produce Urease

pathogen, although a sterile urine culture does not preclude the sequestration of bacteria within the calculus itself.

There is debate about the incidence of associated metabolic anomalies in patients with struvite calculi. Resnick has advocated the performance of a metabolic evaluation for all patients with infection calculi because of a high incidence of positive findings. Conversely, Lingeman has studied 22 patients with infection calculi and noted that patients with pure struvite calculi were significantly less likely to have metabolic anomalies on 24-hour urine evaluation than were those patients with mixed compositions of struvite and calcium oxalate (Resnick, 1981; Lingeman et al, 1995).

KEY POINTS: INFECTION CALCULI (STRUVITE)

- Women produce more infection calculi than men do.
- The urine pH is usually above 6.5 to 7.0.
- Urea-splitting organisms are frequent.
- Infection calculi are the most likely to produce staghorn stones.

Low Urine Volumes (<2000 mL)

Some patients will exhibit few abnormalities on a complete evaluation other than low urine volumes. From a simplistic view, a low volume of urine output will concentrate the molecular components of crystal formation and raise the supersaturation risk. Intuitively, a patient with a relative state of dehydration will trend toward acidic urine, lowering the urine pH toward the pKa of uric acid (5.5) and potentially consuming titratable buffers such as citrate.

Table 43–10. Potential Causes of Erroneous 24-Hour Urine Collection

Error in collection technique (e.g., improper use of preservatives, ice)
Failure to collect a full 24 hours' worth of urine
Changes in the patient's diet for the sake of the study
Intermittent indiscretions in diet
Failure of specimen to accurately represent "typical" day
Bacterial contamination

Many patients with low urine volumes work in professions that induce high insensible losses of fluid (manual labor, outdoor exposure) (Sakhaee et al, 1987; Borghi et al, 1990, 1993a). Many work in environs that do not allow easy access to fluids and work breaks (assembly line, surgeons). A focused social history should elucidate these factors and allow proper identification and subsequent counseling.

No Disturbances

Pak has estimated that 3% of all patients undergoing a full metabolic evaluation will demonstrate no abnormalities (Pak et al, 1980a). **Whereas, on the surface, these patients may present less of a diagnostic challenge, there is always a concern that the collections are not representative of the patient's true metabolic state** (Table 43–10). This could be secondary to an error in collection technique, failure to collect a full 24 hours' worth of urine, changes in the patient's diet for the sake of the study, or intermittent indiscretions in diet. Furthermore, a 24-hour urine collection represents a pooled sample. Heavy oxalate loading at one particular meal or bolus replacement of fluids at the end of a workday may produce average values that look normal but actually hide periods of extreme urine parameters that promote stone formation. Finally, most patients will collect the requested 24-hour specimens on days when they are home and able to stay close to the collection container. For most, this occurs on a weekend or nonworking day. It is possible (and quite likely) that collections on these days do not represent the patient's typical metabolic milieu that exists during the rest of the week (Rodgers et al, 1994, 1995; Norman, 1996; Hess et al, 1997).

The diagnostic criteria for the 12 principal classifications described in this section are summarized in Table 43–11.

USE OF STONE ANALYSIS TO DETERMINE METABOLIC ABNORMALITIES

Questions have arisen about the necessity of both chemical stone analysis and metabolic evaluation for patients with nephrolithiasis. **Although stone composition analysis is not always feasible or desirable, there is helpful information from such an investigation that can aid with preventive therapy.** Unfortunately, chemical and mineralogic names of common calculi are sometimes used interchangeably, causing significant confusion for the clinician. A list of these names is therefore provided in Table 43–12.

Parks demonstrated that urine supersaturation values do in fact coincide with the stones that patients actually produce (Parks et al, 1997). Although this may seem intuitive, it is

Table 43–11. Diagnostic Criteria

	Serum			Urine							
	Ca	*P*	*PTH*	*Ca Fasting*	*Ca Load*	*Ca Restricted*	*UA*	*Ox*	*Cit*	*pH*	*Mg*
Absorptive hypercalciuria type 1	N	N	N	N	↑	↑	N	N	N	N	N

Infection lithiasis	N	N	N	N	N	N	N	N	↓	↑	N

Fasting samples represent 2-hour collections obtained in the morning after an overnight fast. Calcium load samples are obtained during a 4-hour period subsequent to oral ingestion of 1 g calcium.
PTH, immunoreactive parathyroid hormone; ↑ high; ↓ low; N, normal; UA, uric acid; Ox, oxalate; Cit, citrate; Mg, magnesium.

Table 43–12. Mineralogic Names of Renal Calculi

Calcium oxalate monohydrate	Whewellite
Calcium oxalate dihydrate	Weddellite
Calcium hydrogen phosphate dihydrate	Brushite
Tricalcium phosphate	Whitlockite
Carbonite-apatite	Carbonite-apatite
Magnesium ammonium phosphate	Struvite
Cystine	None
Uric acid	None

important to know that medications used to target specific pathophysiologic processes will produce the necessary desired effects. Indeed, in their study, treatments that reduced stone rates also reduced the supersaturation values for the historical stone composition for that patient. If the development of calculi is due to prolonged supersaturation of various crystals (e.g., calcium oxalate, urate), then it is further reassuring that "snapshot," pooled urine supersaturation measurements accurately track stone admixtures and are a reliable index of long-term, "average" renal and urine supersaturations.

Other investigators have found that knowledge of the stone composition can be a helpful adjunct to a metabolic evaluation. **Since most stones are a mixture of more than one component, the relative ratios or predominance of any particular molecule may have predictive value.** In an analysis of almost 1400 patients who had both stone analysis and a complete metabolic evaluation, Pak noted that calcium apatite and mixed calcium oxalate–calcium apatite stones were associated with the diagnoses of renal tubular acidosis and primary hyperparathyroidism (odds ratio ≥ 2) but not with chronic diarrheal syndromes (Pak et al, 2003b). As the phosphate content of the stone increased from calcium oxalate to mixed calcium oxalate–calcium apatite and finally to calcium apatite, the percentage of patients with renal tubular acidosis increased from 5% to 39%, and the percentage of those with primary hyperparathyroidism increased from 2% to 10%. Not surprisingly, pure and mixed uric acid stones were strongly associated with a gouty diathesis; brushite stones were associated with renal tubular acidosis. As expected, there was a strong association between infection stones and infection and between cystine stones and cystinuria.

These findings were further supported by Kourambas and colleagues (2001). In a consecutive series of 100 patients, they correlated the findings of stone composition with metabolic results. Like Pak, they noted a significant risk of renal tubular acidosis in those producing predominantly calcium phosphate calculi. They suggested that the finding of a noncalcareous stone could simplify an evaluation by focusing the ensuing evaluation on the most obvious cause. Pure uric acid calculi are found in gouty diathesis and may not therefore require further testing. Likewise, pure cystine calculi do not require further testing.

Finally, Lingeman and associates (1995) noted that the finding of pure struvite or calcium apatite in a staghorn calculus predicted a low likelihood of finding other metabolic abnormalities during a workup. In their series, only 2 of 14 patients with pure infection stones had additional abnormalities compared with 7 of 7 patients with mixed chemical compositions. They therefore suggest that those patients with pure infection stones will not benefit from additional evaluation.

KEY POINTS: STONE ANALYSIS

- Stone analysis may obviate the need for a complete metabolic evaluation.
- Stone composition can direct metabolic investigation.

THE ECONOMICS OF METABOLIC EVALUATION

There is no doubt that the costs associated with the treatment of nephrolithiasis are substantial. In 1984, Shuster and Scheaffer estimated that the average stone episode cost approximately $2000, exclusive of recurrences. At the time, this was based on a predominance of open surgical approaches

with an average hospital stay lasting 4 to 5 days. The average annual cost of recurrence for a current stone case was conservatively estimated to be in the $300 to $400 range. On the basis of these *conservative* projections, they estimated that the entire national population of white men in the age range of 18 to 60 years yielded an annual cost due to kidney stones approaching $315,000,000.

By 1993, the estimated costs continued to climb, despite advances in technology and decreases in inpatient care. Indeed, Clark and associates (1995) performed a review of prevalence data for urolithiasis and the relative frequency of surgical treatments from Civilian Health and Medical Program of the Uniformed Services claims data. They found that the total charges for evaluation, hospitalization, and treatment were estimated to be $1.23 billion per year. Professional charges for those who were hospitalized were estimated to be $183 million. Outpatient evaluation of urolithiasis was expected to cost $278 million. Indirect costs for lost wages were estimated to be $139 million. This totaled a staggering annual cost of $1.83 billion in the United States alone.

As we begin the 21st century, one can only assume that costs have not decreased but rather have continued their meteoric climb. **Recent evidence that obesity confers an increased risk of nephrolithiasis is sobering, considering the epidemic of obesity that is enveloping the United States** (Curhan et al, 1998a; Ekeruo et al, 2004; Morrill and Chinn, 2004; Rigby et al, 2004; Strumpf, 2004; Taylor et al, 2005).

With these figures in mind, prudence dictates that medical prevention could help curb runaway costs and prevent long-term sequelae of recurrent nephrolithiasis. As an example, Madore has found an association between nephrolithiasis and the eventual development of hypertension (Madore et al, 1998a, 1998b). This ubiquitous condition has its own attendant costs and risk of end-organ damage, such as cardiovascular disease and renal failure. As these subsequent disorders have their own costs and risks, any reasonable chance to break the chain of events should be sought.

The emergence and instant appeal of shockwave lithotripsy and improved endoscopy in the mid-1980s prompted some authors to remind the urologic community that medical assessment was still a viable option (Resnick and Pak, 1987; Preminger, 1994). **However, office visits, serum studies, and 24-hour urine studies have their own costs. Is there a break-even point at which the costs of a metabolic evaluation, pharmacologic prophylaxis, and continued office visits are less than the expense of surgical management?** This question has been the topic of several studies.

Chandhoke (2002) compared the cost of medical prophylaxis with the cost of clinical management of recurrent stone episodes. In addition, he determined the stone recurrence rate without prophylaxis (stone frequency) at which these two treatment approaches became cost equivalent. This review conducted a cost survey in 10 countries to compare costs of medical prophylaxis and management of recurrent acute stone episodes. Costs of an acute stone episode included an emergency department visit, associated radiographic imaging to confirm diagnosis of a symptomatic stone, and outpatient treatment of upper urinary tract stones that did not pass spontaneously. Costs of medical management included an initial limited metabolic evaluation, drug therapy, follow-up office visit every 6 months that included a 24-hour urinalysis, and radiographic imaging of the kidneys, ureters, and bladder once a year. Not surprisingly, the costs of medical prophylaxis and management of an acute stone episode varied significantly from country to country. The stone frequency at which costs of these management options became equivalent ranged from 0.3 to 4 stone episodes a year. **This study concluded that medical management of a first stone episode is not cost-effective and that individual decisions should be determined by local costs.**

Researchers at the University of Texas, Southwestern Medical Center have formulated a decision tree model to evaluate the cost-effectiveness and stone recurrence rates of common management strategies in stone formers (Lotan et al, 2004). They evaluated six common medical strategies, namely, dietary measures alone (conservative), empirical drug treatment (empirical), and directed drug therapy based on simple or comprehensive metabolic evaluation. The model made reasonable assumptions about costs for evaluation, medications, emergency treatment, and surgery for stone recurrence. A review of the literature guided estimations of stone recurrence and risk reduction from various medical therapies. They found that first-time stone formers were best treated with a conservative approach since it was the least costly and yielded a stone formation rate of 0.07 stone per patient yearly. For recurrent stone formers, conservative treatment was less costly than drug treatments, but it was associated with a higher stone recurrence rate (0.3 stone per patient yearly). Directed medical therapies were more costly than conservative treatment ($885 to $1187 versus $258 yearly), but they provided the obvious advantage of decreasing recurrence rates by 60% to 86%.

The authors went on to compare the expense of the simple medical evaluation and associated management as described earlier in this chapter and noted it to be more costly than empirical treatment but also more effective. Importantly, a complete evaluation with attendant treatment offered no advantage in cost or efficacy over empirical treatment or modified simple metabolic evaluation and management. The Dallas authors recommended that first-time stone formers be treated with conservative therapy because it is both cost-effective and efficacious. In contrast, however, **recurrent stone formers should be treated medically after a simplified evaluation because of the high recurrence rate of stone formation.**

KEY POINTS: ECONOMICS OF METABOLIC EVALUATION

- A metabolic evaluation may not be economically sound if it is applied to all patients with stone disease.
- Most first-time stone formers may not benefit economically from a metabolic evaluation unless initial screening puts them in a high-risk category.
- Recurrent stone formers are best treated with a metabolic evaluation and directed medical therapy.

CONSERVATIVE MEDICAL MANAGEMENT

Certain conservative recommendations should be made for all patients regardless of the underlying cause of the stone disease. Unfortunately, it can be difficult to reach consensus regarding specific details from the available literature.

Fluid Recommendations

Volume

One mainstay of conservative management is the forced increase in fluid intake to achieve a daily urine output of 2 liters (Borghi et al, 1999). Increased urine output may have two effects. First, the mechanical diuresis that ensues may prevent urine stagnation and the formation of symptomatic calculi. More likely is that the dilute urine alters the supersaturation of stone components. Indeed, Pak and colleagues measured in vitro and in vivo effects of urine dilution and discovered that both significantly reduced the urinary activity product ratio (state of saturation) of calcium phosphate, calcium oxalate, and monosodium urate (Pak et al, 1980b). Moreover, the formation product ratio, that is, the minimum supersaturation needed to elicit spontaneous nucleation of calcium oxalate, significantly increased.

Researchers at the University of Chicago have demonstrated that failure to increase urine output is one of three strong predictors of relapse for those patients observed in a dedicated stone clinic (Strauss et al, 1982a). The previously described stone clinic effect has primarily been attributed to increases in fluid intake and attendant increases in urine output (Hosking et al, 1983).

However, although the concept of increased fluid intake is simple, it can be difficult to achieve compliance of patients. Anecdotally, most physicians with an interest in kidney stone disease have seen that many patients are unable to maintain increased urine output over the long term. This general impression has been borne out in an analysis of urine output changes from a large series of 2877 patients (Parks et al, 2003a). In this amalgam of university and private practice patients, the average increase in urine volume was only 0.3 liter per day. In addition, intermittent compliance may not be effective, as small, early stones may develop during periods of intense dehydration. At least one author has suggested that if a patient is able to voluntarily force fluid intake long enough to dilute renal concentrating abilities, thirst mechanisms will take over and help maintain a high fluid intake and high urine output (Burns and Finlayson, 1981). Unfortunately, the more recent data from Parks and colleagues has not proved this finding to be reliable.

Water Hardness

If water intake is so important, is there a difference in water hardness that might ameliorate or augment its benefit? This concept has been the topic of conflicting articles within the general urologic and epidemiologic literature. In one interesting study, patients with a known history of calcium nephrolithiasis were divided according to postal zip codes; 24-hour urine measurements were compared, as was the history of stone episodes (Schwartz et al, 2002). Although the 24-hour urine calcium, magnesium, and citrate levels increased directly with drinking water hardness, no significant change was found in urinary oxalate, uric acid, pH, or volume. Most important, the number of total lifetime stone episodes was similar between patients residing in areas with soft public water and hard public water. Patients consuming the softest water decile formed 3.4 lifetime stones, and those who consumed the hardest water developed 3.0 lifetime stones. **The authors noted that although water hardness can alter urinary parameters, this ultimately appears to have little effect on clinical outcome.**

These findings are further supported by earlier work from Shuster and associates (1982). They examined 2295 patients from two regions: the Carolinas, which had soft water and high stone incidence; and the Rockies, which had hard water and low stone incidence. Home tap water samples of patients hospitalized for urinary stones were compared with those of controls. After adjustment for environmental factors, no significant difference between the two groups was obtained in tap water calcium, magnesium, and sodium concentrations. An incidental but potentially important finding was that those consuming water from a private well had an estimated relative risk of stone formation of 1.5 compared with those using public water. **They ultimately concluded that water hardness should be a minor concern with respect to stone formation.**

Unfortunately, this issue has not been completely put to rest; there is still evidence that hard water may confer some excess risk of stone formation. In a well-controlled study involving fixed diets and a crossover design, 18 subjects with a history of calcium nephrolithiasis drank hard water, soft water, or tap water (Bellizzi et al, 1999). The urinary levels of calcium demonstrated a significant 50% increase in the absence of changes of oxalate excretion. Whereas these changes are of concern, stone events were not used as a primary outcome.

Carbonated Beverages

A number of studies suggest that carbonated water offers increased protection against recurrent stone formation compared with still water (Rodgers, 1997, 1998; Bren et al, 1998; Caudarella et al, 1998; Coen et al, 2001). These studies focused primarily on carbonated water, which has been demonstrated to increase urinary citrate levels.

Other types of carbonated beverages have also been examined. One study has demonstrated that increased intake of soda can confer an increased risk of subsequent stone recurrence (Shuster et al, 1992). The study sample consisted of 1009 male subjects, who reported consuming at least 160 mL/day of soft drinks. Half of the subjects were randomized to refrain from consuming soft drinks; the remaining subjects served as controls. The intervention group had an observed 6.4% advantage in actuarial 3-year freedom from recurrence over the control group. One important secondary finding was that those who reported that their most consumed drink was acidified by phosphoric acid but not citric acid had a 15% higher 3-year recurrence-free rate than the controls. Meanwhile, those who consumed drinks acidified by citric acid had no increase in stone episodes compared with controls.

Additional epidemiologic studies have demonstrated the effects of particular fluids on the risk of stone recurrence (Curhan et al, 1996a, 1998b). For both men and women, there was a decrease in the risk of nephrolithiasis for those who

consumed increased volumes of water, caffeinated or decaffeinated coffee, tea, beer, and wine. Conversely, daily servings of apple or grapefruit juice increased the risk of stone events. **Despite the epidemiologic evidence, the supersaturation risks associated with grapefruit juice have largely been discredited by subsequent evaluations** (Goldfarb and Asplin, 2001; Trinchieri et al, 2002; Honow et al, 2003).

In contrast to these epidemiologic findings, recent evidence suggests that caffeine intake may increase the risk of stone recurrence in calcium stone formers by increasing the excretion of calcium. Caffeine increased urinary calcium/creatinine, magnesium/creatinine, citrate/creatinine, and sodium/creatinine but not oxalate/creatinine in stone formers and controls. Furthermore, supersaturation calculations increased, despite the noted increases in the inhibitors citrate and magnesium (Massey and Sutton, 2004).

Increased Citrus Juices

Lemonade and orange juice have long been used as an adjunct to water to provide increased urine volume as well as increased urinary citrate excretion. In a study of 12 hypocitraturic patients, lemonade made from reconstituted lemon juice provided enough citrate to correct the hypocitraturia in seven subjects (Seltzer et al, 1996). Urinary calcium excretion decreased an average of 39 mg daily, whereas oxalate excretion was unchanged. The lemonade mixture was well tolerated; only two patients complained of mild indigestion that did not require cessation of therapy. Wabner and Pak (1993) have similarly evaluated the effects of orange juice on the urinary parameters of normal subjects and found that compared with potassium citrate, orange juice delivered an equivalent alkali load and caused a similar increase in urine pH (6.48 versus 6.75 from 5.71) and urinary citrate (952 versus 944 from 571 mg/day). Therefore, orange juice, like potassium citrate, decreased urinary undissociated uric acid levels and increased the inhibitor activity (formation product) of brushite (calcium phosphate). However, orange juice increased urinary oxalate and did not alter calcium excretion, whereas potassium citrate decreased urinary calcium without altering urinary oxalate. They concluded that orange juice could be beneficial in the control of calcareous and uric acid nephrolithiasis.

Overall, most evidence suggests that it is not the type of fluid ingested that is important for stone prevention but the absolute amount of fluid taken in per day. We therefore encourage all of our stone formers to drink at least 3000 mL/day to maintain a urine output of more than 2500 mL/24 hours.

Dietary Recommendations

Although metabolic abnormalities probably contribute to the majority of risk factors for recurrent nephrolithiasis, increasing evidence suggests that dietary changes are having an important impact on renal stone disease. Indeed, studies have documented an increasing incidence of nephrolithiasis along with a greater propensity of female stone disease; a more complete discussion of these trends can be found in Chapter 42 (Pak et al, 1997; Ramello et al, 2000; Trinchieri et al, 2000; Coward et al, 2003; Hesse et al, 2003; Stamatelou et al, 2003; Amato et al, 2004). Therefore, alterations in diet and physical activity may significantly reduce the incidence of recurrent nephrolithiasis.

KEY POINTS: FLUID RECOMMENDATIONS

- Patients should be strongly encouraged to consume enough fluids to produce 2 liters of urine per day.
- Water hardness is unlikely to play a significant role in recurrence risk.
- Carbonated water may confer some protective benefit.
- Soda flavored with phosphoric acid may increase stone risk, whereas soda with citric acid may decrease risk.
- Citrus juices (particularly lemon juice) may be a useful adjunct to stone prevention.

Protein Restriction

Epidemiologic studies from a number of countries have shown that the incidence of renal stones is higher in populations in which there is an increased animal protein intake. For example, in the northern and western regions of India, animal protein intake is approximately 100% greater than in the southern and eastern regions, and the rate of kidney stones is four times greater. In the United Kingdom, the frequency of upper tract stone disease correlates with the per capita expenditure on foodstuffs (Robertson et al, 1979, 1982). This effect may be partly because protein intake is higher in affluent people, and stone formation, for some reason, seems to be higher in the economically advantaged. When populations are matched for economic status, the intake of protein and other dietary constituents does not differ in patients with recurrent stones and controls. Even in subjects thus matched, however, patients with stone disease secrete greater quantities of calcium in the urine than do controls for a given intake of protein (Wasserstein et al, 1987). Thus, patients with stone disease may be more sensitive to dietary protein loading than are normal subjects.

Protein intake increases urinary calcium, oxalate, and uric acid excretion and the mathematically calculated probability of stone formation even in normal subjects. Indeed, according to Burns and Finlayson (1981), ingestion of protein is second only to ingestion of vitamin D in enhancing intestinal absorption of calcium. Early investigations of purine loading in controlled clinical laboratory settings confirmed the risk of hypercalciuria and hyperuricosuria with a diet high in animal protein (Pak et al, 1978; Fellstrom et al, 1983; Breslau et al, 1988). Patients with stone disease also exhibit inappropriate hypercalciuria in response to carbohydrate, sodium, and oxalate intake. In one acute study, dietary protein restriction resulted in a decrease in calcium, phosphate, and oxalate (Liatsikos and Barbalias, 1999). In another study in hypercalciuric patients, protein restriction resulted in decreased urinary uric acid and increased urinary citrate as well (Giannini et al, 1999).

Borghi and colleagues (2002) have provided further support to the importance of dietary protein in stone formation. In a prospective fashion, patients were randomized to either a low-protein, low-salt, moderate-calcium diet or a low-calcium diet. Although it is difficult to separate the potential effects of the three facets of the first diet, there was a convincing 50% reduction in stone events compared with those patients on the low-calcium diet.

Not all investigators have noticed the relationship between intake of meat and hypercalciuria. Brockis and colleagues (1982) demonstrated that mean urinary excretion patterns of calcium and oxalate were similar in matched groups of Seventh Day Adventists (vegetarians) and Mormons (nonvegetarians). A large study at the University of Pennsylvania found that patients with recurrent nephrolithiasis consumed a diet similar in composition to that of case controls (Goldfarb, 1994). Most studies, however, suggest that an increased intake of meat may exacerbate calcium oxalate stone disease.

Sodium Restriction

Sodium restriction has been widely recommended as an important element of dietary prevention of recurrent nephrolithiasis (Massey and Whiting, 1995). Indeed, the evidence implicating excess sodium ingestion as a cause of calcium stone disease comes from several authors in different countries. Ito and colleagues from Japan have noticed that calcium stone formers had increased levels of sodium ingestion compared with the daily recommended allowances for the Japanese nation (Ito et al, 1993). They also found that stone formers consumed larger amounts of animal protein. They did not comment on whether the increased sodium ingestion was caused by the protein excess or whether it acted as an independent risk factor.

Researchers in Dallas, Texas, have confirmed the effects of salt loading in a controlled crossover study involving normal volunteers. In their study, 14 normal subjects participated in two phases of study of 10 days' duration each—a low-sodium phase (basal metabolic diet containing 50 mmol sodium per day) and a high-sodium phase (basal diet plus 250 mmol sodium chloride per day). The high sodium intake significantly increased urinary sodium (34 to 267 mmol/day), calcium (2.73 to 3.93 mmol/day), and pH (5.79 to 6.15) and significantly decreased urinary citrate (3.14 to 2.52 mmol/day). They noted that a high sodium intake not only increased calcium excretion but also increased urine pH and decreased citrate excretion. **The net effect of a high sodium diet was an increased propensity for the crystallization of calcium salts in urine** (Sakhaee et al, 1993).

The investigation by Borghi involving dietary manipulation additionally included a low-salt diet, limited to 50 mmol of sodium chloride per day (Borghi et al, 2002). **In combination with animal protein restriction and moderate calcium ingestion, a reduced sodium diet will decrease stone episodes by approximately 50%.** Further work from Italy has demonstrated that calcium stone formers who ingest large quantities of daily salt are more likely to suffer from decreased bone mineral density (Martini et al, 2000). In this study of 85 patients, all female patients were premenopausal, underscoring the risks of further osteopenia that they might suffer later in life. After adjustment for calcium and protein intakes, age, weight, body mass index, urinary calcium excretion, urinary citrate and uric acid excretion, and duration of stone disease, multiple-regression analysis showed that a high sodium chloride intake (≥16 g/day) was the single variable that was predictive of risk of low bone density in calcium stone–forming patients (odds ratio = 3.8).

KEY POINTS: DIETARY RECOMMENDATIONS

- Randomized studies have confirmed the advantage of a diet with moderate animal protein (meat) intake.
- Randomized trials have demonstrated a benefit of dietary sodium restriction in both normal volunteers and stone formers.

Obesity

Obesity has been associated with impaired carbohydrate tolerance and an inappropriate calcium response to glucose ingestion. Thus, the hypercalciuria seen in meat eaters may be a function of increased body weight (Menon and Krishnan, 1983). Trinchieri and colleagues found that daily urinary oxalate excretion was related to body mass index in a group of stone formers (Trinchieri et al, 1998b). The association between body size and risk of stone formation was studied formally by the Curhan group (Curhan et al, 1998a). In two large cohorts, the Health Professionals Follow-Up Study and the Nurses' Health Study, the prevalence of stone disease history and the incidence of new stone formation were directly associated with weight and body mass index. The magnitude of the association was greater in women than in men.

These same cohorts of patients have been continually observed, and the group from Boston has provided an update on the role of obesity and nephrolithiasis. **They demonstrated that increased body mass index, larger waist size, and weight gain correlated with an increased risk of stone episodes. This increased stone risk was still more pronounced for women than for men** (Taylor et al, 2005).

In a review of a large national database, Powell and colleagues (2000) examined the serum and 24-hour urine parameters from nearly 6000 patients with a history of nephrolithiasis. Within this cohort, obese patients had increased urinary excretion of sodium, calcium, magnesium, citrate, sulfate, phosphate, oxalate, uric acid, and cystine. Furthermore, obesity was associated with increased urine volumes and urine osmolality compared with the nonobese patients. Interestingly, these metabolic changes were associated with an increased rate of stone episodes only for obese women, rather than for obese men.

Clinicians at Duke University have specifically evaluated the metabolic disturbances of obese patients, defined as a body mass index greater than 30 (Ekeruo et al, 2004). They determined that the most common presenting metabolic abnormalities among obese patients included gouty diathesis (54%), hypocitraturia (54%), and hyperuricosuria (43%), which presented at levels that were significantly higher than those found in nonobese stone formers. Chemical stone analysis showed a predominance of uric acid calculi, implicating excessively acid

urine in these subjects. Directed medical therapy and dietary recommendations were able to dramatically reduce stone episodes for these patients.

Studies suggest that the increased incidence of uric acid stone formation in obese stone formers may be secondary to the production of more acidic urine than in "normal-sized" patients. Combined data from the two largest stone centers in the United States found that urine pH appears to be directly correlated with body size (Maalouf et al, 2004). As body mass increases, the urine pH will decrease. This finding does not appear to be associated with diet but is probably a result of the increased incidence of type 2 diabetes in obese patients. As diabetics have impaired ammonium excretion, these patients have been shown to have an increased incidence of uric acid stone formation (Pak et al, 2003c; Abate et al, 2004).

If obesity is a risk for stone disease, what is the impact of weight-reducing diets on stone formation? Current dietary fads include low-carbohydrate, high-protein, high-fat diets (Atkins diet, South Beach diet, Sugar Busters diet). Experimental evidence suggests that such diets may predispose a patient to increased stone risk (Reddy et al, 2002). In a study of the Atkins diet, 10 healthy subjects engaged in a low-carbohydrate, high-protein diet for 6 weeks under the care of a clinical dietitian. After 6 weeks, urine pH decreased from 6.09 to 5.67, net acid excretion increased by 51 mEq/day, and urine citrate levels decreased from 763 mg/day to 449 mg/day. In addition, urine saturation of undissociated uric acid increased more than twofold; urinary calcium levels increased from 160 mg/day to 248 mg/day, causing an estimated calcium balance decrease of 90 mg/day. **Therefore, the consumption of a low-carbohydrate diet delivers a marked acid load to the kidney, increases the risk for stone formation, and may increase the risk for bone loss.** To date, there have been no well-performed investigations of the long-term clinical effects of this type of diet with respect to actual stone formation. Yet, evidence suggests that alkali therapy may significantly combat acidosis and the potential for stone formation in patients on a low-carbohydrate, high-protein diet.

KEY POINTS: OBESITY

- Obesity is an independent risk factor for nephrolithiasis, particularly for women.
- Obese patients have a higher propensity for uric acid calculi.
- High-protein, low-carbohydrate diets may increase the risk of stone formation.

Role of Dietary Calcium

The preponderance of evidence now supports the maintenance of a moderate calcium intake in the face of calcareous nephrolithiasis (Curhan et al, 1993; Curhan, 1997; Takei et al, 1998; Trinchieri et al, 1998a; Martini and Wood, 2000; Lewandowski et al, 2001; Borghi et al, 2002; Heller et al, 2003; Taylor et al, 2004). **Older recommendations to significantly restrict calcium intake probably led to an increase in available intestinal oxalate. As a result, this limitation in dietary calcium may subsequently increase oxalate absorption, thereby raising the supersaturation of calcium oxalate.** As noted earlier, a prospective, randomized study has shown that patients on a moderate-calcium diet, combined with salt restriction and moderation of animal protein, had half as many stone episodes as those who attempted to follow a calcium-restricted diet (Borghi et al, 2002). Review of a large cohort of middle-aged nurses revealed that there was a decreased incidence of nephrolithiasis in those subjects who had increased levels of dietary calcium (Curhan, 1997; Curhan et al, 1997). Interestingly, this protection did not remain for those who received increased calcium intake from supplements instead of from dietary sources (i.e., dairy products).

There is further evidence to suggest that calcium supplementation can be safe if attention is paid to preparation and especially to timing. In a review of postmenopausal women, authors have demonstrated that initiation of calcium supplementation does not have deleterious effects on urinary calcium, oxalate, or citrate levels. Furthermore, calcium supplement with a meal or combined calcium supplement and estrogen therapy was not associated with a significant increased risk of calcium oxalate stone formation in the majority of postmenopausal osteoporotic patients (Domrongkitchaiporn et al, 2002b). Additional work from the same group has determined that the timing of calcium supplementation may have positive or negative effects (Domrongkitchaiporn et al, 2004). In a study of healthy male recruits, the authors compared the urinary effects of calcium carbonate supplementation taken with meals versus at bedtime. In both instances, urinary calcium excretion increased equal amounts. However, for those taking the calcium supplement with meals, this increase was offset by an equally significant decrease in urinary oxalate. As a result, there was no increase in urine supersaturation of calcium oxalate when calcium supplementation was taken with meals, a protection that did not remain for the nighttime bolus ingestion.

Evidence also suggests that the type of calcium supplementation may have an impact on the potential of stone formation. Two long-term studies from researchers in Dallas document that supplementation with calcium citrate does not have a significant impact on stone formation. Calcium citrate is an over-the-counter calcium preparation that provides 950 mg of calcium citrate and 200 mg of elemental calcium in each tablet. Like other available calcium supplements, calcium citrate will significantly increase urinary calcium excretion; yet, this preparation offers the benefit of also increasing urinary citrate excretion. The concomitant increase in citraturia potentially offsets the lithogenic potential of calcium supplement–induced hypercalciuria and therefore provides a more "stone-friendly" calcium supplement (Sakhaee et al, 2004).

A clinical trial was completed that further studied the effects of long-term calcium citrate supplementation in premenopausal women. This study demonstrated that the urine saturation of calcium oxalate and calcium phosphate (brushite) did not significantly change during calcium citrate therapy. It appears that the lack of calcium supplement–induced hypercalciuria was secondary to the downregulation of intestinal calcium absorption due to prolonged calcium supplementation and the inhibitory effects of

citrate included in the calcium citrate preparation. The results of this long-term calcium citrate trial suggest that calcium supplementation with calcium citrate does not increase the propensity for crystallization of calcium salts within the urine. This protective effect is most likely due to an attenuated increase in urinary calcium excretion (from a decrease in fractional intestinal calcium absorption), a decrease in urinary phosphorus, and an increased citraturic response (Sakhaee et al, 1994).

KEY POINTS: ROLE OF DIETARY CALCIUM

- Dietary calcium avoidance actually increases stone recurrence risk.
- Calcium supplementation is likely to be safest when it is taken with meals.
- Calcium citrate appears to be a more stone-friendly calcium supplement because of the additional inhibitor action of citrate.

Oxalate Avoidance

Since less than 10% to 15% of urinary oxalate is usually derived from dietary sources, it is unclear how helpful it is to promote the strict avoidance of oral oxalate loading. This is compounded by the fact that oxalate is ubiquitous and found in most vegetable matter. However, it does seem intuitive to avoid large portions of foodstuffs that are rich in oxalate, such as spinach, beets, chocolate, nuts, and tea. Although general advice on a restricted oxalate intake might be given to patients with recurrent nephrolithiasis, a low-oxalate diet would be most useful in patients with enteric hyperoxaluria or those with underlying bowel abnormalities (Holmes and Assimos, 2004). A more extensive list of high-oxalate foods may be found in Table 43–7.

There have been repeated concerns raised regarding the risk of vitamin C (ascorbic acid) ingestion and the possibility of its conversion to oxalate with subsequent urinary excretion. Unfortunately, conflicting evidence has been presented by multiple authors (Weaver, 1983; Trinchieri et al, 1991, 1998b; Urivetzky et al, 1992; Curhan et al, 1996b, 1999; Baxmann et al, 2003; Traxer et al, 2003). In fact, conflicting conclusions have even been reported from the same group of authors, underscoring the need for close scrutiny of presented data. Some of the confusion stems from differences in study endpoints. Whereas the ingestion of large amounts of vitamin C may demonstrate increases in 24-hour oxalate excretion and therefore calcium oxalate supersaturation, this does not guarantee an eventual increase in the formation of symptomatic calculi.

In the end, it seems reasonable to avoid heavy dosing of vitamin C. Limiting one's intake to a maximum daily dose of less than 2 g is an easy recommendation to follow (Traxer et al, 2003).

KEY POINTS: OXALATE AVOIDANCE

- Avoidance of excess dietary oxalate loading is reasonable and intuitive.
- Vitamin C in large doses may increase the risk of stone recurrence. Doses should probably be limited to 2 g/day.

Conservative Management Summary

It is anticipated that with these conservative measures alone, a significant number of patients may be able to normalize their urinary risk factors for stone formation. Thus, only these conservative measures may be necessary to keep their stone disease under control. After 3 to 4 months of conservative management, patients should be re-evaluated by either standard laboratory assays or a less comprehensive automated urinalysis package. If the patient's metabolic or environmental abnormalities have been corrected, the conservative therapy can be continued and the patient observed every 6 to 12 months with repeated 24-hour urine testing. It is believed that follow-up is essential not only to monitor the efficiency of treatment but also to encourage the patient's compliance. If, however, a metabolic defect persists, a more selective medical therapy may be instituted. For example, if significant hyperuricosuria (urinary uric acid greater than 800 mg/day) persists even after dietary restriction of meat products, medical therapy with allopurinol may be instituted.

SELECTIVE MEDICAL THERAPY FOR NEPHROLITHIASIS

Improved elucidation of the pathophysiologic mechanisms of nephrolithiasis and the formulation of diagnostic criteria for its different causes have made feasible the adoption of selective treatment programs (Pak et al, 1981; Preminger and Pak, 1985). Such programs should reverse the underlying physicochemical and physiologic derangements, inhibit new stone formation, overcome nonrenal complications of the disease process, and be free of serious side effects. The rationale for the selection of certain treatments is the assumption that the particular physicochemical and physiologic aberrations identified with the given disorder are etiologically important in the formation of renal stones (as previously discussed) and that the correction of these disturbances would prevent stone formation. Moreover, **it is assumed that such a selective treatment program is more effective and safe than "random" therapy. Despite a lack of conclusive experimental verification, these hypotheses appear reasonable and logical.** Common medications used to treat urinary stone disease and their expected actions are summarized in Table 43–13. Medication dosages are noted in Table 43–14, and side effects are outlined in Table 43–15. A simplified treatment algorithm outlining basic evaluation and management is illustrated in Figure 43–10.

Table 43-13. Physicochemical and Physiologic Effects of Pharmacologic Therapy

	Sodium Cellulose Phosphate	*Orthophosphate*	*Thiazide*	*Allopurinol*	*Potassium Citrate*
Urinary calcium	Marked decrease	Mild decrease	Moderate decrease	No change	Mild decrease or no change
Urinary phosphorus	Mild increase	Marked increase	Mild increase or no change	No change	No change
Urinary uric acid	No change	No change	Mild increase or no change	Marked decrease	No change
Urinary oxalate	Mild increase	Mild increase	Mild increase or no change	No change or mild decrease	No change
Urinary citrate	No change	Mild increase	Mild decrease	No change	Marked increase
Calcium oxalate saturation	Mild decrease or no change	Mild decrease	Mild decrease	No change	Moderate decrease
Brushite saturation	Moderate decrease	Mild increase	Mild decrease	No change	No change

Table 43-14. Dosages of Common Medications Used to Prevent Urinary Calculi

Thiazide diuretics	
Hydrochlorothiazide	25 mg PO bid
Chlorthalidone	25-50 mg PO daily
Indapamide	2.5 mg PO daily
Sodium cellulose phosphate	10-15 g/day divided with meals
Orthophosphate	0.5 g PO tid
Potassium citrate	20 mEq PO bid-tid
Allopurinol	300 mg PO daily
Magnesium gluconate	0.5-1.0 g tid
Pyridoxine (B_6)	100 mg PO daily
D-Penicillamine	250 mg PO daily (titrated to effect)
α-Mercaptopropionylglycine	100 mg PO bid (titrated to effect)
Captopril	25 mg PO bid-tid
Acetohydroxamic acid	250 mg PO bid-tid

Table 43-15. Potential Side Effects of Medications Used to Prevent Urinary Lithiasis

Medication	*Side Effect*
Thiazide diuretics: hydrochlorothiazide, chlorthalidone, indapamide	Potassium wasting, muscle cramps, hyperuricosuria, intracellular acidosis, hypocitraturia
Sodium cellulose phosphate	Gastrointestinal distress, hypomagnesemia, hyperoxaluria, parathyroid hormone stimulation
Orthophosphate	Similar to sodium cellulose phosphate, soft tissue calcification
Potassium citrate	Gastrointestinal upset, hyperkalemia
Allopurinol	Rash, myalgia
Magnesium gluconate	Diarrhea
Pyridoxine (B_6)	Diarrhea
D-Penicillamine	Nephrotic syndrome, dermatitis, pancytopenia
α-Mercaptopropionylglycine	Rash, asthenia, rheumatologic complaints, gastrointestinal distress, mental status changes
Captopril	Rash, cough, hypotension
Acetohydroxamic acid	Thromboembolic phenomena, tremor, headache, palpitations, edema, gastrointestinal distress, loss of taste, rash, alopecia, anemia, abdominal pain

Efficacy Outside of an Academic Center

One potential criticism of the "selective" metabolic management of nephrolithiasis is that the collection of multiple urine and serum studies can be too time-consuming to be feasible outside of an academic medical center with its dedicated research staff. **Whereas a commitment to follow-up can be tedious, it should be no worse for patients with kidney stones than it is for those observed for cancer or voiding dysfunction.**

Indeed, Lingeman and colleagues (1998) compared the results of patient management from seven private practices with that achieved by a dedicated university clinic. Of note, the specialized stone management software and laboratory resources of the university clinic supported the private centers. They found that supersaturation values were effectively reduced in the network and stone clinic and that the reduction was proportional to the initial supersaturation value and increase in urine volume. The stone clinic achieved a greater supersaturation reduction, higher fraction of patient follow-up, and greater increase in urine volume, but the treatment effects in the network were nevertheless substantial and significant.

This finding is supported by another study demonstrating the efficacy of medical prophylaxis administered in a private practice setting (Mardis et al, 2004). Compared with conservative measures of dietary recommendations and fluid management, active pharmacologic treatment achieved a significantly greater reduction in stone episodes. These findings prompted the authors to conclude that medications validated in trials and guided by metabolic evaluation lower stone recurrence when they are used in a private practice setting as they do in clinical trials from academic medical centers.

Absorptive Hypercalciuria

Sodium Cellulose Phosphate

There is currently no treatment program that is capable of correcting the basic abnormality of absorptive hypercalciuria type 1, although several drugs are available that have been shown to restore normal calcium excretion. When sodium cellulose phosphate is given orally, this nonabsorbable ion exchange resin binds calcium and inhibits calcium absorption (Pak et al, 1974). However, this inhibition is caused by limitation of the amount of intraluminal calcium available for

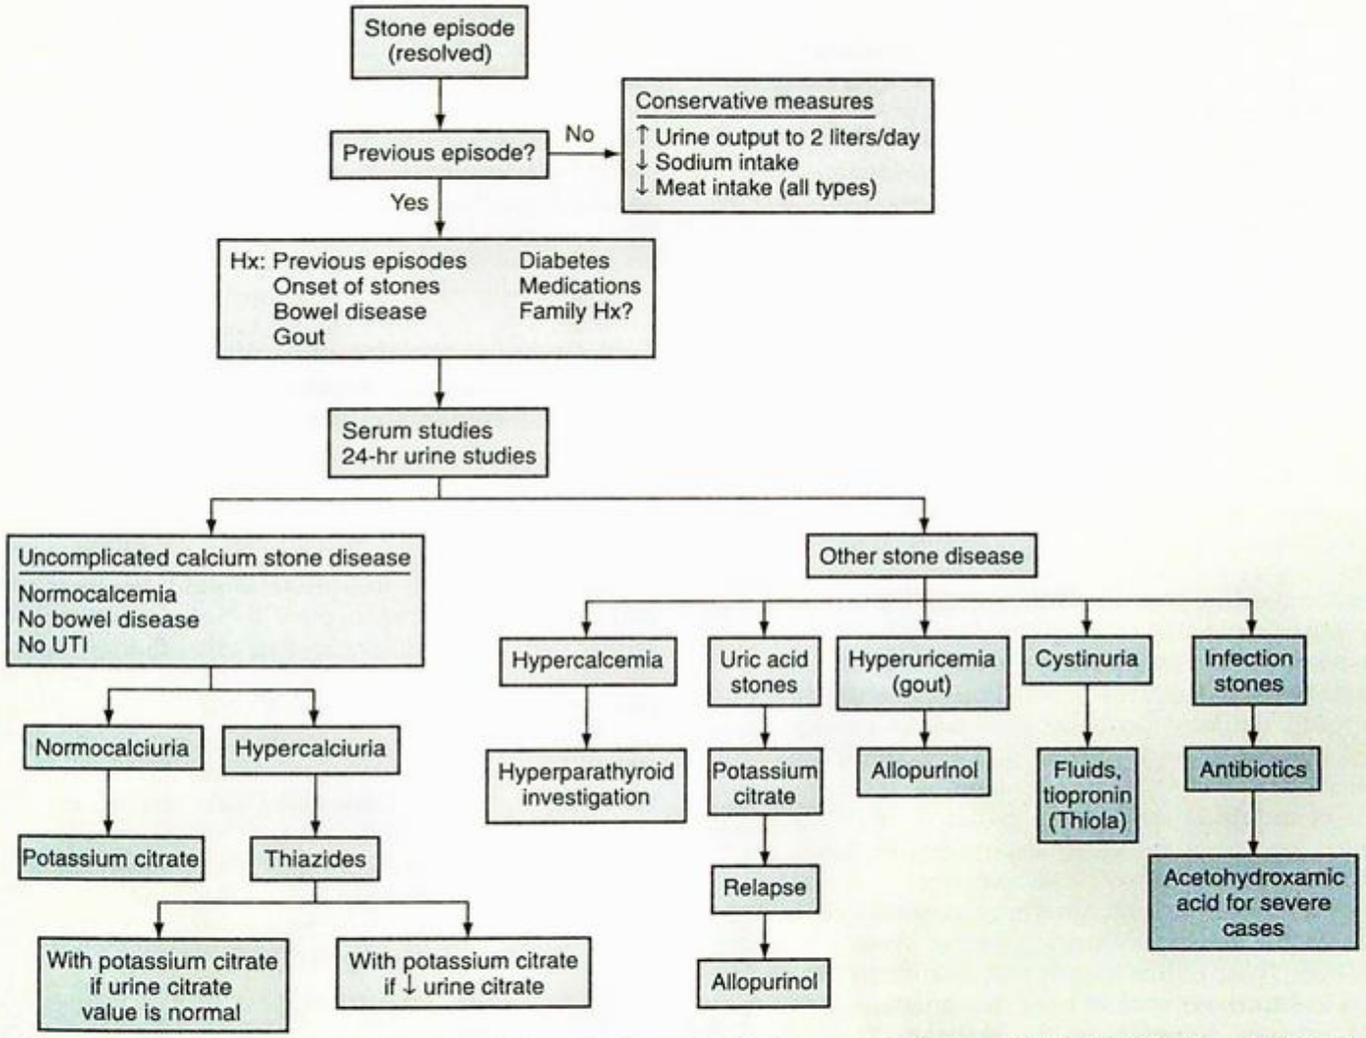

Figure 43–10. Simplified treatment algorithm for the evaluation and medical management of urinary lithiasis. (Modified from C. Y. Pak.)

absorption, not by correction of the basic disturbance in calcium transport. Nevertheless, in one series, sodium cellulose phosphate decreased intestinal calcium absorption by 85% in patients with absorptive hypercalciuria and recurrent nephrolithiasis (Blacklock and Macleod, 1974). Acute treatment with cellulose phosphate can decrease urinary calcium excretion by 50% to 70% (Hayashi et al, 1975).

This mode of action accounts for the three potential complications of sodium cellulose phosphate therapy. First, sodium cellulose phosphate may cause a negative calcium balance and parathyroid stimulation when it is used in patients with normal intestinal calcium absorption or with renal or resorptive hypercalciuria. Second, the treatment may cause magnesium depletion by binding magnesium as well. Third, sodium cellulose phosphate may produce secondary hyperoxaluria by binding divalent cations in the intestinal tract, reducing divalent cation–oxalate complexation, and making more oxalate available for absorption (Hayashi et al, 1975). These complications may be overcome by using the drug only in documented cases of absorptive hypercalciuria type 1, applying oral magnesium supplementation (1.0 to 1.5 g magnesium gluconate twice per day, separately from sodium cellulose phosphate), and imposing a moderate dietary restriction of oxalate (Pak, 1981). When these precautions are followed, sodium cellulose phosphate at a dosage of 10 to 15 g/day (given with meals) has been shown to reduce urinary calcium and the saturation of calcium salts (calcium phosphate as well as calcium oxalate). In this same study, stone events were reduced by 78%.

The clinical efficacy of this medication has been questioned, however, as Backman and colleagues (1980) have demonstrated that patients with calcareous nephrolithiasis tolerated sodium cellulose phosphate poorly with a high rate of gastrointestinal distress. In addition, they noted a 47% recurrence rate at 2 years. Hautmann and coworkers (1978) had previously demonstrated better efficacy for this medication but also noted significant oxaluria, with 8 of 27 patients having to stop the medication for this reason alone.

Unfortunately, despite early enthusiasm, the use of sodium cellulose phosphate has largely fallen out of favor because of excessive gastrointestinal side effects and costs. The use of sodium cellulose phosphate may still make sense for patients with intractable stone disease due to profound absorptive hypercalciuria type 1 (urinary calcium excretion above 500 mg/day), but only after all other treatment options have been exhausted.

Thiazides

Thiazide diuretics are not considered a selective therapy for absorptive hypercalciuria since they do not decrease intestinal calcium absorption in this condition (Pak, 1979). However, this class of medications has been widely used to treat absorptive hypercalciuria because of its hypocalciuric action and the high cost and inconvenience of alternative therapy (sodium cellulose phosphate). The use of thiazides was first described by Yendt and colleagues (1966) for the treatment of undifferentiated hypercalciuria.

Thiazides directly stimulate calcium resorption in the distal nephron while promoting excretion of sodium. Long-term thiazide therapy results in volume depletion, extracellular volume contraction, and proximal tubular resorption of sodium and calcium. Thiazides may increase urinary excretion of magnesium and zinc, but these responses are not consistent. Potassium losses from thiazide therapy can cause hypocitraturia due to hypokalemia with intracellular acidosis.

Studies indicate that thiazide may have a limited long-term effectiveness in absorptive hypercalciuria type 1 (Zerwekh and Pak, 1980; Preminger and Pak, 1987). Despite an initial reduction in urinary excretion, the intestinal calcium absorption remains persistently elevated. These studies suggest that the retained calcium may be accreted in bone at least during the first few years of therapy. Bone density, determined in the distal third of the radius by photon absorptiometry, increases significantly during thiazide treatment in absorptive hypercalciuria, with an annual increment of 1.34%. With continued treatment, however, the rise in bone density stabilizes and the hypocalciuric effect of thiazide becomes attenuated. These results suggest that thiazide treatment may cause a low turnover state of bone that interferes with a continued calcium accretion in the skeleton. The "rejected" calcium would then be excreted in urine. In contrast, bone density is not significantly altered in renal hypercalciuria, in which thiazide has been shown to cause a decline in intestinal calcium absorption commensurate with a reduction in urinary calcium.

Further work on this topic has been reported (Pak et al, 2003a). In this study, 28 patients with absorptive hypercalciuria type 1 were managed with thiazide (20) or indapamide (8) and potassium citrate for 1 to 11 years while they were maintained on a diet low in calcium oxalate. Serum and urine chemistry studies and bone mineral density were obtained at baseline and at the end of treatment. During treatment, urinary calcium significantly decreased but urinary oxalate did not change. Urine pH and citrate significantly increased, and urine saturation of calcium oxalate significantly decreased by 46%. Stone formation rate decreased significantly from 2.94 to 0.05 per year. Notably, L2-4 bone mineral density increased significantly by 5.7% compared with normal peak value and by 7.1% compared with normal age- and gender-matched values. The authors concluded that **dietary restriction of calcium and oxalate, combined with thiazide and potassium citrate, satisfactorily controlled hypercalciuria but prevented complications commonly associated with sodium cellulose phosphate therapy.**

Although side effects are generally mild, they occur in about 30% to 35% of patients treated with thiazide. Side effects are usually seen on initiation of treatment but disappear with continued treatment. Lassitude and sleepiness are the most common symptoms and can occur in the absence of hypokalemia. **Potassium supplementation should always be considered, particularly in patients with evident potassium deficiency, patients receiving digitalis therapy, and those individuals who develop hypocitraturia.** On occasion, thiazides unmask or induce primary hyperparathyroidism. They may also cause impaired carbohydrate tolerance and hyperuricemia. A more distressing complication is decreased libido or sexual dysfunction seen in a small percentage of patients.

Guidelines for the Use of Sodium Cellulose Phosphate or Thiazides in Absorptive Hypercalciuria

Neither sodium cellulose phosphate nor thiazides correct the basic, underlying physiologic defect in absorptive hypercalciuria. Some guidelines are offered until more selective therapy can be developed.

Sodium cellulose phosphate should be used only in patients with severe absorptive hypercalciuria type 1 who are resistant to or intolerant of thiazide therapy. In patients with absorptive hypercalciuria type 1 who may be at risk for bone disease (growing children, postmenopausal women), thiazide is the first choice and should be combined with potassium citrate and dietary restrictions. If thiazide loses its hypocalciuric action (after long-term treatment), a drug holiday may be instituted and then thiazide therapy may be resumed. The authors recommend that potassium citrate and dietary alterations continue during this time.

Other Hypocalciuric Agents

Other agents may be used in place of hydrochlorothiazide for the treatment of hypercalciuria. These medications include chlorthalidone (25 to 50 mg/day) and indapamide (2.5 mg/day). Indapamide is technically not a thiazide but does share a successful hypocalciuric effect with the other agents. Trichlormethiazide has also been employed at a dose of 4 mg/day, yet this medication is no longer available in the United States. All three agents have been shown to be equally efficacious yet may improve compliance of patients with more convenient once-a-day dosing (Jaeger et al, 1986; Lemieux, 1986; Coe et al, 1988; Ettinger et al, 1988; Ohkawa et al, 1992; Borghi et al, 1993b; Martins et al, 1996).

Amiloride in combination with thiazide (Moduretic) may be more effective than thiazide alone in reducing calcium excretion (Maschio et al, 1981; Leppla et al, 1983). However, this medication does not augment citrate excretion. Since amiloride is a potassium-sparing agent, potassium replacement is not necessary and could, in fact, be problematic. **It is not advisable to provide potassium citrate to patients receiving a potassium-sparing diuretic.** Whereas the potassium-sparing effects of amiloride may be beneficial, the use of triamterene, another potassium-sparing agent, should be undertaken with caution because of reports of triamterene stone formation (Watson et al, 1981; Werness et al, 1982; Ettinger, 1985; Sorgel et al, 1985).

Absorptive Hypercalciuria Type 2

In absorptive hypercalciuria type 2, no specific drug treatment may be necessary since the physiologic defect is not as severe

as in absorptive hypercalciuria type 1. In addition, many patients show disdain for drinking fluids and therefore excrete concentrated urine. A low calcium intake (400 to 600 mg/day) and high fluid intake (sufficient to achieve a minimum urine output of more than 2 liters/day) would seem ideally indicated, since normocalciuria could be restored by dietary calcium restriction alone, and increased urine volume has been shown to reduce urine saturation of calcium oxalate.

Orthophosphate

Orthophosphate (neutral or alkaline salt of sodium or potassium, 0.5 g phosphorus three to four times/day) has been shown to inhibit 1,25-dihydroxyvitamin D synthesis (Van Den Berg et al, 1980; Insogna et al, 1989). **However, there is as yet no convincing evidence from randomized trials that this treatment restores normal intestinal calcium absorption.** Orthophosphate reduces urinary calcium probably by directly impairing the renal tubular reabsorption of calcium and by binding calcium in the intestinal tract. Urinary phosphorus is markedly increased during therapy, a finding that reflects the absorbability of soluble phosphate. Physicochemically, orthophosphate reduces the urine saturation of calcium oxalate but increases that of brushite. Moreover, the urinary inhibitor activity is increased, probably owing to the stimulated renal excretion of pyrophosphate and citrate. Although contrary reports have appeared, this treatment program has been reported to cause soft tissue calcification and parathyroid stimulation (Dudley and Blackburn, 1970). It may be particularly indicated in absorptive hypercalciuria type 3. Orthophosphate is contraindicated in nephrolithiasis complicated by urinary tract infection because of the increased phosphorus load.

A formulation of low-release, neutral potassium phosphate has been developed to obviate the aforementioned problems with currently available orthophosphate preparations. This potassium phosphate preparation (UroPhos-K) is embedded in a wax matrix to provide slow release of the orthophosphate. This restricted release limits the amount of gastrointestinal upset found with most current orthophosphate preparations. In addition, UroPhos-K contains phosphate salts of potassium and does not contain sodium. Therefore, this preparation does not provide a sodium load that could offset the hypocalciuric action of the orthophosphate. Finally, this medication is designed to yield a pH of 7.0 compared with 7.3 for some available orthophosphate preparations. Therefore, it is less likely that the crystallization of calcium phosphate may occur in the urine (Breslau et al, 1995).

A randomized prospective double-blind trial was performed in 21 patients with documented stone formation and absorptive hypercalciuria type 1. Patients received either UroPhos-K or placebo in a double-blinded fashion. No significant gastrointestinal side effects were noted with the slow-release potassium phosphate preparation, nor was there a significant increase in fasting serum potassium or phosphorus concentration. However, the UroPhos-K treatment did significantly reduce urinary calcium from 288 mg/day to 171 mg/day without altering oxalate excretion. Moreover, the urine saturation of calcium oxalate was significantly reduced without altering brushite saturation. Also noted was a significant increase of inhibitor activity secondary to increased urinary citrate and pyrophosphate, thereby inhibiting the potential crystallization of calcium oxalate in the urine (Breslau et al, 1998; Heller et al, 1998). This medication is not yet approved for use in the United States.

Dietary Bran

Rice bran also binds intestinal calcium and increases urinary pyrophosphate (Ebisuno et al, 1991). In an uncontrolled long-term study, rice bran reduced stone recurrences. In another study, 73 patients with recurrent urinary stone formation were treated with 40 g of unprocessed bran daily. Hydrochlorothiazide was added during the summer months. During a 2-year follow-up, three fourths of the patients were free of stones. The combination of thiazide and bran was superior to bran alone in preventing stone formation (Ala-Opas et al, 1987).

KEY POINTS: ABSORPTIVE HYPERCALCIURIA

- Sodium cellulose phosphate effectively decreases the absorption of intestinal calcium but has largely been abandoned because of gastrointestinal intolerance and side effects.
- Thiazides do not treat the underlying cause of absorptive hypercalciuria but do manage its symptoms.
- Orthophosphates may have a role in the treatment of absorptive hypercalciuria when other methods are ineffective.

Renal Hypercalciuria

Thiazide is ideally indicated for the treatment of renal hypercalciuria. This diuretic has been shown to correct the renal leak of calcium by augmenting calcium reabsorption in the distal tubule and by causing extracellular volume depletion and stimulating proximal tubular reabsorption of calcium. The ensuing correction of secondary hyperparathyroidism restores normal serum 1,25-dihydroxyvitamin D concentration and intestinal calcium absorption. Thiazide has been shown to provide a sustained correction of hypercalciuria commensurate with a restoration of normal serum 1,25-dihydroxyvitamin D concentration and intestinal calcium absorption for up to 10 years of therapy (Preminger and Pak, 1987).

Physicochemically, the urinary environment becomes less saturated with respect to calcium oxalate and brushite during thiazide treatment, largely because of the reduced calcium excretion. Moreover, urinary inhibitor activity, as reflected in the limit of metastability, is increased by an unknown mechanism. These effects are shared by hydrochlorothiazide (25 mg twice/day), chlorthalidone (25 to 50 mg/day), and indapamide (2.5 mg/day). **Potassium citrate supplementation (40 to 60 mEq/day) is advised, since this medication has been shown to be effective in averting hypokalemia and in increasing urinary citrate when it is administered to patients with calcium nephrolithiasis taking thiazide** (Nicar et al, 1984; Pak et al, 1985b).

A more complete discussion of the mechanism of action, efficacy, and side effects of thiazides for the treatment of hypercalciuria is presented in the preceding section. Furthermore, Table 43–16 provides a summary of the results of randomized trials involving the use of thiazides for the treatment of hypercalciuria. Of note, a meta-analysis of medical therapies for calculus prevention demonstrated that only thiazides have shown strong evidence for efficacy in randomized trials (Pearle et al, 1999).

KEY POINT: RENAL HYPERCALCIURIA

- Thiazides are first-line therapy for renal leak hypercalciuria.

Primary Hyperparathyroidism

Parathyroidectomy is the optimum treatment of nephrolithiasis in patients with primary hyperparathyroidism (Parks et al, 1980; Fraker, 2000). This therapy may include the resection of a dominant adenoma or removal of all four hyperplastic glands. After removal of abnormal parathyroid tissue, urinary calcium is expected to return to a normal level, commensurate with a decline in serum calcium concentration and intestinal calcium absorption. However, these findings are not always dependable; some patients may suffer from changes in tubular and glomerular functions as a result of long-standing hypercalcemia or hypercalciuria (Farias et al, 1996).

There is no established medical therapy for the nephrolithiasis of primary hyperparathyroidism. Although orthophosphates have been recommended for the disease of mild to moderate severity, their safety or efficacy has not yet been proved. These medications should be used only when parathyroid surgery cannot be undertaken. Estrogen has been reported to be useful in reducing serum and urine concentration of calcium in postmenopausal women with primary hyperparathyroidism (Herbai and Ljunghall, 1983; Marcus et al, 1984; Coe et al, 1986; Selby and Peacock, 1986; Boucher et al, 1989; Diamond et al, 1996; Orr-Walker et al, 2000).

KEY POINT: PRIMARY HYPERPARATHYROIDISM

- Hyperparathyroidism complicated by stone disease is best treated with surgical excision of the adenoma.

Hyperuricosuric Calcium Oxalate Nephrolithiasis

There are two pharmacologic approaches to the management of hyperuricosuric calcium oxalate nephrolithiasis. The first approach involves decreasing the production of uric acid. For this management, allopurinol (300 mg/day) may be used to interfere with the ability of xanthine oxidase to convert xanthine to uric acid (Coe, 1978). The resultant decrease in serum uric acid will ultimately lead to a decrease in urinary uric acid as well. **The use of allopurinol in hyperuricosuria associated with dietary purine overindulgence may also be reasonable if patients are unable or unwilling to comply with dietary purine restriction.** Physicochemical changes ensuing from restoration of a normal urinary uric acid level include an increase in the urinary limit of metastability of calcium oxalate (Pak et al, 1978). Thus, the spontaneous nucleation of calcium oxalate is retarded by treatment, probably by inhibition of monosodium urate–induced stimulation of calcium oxalate crystallization (Pak et al, 1979; Coe et al, 1980). Because of the potential exaggeration of monosodium urate–induced calcium oxalate crystallization, a moderate sodium restriction (150 mEq/day) is also advisable.

There are few convincing randomized trials demonstrating the efficacy of allopurinol for the treatment of hyperuricosuria. However, one study by Ettinger and colleagues (1986) does stand out. In this double-blind, prospective, randomized trial, allopurinol was given to 60 patients with hyperuricosuria, normocalciuria, and recurrent calcium oxalate stones. A 6-month "grace period" was established, during which time any new calculus that was passed was not considered to represent failure of therapy. With a follow-up of up to 39 months, new stone events (stone growth or recurrence) occurred in 58% of the patients receiving placebo and in 31% of the patients receiving allopurinol. The placebo group had 63.4% fewer calculi, whereas the allopurinol group had 81.2% fewer calculi. The mean rate of calculus events was 0.26 per patient per year in the placebo group and 0.12 in the allopurinol group. The allopurinol group had a significantly longer time before the recurrence of stones.

Alternatively, management of hyperuricosuria may be approached by altering the urinary milieu such that uric acid remains in a dissolved state (Pak and Peterson, 1986). Central to this approach would be the obvious advantage of copious amounts of dilute urine to maintain uric acid at a low concentration. Attempts to maintain the urine at a pH above the pKa may also be successful by promoting dissolution of this molecule (Pak et al, 1986b). This effect is usually achieved by the use of an alkalinizing agent such as potassium citrate (at a dose of 30 to 60 mEq/day in divided doses). In the study by Pak, the treatment produced a sustained rise in urine pH by 0.55 to 0.85 to the high-normal range. Urinary citrate levels rose by 249 to 402 mg/day. Commensurate with these changes, urine saturation of calcium oxalate (relative saturation ratio) and the amount of undissociated uric acid declined significantly. Stone formation declined from 1.55 per patient-year to 0.38 per patient-year during a mean treatment period of 2.35 years. Stones ceased to form in 16 of 19 patients during treatment.

There is some evidence that changes in urine pH alone are inadequate for the management of hyperuricosuria (Pak et al, 2002b). If this is the case, the efficacy of citrate for the management of hyperuricosuric calcium nephrolithiasis may stem from the inhibitory activity of citrate with respect to calcium and oxalate crystallization.

Potassium citrate may be particularly useful in patients with mild to moderate hyperuricosuria (<800 mg/day), especially in whom hypocitraturia is also present.

Table 43–16. Randomized Trials of Diuretic Therapy for the Prevention of Calcium Oxalate Stones

Year	Author	Diagnosis	Agent	No. of Patients	No. of Controls	Efficacy	Follow-up	Comments
1981	Brocks et al	Recurrent calcium stones	Bendroflumethiazide, 2.5 mg tid	29	33	83% remission in controls, 85% in treated: not significant	1.6 years	Not all patients were hypercalciuric Only 16% of expected stones formed in controls, 24% in treated
1982	Scholz et al	Recurrent calcium stones	Hydrochlorothiazide, 25 mg bid	25	26	77% remission in controls, 76% in treated: not significant	1 year	Fasting urinary calcium increased before treatment, decreased with thiazides, but not in controls Urine output increased in both groups, indicating that hydration was sufficient
1984	Laerun and Larsen	Recurrent stone formers	Hydrochlorothiazide, 25 mg bid	25	25	45% remission in controls, 75% in treated: significant difference Controls formed 21 stones, treated formed 230 stones: not significant	3 years	General practice study 75% of patients did not have hypercalciuria Differences seen only after 18 months
1988	Ettinger et al	Recurrent calcium stones	Chlorthalidone, 25 or 50 mg/day	42	31	55% remission in controls, 86% in treated: significant	3 years	Only 15% of patients had hypercalciuria Compliance to diet not encouraged or assessed; to drugs, assessed Urine output not measured 16% dropout rate in controls, 35%–40% dropout rate with chlorthalidone
1984	Wilson et al	Recurrent calcium stones	Hydrochlorothiazide, 100 mg/day	21	23	65% remission in controls, 70% in treated: not significant 0.32 stone per year in controls; 0.15 stone per year in treated: significant	<3 years	Not all patients hypercalciuric Other treatments—phosphates, magnesium, allopurinol—were ineffective
1992	Okhawa et al	Idiopathic hypercalciuria	Trichlormethiazide, 4 mg/day	82	93	86% remission in controls, 92% in treated: not significant Stone formation rate significantly lowered in treated patients	3 years	Multi-institutional study All patients had hypercalciuria Many were single stone formers
1993	Borghi et al	Idiopathic hypercalciuria	Indapamide, 2.5 mg/day, or indapamide plus allopurinol, 300 mg/day	25	25	65% remission in controls, 95% in treated: significant		Urinary output did not rise in either group; thus, hydration may not have been effective
Total				249	256	73% remission in controls, 85% in treated patients		Beneficial effects with treatment seen only in trials with follow-up of ≥2 years

KEY POINTS: HYPERURICOSURIC CALCIUM OXALATE NEPHROLITHIASIS

- Patients with hyperuricosuria should be instructed to decrease dietary purine intake.
- Allopurinol can decrease uric acid production and may be ideal for those patients with a history of gout.
- Potassium citrate can effectively alter the urinary milieu in patients with hyperuricosuria by decreasing the supersaturation of uric acid and calcium oxalate.

Enteric Hyperoxaluria

The management of patients with enteric hyperoxaluria usually involves directed therapy that addresses several abnormalities or abnormal physiology. Oral administration of large amounts of calcium (0.25 to 1.0 g, four times/day) or magnesium has been recommended for the control of calcium nephrolithiasis of ileal disease (Worcester, 2002). Although urinary oxalate may decrease (probably from binding of oxalate by divalent cations), the concurrent rise in urinary calcium may obviate the beneficial effect of this therapy, at least in some patients (Barilla et al, 1978). Lindsjo and colleagues (1989) described an interesting organic marine hydrocolloid that had been charged with calcium (Ox-Absorb) for the purposes of oxalate binding in patients with enteric hyperoxaluria. In their clinical studies of 19 patients with intestinal disorders and stone formation, urinary oxalate excretion was significantly lower during treatment with the organic marine colloid than off treatment. Most patients experienced improvement of bowel function, and those with severe stone formation showed decreases in incidence.

Cholestyramine has also been suggested for the management of calculi in this disorder (Stauffer, 1977). This medication may be useful by binding bile salts in the bowel lumen, thereby decreasing the irritation of the colonic mucosa and the subsequent hyperabsorption of oxalate (Caspary et al, 1977). The replacement of dietary fat with medium-chain triglycerides may be helpful in those patients who also have malabsorption.

Patients may exhibit hypomagnesiuria due to impaired intestinal absorption of magnesium. Since magnesium has been shown to complex oxalate, hypomagnesiuria may increase the urine saturation of calcium oxalate (Caudarella et al, 1993). Whereas oral magnesium supplements may correct hypomagnesiuria, they may also provoke further diarrhea. Magnesium gluconate (0.5 to 1.0 g, three times/day) appears to be better tolerated than magnesium oxide or hydroxide. **Treatment with potassium citrate (60 to 120 mEq/day) may correct the hypokalemia and metabolic acidosis in patients with enteric hyperoxaluria and, in some individuals, increase urinary citrate toward normal.** Consideration should be given to providing the liquid form of potassium citrate in patients with rapid gastrointestinal transit times; the liquid form of this medication may be better absorbed than the slow-release, wax matrix pills.

A high fluid intake is recommended to ensure adequate urine volume. Since excessive fluid loss may be present, an antidiarrheal agent may be necessary before sufficient urine output can be achieved. Calcium citrate may theoretically have a role in management of enteric hyperoxaluria. This treatment may lower urinary oxalate by binding oxalate in the intestinal tract. Calcium citrate may also raise the urine concentration of citrate and pH by providing an alkali load (Harvey et al, 1985). Finally, calcium citrate may correct the malabsorption of calcium and adverse effects on skeleton by providing an efficiently absorbed formulation of calcium.

KEY POINTS: ENTERIC HYPEROXALURIA

- Fluid intake should be strongly encouraged to correct the relative state of dehydration.
- Dietary calcium may help bind intestinal oxalate and decrease its absorption.
- Slow-release formulations of citrate should be avoided.

Hypocitraturic Calcium Oxalate Nephrolithiasis

In patients with hypocitraturic calcium oxalate nephrolithiasis, potassium citrate treatment is capable of restoring the normal urinary citrate level, lowering the urine saturation, and inhibiting the crystallization of calcium salts. Since hypocitraturia is found in a number of different conditions, each is addressed individually.

Distal Renal Tubular Acidosis

Potassium citrate therapy is able to correct the metabolic acidosis and hypokalemia found in patients with distal renal tubular acidosis (Preminger et al, 1985). In addition, this medication is capable of restoring normal urinary citrate levels, although large doses (up to 120 mEq/day) may be required in severe acidotic states. With correction of the acidosis, urinary calcium should decline into the normal range. Since urine pH is generally high to begin with in patients with renal tubular acidosis, the overall rise in urine pH is small.

Potassium citrate therapy typically produces a sustained decline in the urine saturation of calcium oxalate (from reduction in urinary calcium and in citrate complexation of calcium). The urine saturation of calcium phosphate does not increase since the rise in phosphate dissociation is relatively small and is adequately compensated by a decline in ionic calcium concentration. In addition, the inhibitory activity against the crystallization of calcium oxalate and calcium phosphate is augmented by the direct action of citrate.

Investigators from Thailand have suggested that the target dose of potassium citrate for children with distal renal tubular acidosis should be 3 to 4 mEq/kg/day in divided doses (Domrongkitchaiporn et al, 2002c; Tapaneya-Olarn et al, 2002).

Chronic Diarrheal States

The full management of enteric stone disease is discussed earlier in this chapter. Part of the entire management should

involve the use of citrate to correct the acidosis that accompanies the chronic bicarbonate losses with diarrhea. The amount of potassium citrate depends on the severity of hypocitraturia in these patients; dosages range from 60 to 120 mEq in three or four divided doses.

It is recommended that a liquid preparation of potassium citrate be used rather than the slow-release tablet preparation since the slow-release medication may be poorly absorbed as a result of rapid intestinal transit time. In addition, frequent dose schedules (three or four times a day) for the liquid preparation are necessary because this form of the medication has a relatively short duration of biologic action.

Thiazide-Induced Hypocitraturia

Noted previously, thiazide therapy may cause hypocitraturia due to thiazide-induced hypokalemia with resultant intracellular acidosis (Nicar et al, 1984). Therefore, it should be a common practice to administer potassium supplementation, preferably in the form of potassium citrate, to patients receiving thiazides for treatment of hypercalciuria. Potassium citrate has been shown to be as effective as potassium chloride in correction of thiazide-induced hypokalemia. Moreover, the addition of potassium citrate not only prevents a fall in urinary citrate during thiazide therapy but may raise citrate excretion (Pak et al, 1985b).

Idiopathic Hypocitraturic Calcium Oxalate Nephrolithiasis

This entity includes hypocitraturia occurring alone as well as in conjunction with other abnormalities (e.g., hypercalciuria or hyperuricosuria). Stones formed in this condition are predominantly composed of calcium oxalate. Potassium citrate therapy may produce a sustained increase in urinary citrate and a decline in the urine saturation of calcium oxalate (Pak and Fuller, 1986). Two agents have been used for the treatment of hypocitraturia: sodium-potassium citrate, commonly used in Europe; and potassium citrate, in liquid form or as a wax matrix tablet, used in the United States. The usual therapeutic dose is 30 to 60 mEq/day given in divided doses or as a single evening dose (Berg et al, 1992). Sodium citrate does not lower urinary calcium excretion, perhaps as a result of the increased sodium load associated with this therapy (Sakhaee et al, 1983; Preminger et al, 1988).

In general, citrate is well tolerated, although the potential for gastric upset is real. The current formulation of potassium citrate embedded within a wax matrix may help alleviate the risk of gastric irritation. Patients are strongly encouraged to take this medication with meals to act as a further buffer.

KEY POINTS: HYPOCITRATURIC CALCIUM OXALATE NEPHROLITHIASIS

- Citrates are generally well tolerated with only a small risk of gastrointestinal upset.
- Citrates are first-line therapy for renal tubular acidosis, thiazide-induced hypocitraturia, and idiopathic hypocitraturia.

Hypomagnesiuric Calcium Nephrolithiasis

Hypomagnesiuric calcium nephrolithiasis is characterized by low urinary magnesium level, hypocitraturia, and low urine volume. Therefore, **management should include restoration of urinary magnesium levels with either magnesium oxide or magnesium hydroxide as well as correction of the hypocitraturia with potassium citrate.** The administration of magnesium salts was first advocated on the grounds that it reduced urinary excretion of oxalate. Some magnesium salts increase urinary magnesium excretion and thus produce a more favorable magnesium-to-calcium ratio in the urine, a condition that offers relative protection against stone formation. Magnesium decreases renal tubular citrate resorption through the chelation of citrate and thus increases urinary citrate excretion. Melnick and coworkers (1971) found that stone recurrence dropped from 6 stones per year to 0.073 stone per year in a group of 149 recurrent calcium oxalate stone formers treated with magnesium oxide. Prien and Gershoff (1974) reported that about 70% of patients administered 300 mg of magnesium oxide and 100 mg of pyridoxine demonstrated complete cessation of stone formation. Johansson and associates (1980) treated 56 patients with 400 to 500 mg of magnesium hydroxide; 80% of the treated patients were free of stones, in comparison to 50% who did not receive magnesium supplementation. The rate of stone formation dropped from 0.8 stone per year to 0.03 stone per year in the treated patients and from 0.5 stone per year to 0.22 stone per year in the control subjects. At least one randomized trial showed no difference in recurrence rates between treated and untreated patients (Ettinger et al, 1988).

Several magnesium salts have been used for the treatment of stone disease. Magnesium oxide and magnesium hydroxide are poorly absorbed and produce only a slight decrease in urinary oxalate and a modest increase in urinary magnesium (Barilla et al, 1978; Johansson et al, 1980). Urinary calcium levels are increased during magnesium oxide supplementation (Melnick et al, 1971; Fetner et al, 1978; Tiselius et al, 1980), and thus urine saturation of calcium oxalate is not significantly lowered with magnesium oxide. Lindberg and colleagues (1990) found that either magnesium citrate or magnesium oxide induced only modest beneficial changes in urinary biochemistry when administered on an empty stomach. When the magnesium salts were provided with meals, however, they caused more prominent changes in urinary biochemistry and lowered the relative saturation of urine with calcium oxalate or brushite.

Gastrointestinal intolerance is the major side effect of magnesium therapy. At this time, magnesium supplementation is not widely used. Magnesium supplementation may be used with sodium cellulose phosphate in the treatment of patients with absorptive hypercalciuria type I and with potassium citrate in patients with chronic diarrheal syndromes.

A new magnesium preparation (potassium-magnesium citrate) that provides both magnesium and citrate in the same tablet has been developed but is not yet approved for use. This formulation of potassium-magnesium citrate has been shown to provide as much bioavailable potassium as other preparations (Koenig et al, 1991). In addition, magnesium excretion

was significantly increased, as was the excretion of urinary citrate. The ability to deliver potassium has been further studied as it relates to thiazide-induced hypokalemia. This medication was demonstrated to provide just as much bioavailable potassium as other, standard agents (Wuermser et al, 2000).

Finally, Ettinger (1997) has reported on a randomized, double-blind trial of potassium-magnesium citrate versus placebo. In the study, new calculi formed in 63.6% of subjects receiving placebo and in 12.9% of subjects receiving potassium-magnesium citrate. Compared with placebo, the relative risk of treatment failure for potassium-magnesium citrate was 0.16. The authors concluded that potassium-magnesium citrate effectively prevents recurrent calcium oxalate stones and could be depended on to provide up to 85% protection for 3 years.

KEY POINTS: HYPOMAGNESIURIC CALCIUM NEPHROLITHIASIS

- Magnesium supplementation can provide benefits in stone reduction.
- The use of magnesium has been limited by the risk of diarrhea.
- Potassium-magnesium may restore urinary magnesium and citrate levels with minimal gastrointestinal side effects.

Gouty Diathesis

The major goal in the management of gouty diathesis is to increase the urine pH above 5.5, preferably between 6.5 and 7.0 (Khatchadourian et al, 1995). In the past, urine alkalinization has been accomplished with either sodium bicarbonate or various combinations of sodium and potassium alkali therapy. Whereas sodium alkali may enhance dissociation of uric acid and inhibit uric acid stone formation by raising urine pH, this medication may be complicated by the development of calcium-containing stones (calcium phosphate or calcium oxalate). Potassium citrate is advantageous because it not only is a good alkalinizing agent but appears to be devoid of the complication of calcium stones. Potassium citrate should be given at a dose sufficient to maintain urine pH at approximately 6.5 (30 to 60 mEq/day in two or three divided doses). **Attempts at alkalinization of the urine to a pH higher than 7.0 should be avoided. At a higher pH, there is a danger of increasing the risk of calcium phosphate stone formation.** If the urinary uric acid excretion is elevated or hyperuricemia exists, allopurinol (300 mg/day) should be added.

Cystinuria

The object of treatment of cystinuria is to reduce the urine concentration of cystine to below its solubility limit (200 to 300 mg/L) (Pak and Fuller, 1983). The initial treatment program includes a high fluid intake to attempt to produce 2.5 to 3 liters of urine per day. This amount of urine output will dramatically raise the denominator of the concentration fraction and help reduce the supersaturation of urine with respect to cystine. Others have recommended the oral administration of soluble alkali (potassium citrate) at a dose sufficient to raise the urine pH to 6.5 to 7.0 (Chow and Streem, 1998; Joly et al, 1999). This treatment strategy attempts to increase the solubility of the filtered cystine to prevent crystal formation. Whereas alkali therapy may help, it is important to remember that the pKa of cystine is 8.3, which causes two problems. First, it is difficult to achieve a urine pH this high, making excessive alkalinization an unrealistic target. Second, raising the urine pH to these levels will put the patient at risk for the formation of calcium phosphate calculi.

There is good evidence that excess dietary sodium can lead to increases in cystine excretion (Norman and Manette, 1990; Lindell et al, 1995; Rodriguez et al, 1995; Fjellstedt et al, 2001). Indeed, these authors have demonstrated that the restriction of dietary sodium should be an integral aspect of the global management of cystinuric patients. Fjellstedt has even shown that the use of sodium citrate rather than potassium citrate may diminish the efficacy of other medical interventions, such as the sulfhydryl-containing compound α-mercaptopropionylglycine.

When this conservative program is ineffective, **the next line of therapy involves the use of agents that increase cystine solubility in urine through formation of a more soluble mixed disulfide bond (i.e., cystine to drug, rather than cystine to cystine). These agents include D-penicillamine (Cuprimine), α-mercaptopropionylglycine (Thiola, tiopronin), and captopril.**

The first agent studied was D-penicillamine. Interestingly, little has been written specifically about this agent and its use in the treatment of cystinuria since the 1960s and 1970s (Crawhall and Thompson, 1965; McDonald and Henneman, 1965; Lotz et al, 1966; Combe et al, 1993). Although moderately effective, D-penicillamine quickly became associated with frequent side effects including nephrotic syndrome, dermatitis, and pancytopenia. Typical doses start at 250 mg/day and are titrated to effect.

The next medication to be introduced for the treatment of cystinuria was α-mercaptopropionylglycine (Remien et al, 1975; Hautmann et al, 1977; Johansen et al, 1980). This agent also contains a sulfhydryl group that forms a disulfide bond with cystine. Although this agent has been shown to be slightly less effective at capturing cystine molecules in vivo (Harbar et al, 1986), **α-mercaptopropionylglycine is better tolerated than D-penicillamine and therefore enjoys clinical superiority** (Pak et al, 1986a). However, side effects are still possible. Indeed, Pak demonstrated that overall, side effects to α-mercaptopropionylglycine were relatively common and occurred in 64.7% without a history of D-penicillamine treatment, compared with 83.7% who suffered toxic effects of D-penicillamine. Moreover, serious adverse reactions requiring cessation of therapy were less common with α-mercaptopropionylglycine. Among the patients who took both drugs, 30.6% had to stop taking α-mercaptopropionylglycine, whereas 69.4% could not tolerate D-penicillamine. Common side effects include asthenia, gastrointestinal distress, rash, joint aches, and mental status changes. Dosages start at 100 mg, taken orally two times per day, and are titrated to achieve urine concentrations of cystine less than 250 mg per liter of urine. Pak has reported total daily doses as high as 1200 mg (Pak et al, 1986a).

As described earlier in this chapter, Coe and colleagues (2001) have presented an assessment of cystine prophylaxis based on the supersaturation of cystine in the presence of thiol-based medications. In essence, this assay measures how much "room" there is in the patient's urine for more cystine. Demonstration that the urine is not yet fully saturated implies a lower risk for spontaneous stone formation.

Finally, the angiotensin-converting enzyme inhibitor captopril has been used to treat cystinuria because of its available sulfhydryl group. Although this agent enjoyed early enthusiasm (Sloand and Izzo, 1987; Streem and Hall, 1989; Cohen et al, 1995), its popularity seems to have waned (Michelakakis et al, 1993). Side effects are less severe than with the other agents and include fatigue, hypotension, and chronic cough. **Yet, there have been no long-term clinical trials demonstrating the effectiveness of captopril in preventing recurrent cystine stone formation.**

The medical management of cystinuria can be challenging. Whereas the array of medication choices is not particularly complicated, it is often difficult to achieve the patient's compliance (Barbey et al, 2000). Indeed, because of the genetic nature of the disease process, these patients frequently begin their stone formation at a young age, thereby exposing their kidneys to the risk of chronic stone passage and potential parenchymal loss (Lindell et al, 1997) (Fig. 43–11). Assimos and colleagues (2002) have examined the clinical status of 40 cystinuric patients observed at two medical centers and compared their "kidney health" with that of 3964 calcium oxalate stone formers enrolled in a database. The mean serum creatinine concentration for stone-forming cystinuric patients was significantly higher than that of the calcium oxalate cohort. Male gender, increasing number of open surgical stone-removing procedures, and nephrectomy were significant variables associated with an increased serum creatinine concentration. An alarming number of cystinuric patients had undergone nephrectomy for any reason (14%) versus the patients in the calcium oxalate cohort (3%).

Unfortunately, despite the obvious consequences of poor medical compliance, a study suggests that few patients are able to achieve and to maintain targeted goals of medical intervention (Pietrow et al, 2003). Of the 26 patients observed at a dedicated stone center, only 15% achieved and maintained therapeutic success, as defined by urine cystine concentration less than 300 mg/L. An additional 42% achieved therapeutic success but subsequently had failure at an average of 16 months (range, 6 to 27). Of these patients, two thirds were able to regain therapeutic success at an average of 9.4 months (range, 4 to 20); 19% never achieved therapeutic success, whereas an additional 23% failed to present to follow-up appointments or to provide subsequent 24-hour urine studies despite their having been referred to a tertiary care center. The patients' self-assessment of medical compliance was uniformly high regardless of physicians' perceptions or treatment results.

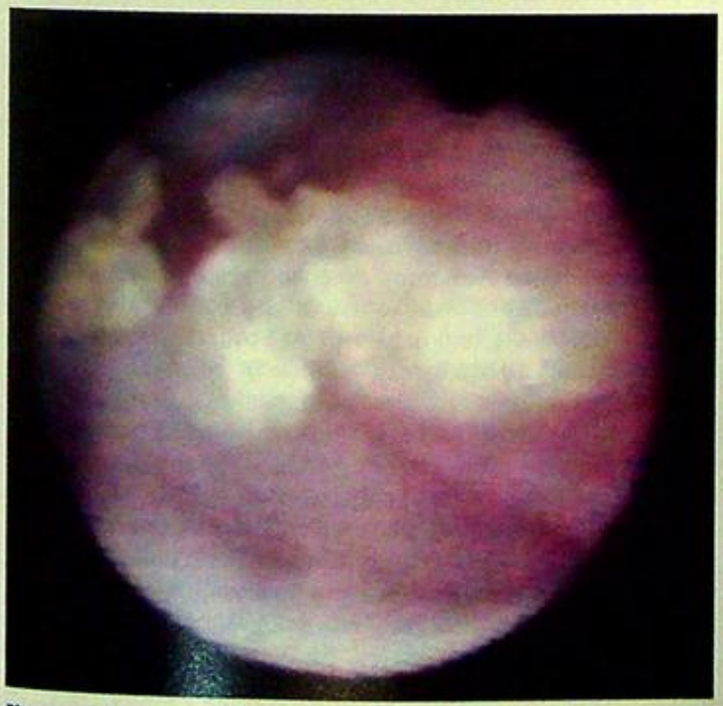

Figure 43–11. Endoscopic view of a renal papilla that has been partially replaced by a cystine calculus.

KEY POINTS: CYSTINURIA

- The medical compliance of patients with cystinuria can be poor.
- Treatment consists of aggressive fluid intake, urine alkalinization, salt avoidance, and use of a cystine-binding agent.
- α-Mercaptopropionylglycine (Thiola) is the most frequently used cystine-binding agent.

Infection Lithiasis

The preferred management of struvite calculi involves aggressive surgical approaches. **The American Urological Association Guidelines Committee has released updated guidelines that strongly recommend endoscopy-based therapy (i.e., percutaneous nephrolithotomy) as the first-line therapy for management of complex renal staghorn calculi** (Preminger et al, 2005). **This report noted that complete elimination of all infected stone material is essential for the prevention of recurrent struvite stone formation.** A complete discussion of surgical therapy for large calculi is beyond the scope of this chapter and can be found in Chapter 44.

The medical management of infection calculi centers on the prevention of recurrence rather than medical dissolution. As such, **long-standing effective control of infection with urea-splitting organisms should be achieved if at all possible with improved bladder health, adequate urine drainage, and suppressive antibiotics** (Hess, 1990; Bichler et al, 2002). Unfortunately, such control is difficult to obtain in the face of residual calculi since stones often harbor organisms and endotoxin within their interstices (Rocha and Santos, 1969; McAleer et al, 2002, 2003). Antibiotics should be tailored to the predominant organism found on culture and sensitivity screening (Hugosson et al, 1990). Notably, culture results do not always correlate well between a patient's urine and a resuspension of stone material (Fowler, 1984).

Therefore, strong clinical suspicion is always indicated, and all patients undergoing removal of presumed struvite calculi should be covered with broad-spectrum antibiotics that account for local resistance patterns. Although cultures may become negative during treatment, recurrence of colonization is likely if residual fragments remain within the collecting system.

After surgical stone removal, residual fragments may be dissolved with hemiacidrin irrigation (Renacidin) under careful observation. Historically, use of this agent was associated with significant toxicity and even death. Closer scrutiny revealed that many if not most of these cases involved the use of irrigation in infected urine or sepsis. Therefore, this agent should be employed only after urinary tract infection or colonization has been brought under control. The renal pelvis is first irrigated with sterile saline solution at a rate of 120 mL/hr for 24 to 48 hours, beginning on the fourth or fifth postoperative day. The height of irrigation is adjusted to the lowest level necessary to maintain the flow rate at 120 mL/hr. If there is leakage around a surgical drain or through the incision, irrigation is stopped until additional healing occurs. The patient is observed carefully for development of fever or any flank discomfort and for elevation of serum creatinine, magnesium, or phosphate levels (Dretler and Pfister, 1984). Occurrence of any of these conditions requires immediate cessation of irrigation.

If, after 48 hours, the patient's condition remains satisfactory and there is no infection, no leakage, and no fever or flank discomfort, irrigation is begun with an appropriate solution. Flow rate is continued at 120 mL/hr through the irrigation tube or catheter. Most authors (Jacobs and Gittes, 1976; Nemoy and Stamey, 1976; Palmer et al, 1987) instruct their patients to stop the irrigation themselves if there is evidence of flank pain at any time.

The progress of irrigation is followed by radiographic tomography of the calculi at intervals. Irrigation is continued for 24 to 48 hours after the last radiographically visible fragments have disappeared. In some instances, the rate of irrigation may be reduced to prevent irritation of the kidney or bladder, or sterile saline solutions may be alternated with irrigating solutions. Chemolysis with various agents is no longer routinely used for the management of struvite calculi.

Acetohydroxamic acid, a urease inhibitor, may reduce the urine saturation of struvite and therefore retard stone formation (Griffith et al, 1978). **When given at a dose of 250 mg three times per day, acetohydroxamic acid has been shown to prevent recurrence of new stones and to inhibit the growth of stones in patients with chronic urea-splitting infections.** At least two studies have demonstrated significant efficacy in randomized, placebo-controlled trials (Williams et al, 1984; Griffith et al, 1991). In these investigations, patients were treated with acetohydroxamic acid as well as with antibiotics. Recurrence rates and subsequent stone growth were significantly less for patients treated with drug therapy compared with placebo. In addition, in a limited number of patients, this agent has caused dissolution of existing struvite calculi (Rodman et al, 1983). **However, a significant percentage of patients receiving chronic acetohydroxamic acid therapy have experienced minor side effects, and 15% developed deep venous thrombosis.** Indeed, Rodman and colleagues (1987) have demonstrated that patients receiving acetohydroxamic acid enter into a state of low-grade intravascular coagulation, requiring careful follow-up for signs of thrombosis.

Several authors have reported high rates of medication cessation due to intolerable side effects. In the randomized studies noted, 22% to 68% of treated patients had to stop therapy and withdraw from the investigation. Reported side effects have been varied and include thromboembolic phenomena, tremor, headache, palpitations, edema, gastrointestinal distress, loss of taste, rash, alopecia, anemia, and abdominal pain. Because of these concerns, this agent is frequently reserved for those patients deemed too ill for surgical management. Other acidifying agents have been reported by Wall and Tiselius (1990) but do not appear to have been widely used. These include ammonium chloride, methenamine hippurate, and ascorbic acid.

KEY POINTS: INFECTION LITHIASIS

- Struvite calculi are best managed with surgical removal rather than by chemical dissolution.
- Recurrent infections (and therefore recurrent calculi) may be avoided with antibiotic prophylaxis.
- Acetohydroxamic acid (Lithostat) can effectively inhibit urease, but its widespread use is precluded by significant side effects.

Ammonium Acid Urate Stones

Ammonium acid urate calculi are infrequently seen in industrialized nations and are often associated with laxative abuse (Dick et al, 1990; Kato et al, 2004). The largest described series has been reported by Soble and colleagues (1999) from the Cleveland Clinic. In their series, 23 women and 21 men ranging in age from 20 to 81 years (mean, 48.7 years) were treated for stones partly composed of ammonium acid urate. Stone composition ranged from 2% to 60% ammonium acid urate (mean, 24.1%) of the total stone mass. No patient had a pure ammonium acid urate stone, although 11 (25%) had stones with ammonium acid urate as the predominant crystal. The authors identified one or more potential risk factors for ammonium acid urate for most patients. Of the patients, 25% had a history of inflammatory bowel disease, with 22.7% having undergone ileostomy diversion; 13.6% admitted to a history of significant laxative use or abuse, 40.9% were morbidly obese, 36.4% had a history of recurrent urinary tract infections, and 20.5% had a history of recurrent uric acid stones. On the basis of these findings, the authors suggested that laxative abuse should not be assumed for all patients with ammonium acid urate calculi; rather, a metabolic evaluation or full history should be sought for each patient.

Medical treatment of these calculi is determined by the underlying cause of the stone. Those with laxative abuse are strongly encouraged to develop a healthier bowel regimen. Those with chronic infections are treated much like those with struvite calculi. Bowel disease is treated, if possible, and standard recommendations of fluid intake, oral calcium, alkalinization, and oxalate reduction are made. Those with a history of uric acid calculi are also treated in a similar manner with

Table 43–17. Medications Associated with Renal Calculus Formation

Calculi formed from drug
Indinavir
Ephedrine

Furosemide
Vitamin C (excess)
Vitamin D (excess)
Laxatives

increased fluid intake, protein and salt restriction, and possibly use of citrates or allopurinol.

Miscellaneous and Drug-Induced Stones

Some stones are formed from supersaturation of medications themselves or may be due to the effects of a particular agent. Several medications have been associated with stone disease and are listed in Table 43–17.

Calculi formed from antiretroviral medications used to treat human immunodeficiency virus infection have been described, particularly with indinavir (Crixivan) (Bach and Godofsky, 1997; Hug et al, 1999; Sundaram and Saltzman, 1999; Saltel et al, 2000). These calculi can be quite soft and often dissipate rapidly during endoscopy or shockwave lithotripsy. **Difficulties may arise during diagnosis as indinavir stones may not be visible on plain film radiography and may even be undetectable on stone protocol CT** (Gentle et al, 1997; Sundaram and Saltzman, 1999). Treatment entails aggressive hydration and endoscopy for those stones that do not pass spontaneously. The radiolucency of the calculi often precludes successful treatment with shockwave lithotripsy. In the short term, patients may be temporarily taken off of indinavir until an aggressive fluid habit can be established. Some patients require cessation of this antiretroviral and the initiation of a different agent.

As described earlier, triamterene, a potassium-sparing antihypertensive agent, may crystallize in the urinary tract, requiring cessation of this medication (Werness et al, 1982; Sorgel et al, 1985). For this reason, triamterene is not recommended as an adjunct to thiazides during the treatment of hypercalciuric states.

Carbonic anhydrase inhibitors may be associated with the formation of calcium-based calculi, particularly calcium phosphate (Kondo et al, 1968; Parfitt, 1969). In this scenario, the use of the medication creates a chronic intracellular acidosis. This in turn creates a urinary milieu reminiscent of a distal tubular acidosis with hyperchloremic acidosis, high urine pH, extremely low urinary citrate, and hypercalciuria. Treatment may be accomplished with potassium citrate replacement or, more logically, cessation of the medication. Topiramate is a relatively new antiepileptic medication with significant promise for the treatment of refractory epilepsy. Unfortunately, it may mimic the effect of a carbonic anhydrase inhibitor and lead to the formation of urinary calculi (Kossoff et al, 2002; Kuo et al, 2002; Lamb et al, 2004). The incidence of such an effect has been reported to be approximately 5% (Kossoff et al, 2002).

Finally, **multiple authors have described calculi that have formed in patients taking supplements containing ephedrine** (Blau, 1998; Powell et al, 1998; Assimos et al, 1999; Hoffman et al, 2003; Bennett et al, 2004; Smith et al, 2004; Whelan and Schwartz, 2004). These calculi are likely to be radiolucent but have been reported to be "visible" on non–contrast-enhanced CT. Ephedrine stones have been treated with a variety of methods, including shockwave lithotripsy, endoscopy, and even alkalinization therapy. Because this supplement has a risk of abuse, it may be difficult to effectively interfere with the formation of future stone events.

MISCELLANEOUS SCENARIOS

Medical Management of Bladder Calculi

In the United States, bladder calculi usually occur in men older than 50 years and are associated with bladder outlet obstruction. The diagnosis of a bladder stone should result in a complete urologic evaluation for factors that cause urine stasis, such as urethral stricture, benign prostatic hyperplasia, bladder diverticulum, and neurogenic bladder.

In contrast to renal stones, **bladder stones are usually composed of uric acid (in noninfected urine) or struvite (in infected urine).** Reports from the United States revealed uric acid stones in nearly 50% of patients with bladder stones (Douenias et al, 1991). Such patients often have bladder outlet obstruction, causing them to decrease fluid intake with the resultant production of concentrated, acidic urine. The occurrence of calcium oxalate or cystine stones in the bladder suggests the presence of calculi in the kidney with subsequent ureteral passage and entrapment in the bladder.

Bladder calculi are usually solitary but may develop in large numbers in the presence of urine stasis (Sarica et al, 1994). **The typical symptoms of a vesical stone are intermittent, painful voiding and terminal hematuria.** Discomfort may be dull, aching, or sharp suprapubic pain, which is aggravated by exercise and sudden movement. Severe pain usually occurs near the end of micturition, as the stone becomes impacted at the bladder neck. Relief may be afforded by assuming a recumbent position. The pain may be referred to the tip of the penis, the scrotum, or the perineum and on occasion to the back or the hip. **Besides pain, there may be an interruption of the urinary stream from impaction of the stone at the bladder neck or urethra.**

Bladder calculi are frequently missed on plain film because of a high component of uric acid and overlying prostatic tissue. Such stones form negative shadows in the cystogram phase of intravenous urography. Ultrasonography is useful for detecting radiolucent calculi. Cystoscopic examination is the surest method for detecting vesical calculi.

Most bladder calculi can be removed by endoscopic techniques. Various lithotripters have been used, including ultrasonic handpieces, lasers, pneumatic devices, and electrohydraulic probes (Ikari et al, 1993; Razvi et al, 1996). Transurethral and percutaneous approaches have been described with good success. Stone dissolution is feasible with the use of Suby G or M solution. This method is protracted and now rarely employed. **Suby's solutions or Renacidin may prove beneficial in irrigating indwelling suprapubic or urethral catheters to decrease and to prevent encrustation and occlusion** (Kennedy et al, 1992; Getliffe et al, 2000). Twice-daily or thrice-daily irrigation with 0.25% or 0.5% acetic acid solution also serves as beneficial prophylaxis against recurrent struvite calculi when catheters must be left indwelling for long periods. Uric acid calculi may be dissolved by irrigation with alkaline solutions.

The mainstay of therapy for the prevention of recurrent bladder calculi involves relief of the bladder outlet obstruction. This treatment may include the performance of a transurethral resection of the prostate or an open prostatectomy, if the gland is large.

Medical Management of Pediatric Calculi

Children may develop urinary calculi from several underlying causes as outlined in Chapter 42. Evaluation and management depend on the causative process.

Neonatal Nephrolithiasis

Neonates with furosemide-induced nephrolithiasis present with hematuria, worsening renal function, and calcific densities on ultrasonography or plain film radiography. Nephrocalcinosis is often present on imaging studies. This same process has been seen in other infants with severe low birth weight or prematurity and no history of loop diuretic use.

Management of neonatal nephrolithiasis entails the obvious optimization of the infant's overall health. **Cessation of furosemide diuresis is considered helpful and standard therapy. There has been previous suggestion that treatment with thiazide diuretics may actually promote the resolution of this process and reverse the likely parenchymal injury** (Noe et al, 1984). **This observation has not been supported by other investigators, however.** Pope and colleagues (1996) noted a 50% resolution rate of the nephrocalcinosis after cessation of loop diuretics, but this was unrelated to any other factor, including the use of thiazides. Instead, a low calcium/creatinine ratio at the time of diagnosis was the best predictor of resolution. Further research by Knoll and Alon (2000) with an animal model of the disease did not demonstrate a therapeutic effect of the use of thiazides on furosemide-induced nephrocalcinosis.

At the very least, this evidence suggests that **neonates treated with loop diuretics should be screened for the development of nephrocalcinosis. Whereas switching to a thiazide diuretic may not actively cause the dissolution of calculi, it at least removes the causative agent and allows the kidney an opportunity to heal and clear the calcium deposits.**

Children and Adolescents

As children reach physical maturity at a younger age, it is not surprising that the incidence of urinary calculi in adolescence appears to be increasing. Within the United States, this finding is probably further related to the increasing prevalence of obesity within this same age group. **Nevertheless, the appearance of urinary calculi during childhood should raise the distinct possibility of an inherited genetic disorder, such as cystinuria, distal renal tubular acidosis, or primary hyperoxaluria.**

The evaluation of pediatric nephrolithiasis has been hampered in the past by a lack of consensus regarding normal laboratory values during 24-hour urine collections in children. Clinicians have therefore relied on calculated ratios to correct for the wide variation in weight within this diverse population of patients. The most important of these has been the urinary calcium/creatinine ratio. A calculated urinary calcium/creatinine ratio above 0.2 has been considered abnormal and frequently prompts intervention.

Several investigators have explored the use of urine supersaturation calculations to assess for stone risk factors in children (Battino et al, 2002; Lande et al, 2005). These calculations may detect abnormalities otherwise overlooked by "traditional" cumulative measurements. At least one of these authors, however, noted that the importance of supersaturation wanes considerably in the face of low urine volumes (Lande et al, 2005).

The medical management of nephrolithiasis and the prevention of subsequent recurrences in children do not differ dramatically from the approaches undertaken for adults. All patients (and their parents) are counseled to improve fluid intake. Dietary recommendations are similar to those made for adults. Dietary calcium is not to be avoided in this age group. Rather, calcium should be sought through the ingestion of dairy and other natural sources rather than with the use of supplements. Such sources will also bind dietary oxalate during meals and may decrease calcium oxalate supersaturation in the urine.

Children with cystinuria or hyperoxaluria are managed as outlined in the previous section within this chapter. The exception to this is a general reticence to begin sulfur-binding agents in cystinuric children without first maximizing fluid intake and the use of citrates to alkalinize the urine.

Children with documented hypocitraturia or distal renal tubular acidosis are usually treated with citrates at a dose of 4 mEq/kg/day (Domrongkitchaiporn et al, 2002a). Hypercalciuria may respond to increased fluid intake and decreased sodium (salt) ingestion, much like in the adult population. Thiazides may be employed for recalcitrant hypercalciuria. The long-term efficacy and safety of thiazides in the pediatric population have not been well studied and established.

Medical Management of Calculi During Pregnancy

The management of calculi during pregnancy is currently undergoing a transformation. These changes, however, are developing mainly within the realm of surgical intervention, not medical therapy. As noted in Chapter 42, **pregnant women create a unique urinary environment that is prone**

to stone formation. Whereas the amount of urinary calcium rises notably (Gertner et al, 1986), **this effect is offset by an accompanying increase in urinary citrate. As a result, it is widely assumed that there is no net increase or decrease in the risk of calculi formation during pregnancy** (Coe et al, 1978; Maikranz et al, 1987). **Because of these temporary physiologic changes, a metabolic evaluation is not generally undertaken to determine the cause of the stone disease until after the woman has delivered and returned to her baseline state of health.**

The acute evaluation of a pregnant woman with suspected renal colic begins with a thorough history and physical examination. A urinalysis specimen is obtained and examined for signs of active urinary tract infection. Patients may also present with vague abdominal pain, unexplained fevers, recurrent urinary tract infections, persistent bacteriuria, or microscopic hematuria. A previous history of nephrolithiasis should also be sought as the increased dilation of the ureters during pregnancy may increase the risk that a preformed stone will break loose and attempt to pass.

Radiation exposure to the fetus should be avidly avoided. Therefore, ultrasonography has become the first-line imaging study to search for calculi during pregnancy. Although this modality provides adequate images of the kidneys, it can be difficult to fully discern the ureters and their contents. In addition, hydronephrosis of pregnancy may be confused with hydronephrosis from an obstructing calculus. **Limited intravenous pyelography may be performed that consists of one scout image followed by one plate taken approximately 30 minutes after the injection of contrast material. Each plain film exposes the fetus to 0.1 to 0.2 rad, well below the threshold of 1.2 rad, when the risk begins to increase.** Radiation exposure should be particularly avoided in the first trimester during the time of organogenesis and the greatest fetal risk.

Approximately 66% to 85% of pregnant women with ureteric colic spontaneously pass the calculi when they are treated conservatively with hydration, analgesics, and, if infected, antibiotics (Jones et al, 1979; Stothers and Lee, 1992). The goal of therapy for the remaining patients is to do the least required to keep the kidney functioning, the patient free from symptoms, and the urine uninfected. **Stents should be placed cystoscopically with minimal radiographic or sonographic monitoring** (Loughlin and Bailey, 1986; Jarrard et al, 1993). Some studies have demonstrated increased encrustation of stents, requiring frequent changes. In some instances, the stents migrated down the ureter because of the physiologic dilation (Stothers and Lee, 1992). Stents are often exchanged every 4 to 6 weeks to avoid excessive encrustation and the risk of obstruction.

Since many expectant mothers take calcium supplementation, a more stone-friendly form of this mineral has been developed (Citracal Prenatal Rx). In this formulation, calcium is bound to citrate, which delivers extra stone inhibitor into the urine, thereby offsetting the effects of worsening absorptive hypercalciuria. Iron and folate are also added to complete the elements commonly found in prenatal multivitamin supplements. Although there are no randomized data to support the use of this supplement, its use does make intuitive sense for patients at risk for recurrent calculi during pregnancy.

A full discussion of the surgical management of calculi during pregnancy is beyond the scope of this chapter. **There is growing evidence, though, that ureteroscopy, with holmium laser lithotripsy performed later during pregnancy, is safe and free of increased risk** (Lifshitz and Lingeman, 2002; Watterson et al, 2002). Indeed, the definitive nature of one uncomplicated ureteroscopy probably represents less risk than the anesthesia associated with multiple stent changes plus the infectious risk of an indwelling foreign body.

KEY POINTS: MEDICAL MANAGEMENT OF CALCULI

- Bladder calculi are best managed with endoscopic techniques. Subsequent recurrence is prevented by relief of the bladder outlet obstruction.
- Neonatal nephrocalcinosis is frequently caused by loop diuretics. Cessation of this medication is essential.
- Neonatal nephrocalcinosis may be reversed by the use of thiazides.
- The majority of ureteral calculi during pregnancy pass spontaneously.
- There is a growing trend toward endoscopic relief of symptomatic calculi during pregnancy.

SUMMARY

Selective medical therapy for nephrolithiasis is highly effective in preventing new stone formation. A remission rate of more than 80% and overall reduction in individual stone formation rate of more than 90% can be obtained in patients with nephrolithiasis. In patients with mild to moderate severity of stone disease, virtually total control of stone disease can be achieved with a remission rate of more than 95%.

Selective pharmacologic therapy for nephrolithiasis also encompasses the advantages of overcoming nonrenal complications as well as averting certain side effects that may be caused by nonselective medical therapy. Despite these advantages, it is clear that selective medical therapy cannot provide total control of stone disease. **A satisfactory response requires continued, dedicated compliance of patients with the recommended program and a commitment by the physician to provide long-term follow-up and care.**

URINARY CALCULI DURING PREGNANCY
STONE REMOVAL: SURGICAL TECHNIQUES AND TECHNOLOGY

HISTORICAL OVERVIEW

Kidney Calculi

Although calculi in the kidney were rare before the Industrial Revolution (Shah et al, 2002), the existence of nephrolithiasis was known to Hippocrates, who described the symptoms of renal colic: "An acute pain is felt in the kidney, the loins, the flank and the testis of the affected side; the patient passes urine frequently; gradually the urine is suppressed. With the urine, sand is passed." It is not certain that Hippocrates performed surgery on patients with renal calculi, but he did describe the following operations: the drainage of tuberculous and nontuberculous pyelonephritic abscesses, the incision of swelling in the loin due to renal tumefaction resulting from stone, and the drainage of kidneys presenting with acute congestion caused by pyelonephritis (Wershub, 1970). In the centuries that followed Hippocrates, there was little scientific progress in the surgical therapy for patients with renal calculi. The alleged first account of a surgical attempt to remove a stone from a patient's kidney is the case of the French archer of Bagnolet. Little is known of the authenticity of this tale of a condemned man afflicted with a renal calculus who agreed to allow surgery on the affected kidney on the condition that if he survived, he would be freed. According to the anecdote, the man survived the open surgical stone removal and was freed in 1474 (Herman, 1973). Unfortunately, neither the hospital nor the surgeons involved maintained any first-hand record of this event, so the veracity of this claim is uncertain. The first verifiable account of renal stone surgery was in 1550, when Cardan of Milan opened a lumbar abscess on a young girl and removed 18 calculi (Desnos, 1972). For the following two centuries, most surgeons were in agreement that the only indication for open renal surgery was the infected calculous kidney, distended by the accumulation of purulent matter, or those kidneys in which the calculus could be palpated in the organ itself.

In 1734, Lafite incised a swelling in a patient's loin and drained considerable purulence. Twenty-two days later, the pus reaccumulated; he probed the incision and found a stone in the region of the kidney. Lafite widened the prior incision and removed two calculi, and the patient recovered well. Four years later, Lafite again removed stones from a man who had undergone drainage of a lumbar swelling 11 years before and who had a persistent urinary fistula. Lafite concluded that it was possible to remove the stones at the time of the first surgical intervention rather than subject the patient to multiple procedures (Ballenger et al, 1933). In 1872, William Ingalls of the Boston City Hospital removed a large calculus from the right kidney of a 31-year-old woman with a persistent pyelocutaneous fistula (Spirnak and Resnick, 1983). Ingalls incised the sinus track of the fistula and extracted the stone with forceps, thus performing the first recorded nephrolithotomy in America. In 1880, Henry Morris of England was the first to remove a stone from an otherwise healthy kidney by nephrolithotomy, extracting a 31-g mulberry calculus from the kidney of a young woman (Dudley, 1973).

As the surgical techniques of nephrolithotomy evolved, renal parenchymal incisions were made in a variety of different ways in an effort to reduce hemorrhagic morbidity. Heineke, in 1879, first described a pyelotomy incision for the extraction of calculi. The operation rapidly found favor and was employed by many surgeons, although it was not possible to extend the incision to permit extraction of large renal calculi without damaging the retropelvic renal artery (Wershub, 1970). Josef Hyrtl in 1882 and Max Brödel in 1902

described a relatively avascular plane near the midline (5 mm posterior) of the convex border of the kidney through which the collecting system of the kidney could be entered. In Europe, credit for the plane was given to Hyrtl; but in England and the United States, it was called Brödel's bloodless line or Brödel's white line (Schultheiss et al, 2000). Although the existence of this avascular plane was an important discovery, surgeons continued to find that bleeding during nephrolithotomy was a considerable problem. Zuckerkandl described an inferior pyelonephrolithotomy, in which a pyelotomy incision was extended into the lower pole of the kidney. Partner recommended a V-shaped incision with two limbs radiating toward the poles of the kidney. Other attempts were made to control the persistent problem of bleeding, including compression of the hilar vessels and various methods of suturing. In 1887, Czerny was the first to approximate the cut edges of the incised kidney with suture to control hemorrhage and to prevent fistula formation. In the same year, Felix Guyon reported that nephrectomy, although efficacious in curing patients suffering from calculous pyonephrosis, was more dangerous than nephrolithotomy because lithiasis was often bilateral (Wershub, 1970). In 1889, Kümmell was the first surgeon to perform a partial nephrectomy for calculous pyonephrosis (Redman, 1983). Lower in 1913 revived interest in pyelolithotomy when he suggested that this technique may be a safer and easier method of removing renal calculi than nephrolithotomy. Although several small series of cases indicated that there might be a higher incidence of stone recurrence after pyelolithotomy, other studies showed that recurrence was no more common than it was after nephrolithotomy (Murphy, 1972). These findings, in conjunction with rapid advancements in the field of radiography, brought about a decided preference for pyelolithotomy (Gil-Vernet and Culla, 1981). In 1943, Dees and Fox reported the first use of coagulum to remove small stones and stone fragments from the renal pelvis and calyces (Marshall, 1983). Fibrinogen and thrombin were used to make a coagulum that was injected into the renal pelvis and produced a flexible cast of the pelvis and calyces. The use of this technique was limited initially owing to the scarcity of materials and the risk of blood-borne disease transmission. However, interest in coagulum pyelolithotomy was renewed when cryoprecipitate was found to be a safe and readily available source of concentrated fibrinogen (Fischer et al, 1980).

An important advance in the open surgical approach to the kidney was the intrasinusally extended pyelolithotomy, pioneered by Gil-Vernet in 1965. Because of its wide applicability and minimal morbidity, this approach to the renal collecting system became the procedure of choice for the majority of renal pelvic calculi. Patients harboring large or complex calculi could be effectively treated with extended pyelolithotomy combined with multiple radial nephrotomies (Wickham et al, 1974). In 1968, **Smith and Boyce described anatrophic nephrolithotomy, a procedure that derived its name from the technique of incising the renal parenchyma along the avascular plane between the anterior and posterior vascular distributions. Because an incision in this plane does not interrupt the blood supply to the renal parenchyma, it does not result in atrophy, hence the term *anatrophic*.** This procedure permits a relatively bloodless operation that encompasses stone removal, reconstruction of the calyceal system, and closure of the renal capsule with preservation of renal function. **Although stone-free rates of these modern surgical techniques were excellent, morbidity was significant, and the search for new techniques and technologies continued.**

Ureteral Calculi

Ambroise Paré is credited with the first account of ureteral calculi in 1564, as he described "the cruel pain [that] tormented the patient in that place where the stone lodged." Paré also stated that death was the consequence of having calculi impacted in both ureters (Murphy, 1972). However, Morris reported in 1898 that "operations on the ureter are an advance of the last few years, but not many have been recorded up to the present time" (Ballenger et al, 1933). Thomas Emmet of New York published an account in 1879 of three female patients with stones impacted at the distal aspect of the ureter. In one patient, he opened the bladder and removed the stone with forceps; in a second patient, he removed a stone by cutting down on it through the vaginal wall. These procedures were the first recordings of a surgeon making a definite diagnosis of ureteral calculus and deliberately and successfully performing a ureterolithotomy. In the years that followed, numerous approaches were used, including intraperitoneal, perineal, sacral, transrectal, and transvaginal. In 1910, **Gibson of New York described an incision parallel to and just above Poupart's ligament, wholly extraperitoneal, by which the lower ureter, even down to its entrance into the bladder, could be readily exposed.** This safe and comparatively easy approach to the ureter placed open ureterolithotomy on sound footing.

The Rise of Endourology

Before the development of endoscopy, attempts to blindly extract calculi were not uncommon. In 1889, Gustav Kolisher performed the first successful stone manipulation, reporting that he "located the stone with a metal-tipped catheter several inches above the ureteric orifice and through it injected 30 cc of sterile oil," displacing the stone (Murphy, 1972).

The development of minimally invasive surgical techniques for the treatment of patients suffering from urinary lithiasis has been greatly dependent on technologic advances in the fields of **fiberoptics, radiographic imaging, and lithotripsy (shockwave, ultrasonic, electrohydraulic, and laser).** These advancements have accelerated the evolution of modern techniques of calculus removal, including **ureteroscopy, percutaneous nephrolithotomy (PNL), and extracorporeal shockwave lithotripsy (SWL). In 1979, Arthur Smith defined the term *endourology* as closed controlled manipulation within the genitourinary tract** (Smith et al, 1979).

Ureteroscopy

The practice of ureteroscopy began by happenstance when, in 1912, Hugh Hampton Young introduced a pediatric cystoscope into the massively dilated ureter of a child with posterior urethral valves (Young and McKay, 1929). Aided by the child's secondary ureteral dilation, Young was able to advance the cystoscope to the level of the renal pelvis, thus becoming the first urologist to view the intrarenal collecting system

endoscopically. Unfortunately, the following three decades held few significant advances in ureteroscopic technology until knowledge of fiberoptics could be put to clinical use. By 1957, Curtiss and Hirschowitz combined a large number of glass fibers into a coherent bundle and fused the fibers at their ends to allow them to move individually along their length, thus creating the first flexible endoscope (Hirschowitz et al, 1957). In 1964, Marshall reported the first urologic use of this new type of flexible endoscope when he passed the scope through an open ureterotomy to the level of the renal pelvis, thereby performing the first flexible ureteroscopy. Subsequently, two of his associates, McGovern and Walzak, performed the first transurethral flexible ureteroscopy when they passed the same 9 French flexible endoscope to inspect a ureteral calculus. Since then, developments in optics and mechanics have greatly improved the design of flexible ureteroscopes.

Currently available ureteroscopes range from 54 to 70 cm in length and have a tapered shaft diameter that increases proximally. As the tip of the ureteroscope is inserted into the ureter and passed retrograde, the ureter is slowly dilated. Initial ureteroscopes had neither a working nor an irrigating channel. Most modern ureteroscopes have a single working channel, and some have a second irrigation channel that serves to distend the ureter and maintain visualization.

Early flexible ureteroscopes were passive, and the subsequent incorporation of active tip deflection has greatly increased their utility. Active deflection refers to deflection of the tip of the endoscope, which is controlled by the surgeon through a lever mechanism on the handle of the endoscope. Flexible ureteroscopes have been introduced with two segments of active deflection, with the active primary site of deflection providing 170 to 180 degrees of up and down movement; the secondary active deflection, located several centimeters proximal to the primary deflection, is a 130-degree one-way downward deflection. This design greatly facilitates entry into the lower pole infundibulum. Other manufacturers have designed flexible ureteroscopes with 270 degrees of deflection, which also facilitates entry into the lower pole infundibulum.

Interestingly, the first reports of rigid ureteroscopy trailed those of flexible ureteroscopy by almost one decade. In 1977, Goodman reported on three cases in which a pediatric cystoscope was used to treat patients with ureteral maladies. These initial rigid ureteroscopes employed a rod-lens system that was large (10 to 13 French) and inflexible, although it provided an optimal image. Most rigid ureteroscopes have replaced this rod-lens system of image transmission with fiberoptics, which allows significant reduction in the size of the endoscope. In addition, the flexibility of the fiberoptic bundles allows the shaft of the endoscope to become somewhat bendable along its vertical axis, hence the term *semirigid ureteroscope*.

Parallel to improvements in rigid and flexible ureteroscopes were advances in intracorporeal lithotripters, including ultrasonic, electrohydraulic, pneumatic, and laser probes, allowing efficient stone fragmentation through the miniaturized modern ureteroscopic equipment. Many new stone retrieval devices, designed to pass through the working channel of a ureteroscope, have been introduced with the capability for manipulation and deflection.

Percutaneous Stone Removal

The first description of percutaneous stone removal was that of Rupel and Brown (1941) of Indianapolis, who removed a stone through a previously established surgical nephrostomy track. It was not until 1955, however, that Goodwin described the first placement of a percutaneous nephrostomy tube to drain a grossly hydronephrotic kidney (Goodwin et al, 1955). Goodwin did not have the benefit of radiographic guidance, and so the drainage tube was placed without imaging. In 1976, Fernstrom and Johannson first reported the establishment of percutaneous access with the specific intention of removing a renal stone. Subsequent advances in endoscopes, imaging equipment, and intracorporeal lithotripters allowed urologists and radiologists to refine these percutaneous techniques through the late 1970s and early 1980s into well-established methods for removal of upper urinary tract calculi.

Extracorporeal Shockwave Lithotripsy

The phenomenon that sound waves can be focused has been known since antiquity. The ancient Greeks, as taught by Dionysius, used this knowledge to construct vaults that allowed them to overhear the conversations of their imprisoned enemies. In the 18th and 19th centuries, cabinets constructed with echo or sound mirrors were capable of transmitting the ticking of a pocket watch over a distance exceeding 60 feet.

High-energy shockwaves have been recognized for many years. Examples of high-energy shockwaves include the potentially window-shattering sonic boom created when aircraft pass beyond the speed of sound and the blast effect associated with explosions. Engineers at Dornier Medical Systems in what was then West Germany, during research on the effects of shockwaves on military hardware, demonstrated that shockwaves are reflectable and therefore focusable. The possibility of application of mechanical shockwaves to human tissue was discovered when, by chance, a test engineer touched a target body at the very moment of impact of a high-velocity projectile. The engineer felt a sensation similar to an electric shock, although the contact point at the skin showed no damage at all (Hepp, 1984). This observation and its potential military applications led Dornier to pursue a method of generating a reproducible shockwave.

Beginning in 1969 and funded by the German Ministry of Defense, Dornier began a study of the effects of shockwaves on tissue. Specifically, the study was to determine if the shockwaves generated by a projectile striking the wall of a military tank would damage the lungs of a crew member leaning against the same wall. During the study, Dornier engineers developed techniques to reproducibly generate shockwaves. In the course of this effort, the engineers discovered that shockwaves generated in water could pass through living tissue (except for the lung) without discernible damage to the tissue but that brittle materials in the path of the shockwaves were fragmented.

At some point, a possible medical application of shockwaves became apparent: if shockwaves could safely pass through tissue but fragment brittle materials, perhaps they could be used to break up kidney stones. Dornier engineers found that lower energy shockwaves, which would be appropriate for medical applications, could be generated in a

predictable and reproducible manner by an underwater electrical spark discharge.

In 1972, on the basis of preliminary studies performed by Dornier Medical Systems, an agreement was reached with Egbert Schmiedt, director of the urologic clinic at the University of Munich, to proceed with further investigation of the therapeutic potential of this technology (Chaussy and Fuchs, 1986). This research was supported by the West German Federal Ministry of Research and Technology, and the development of the Dornier lithotripter progressed through several prototypes, ultimately culminating in February 1980 with the first treatment of a human by SWL. The production and distribution of the Dornier HM3 lithotripter began in late 1983, and SWL was approved by the U.S. Food and Drug Administration in 1984. Since Dornier's pioneering work, numerous other companies have demonstrated that shockwaves capable of stone fragmentation may be generated by electromagnetic induction, microexplosions, focused lasers, and piezoelectric crystals. To date, more than 3000 lithotripters of all types have been placed worldwide, and more than 1 million patients are treated annually with SWL.

RENAL CALCULI

The primary goal of surgical stone management is to achieve maximal stone clearance with minimal morbidity to the patient. The introduction of SWL as well as continuing advancements in the field of endourology has allowed most patients with renal stones to be treated in a minimally invasive fashion. However, as the armamentarium of treatment modalities available to the urologist has increased, new controversies regarding the indications for these therapies have developed. Currently, urologists face the challenge of selecting the optimal treatment modality on the basis of the patient's and the stone's characteristics. Four minimally invasive treatment modalities are available for the treatment of patients with kidney stones and are detailed in this chapter: SWL, PNL, ureteroscopy, and laparoscopic stone surgery. SWL has also been used in combination with PNL ("sandwich technique") as well as with ureterorenoscopic lithotripsy. Recent advancements in endoscopic technology and surgical technique have dramatically reduced the need for open surgical procedures to treat patients with renal and ureteral calculi.

Most (about 80% to 85%) patients harboring "simple" renal calculi can be treated satisfactorily with SWL (Chaussy and Schmiedt, 1984; Krings et al, 1992; Wickham, 1993). To better define those patients with upper urinary tract calculi who are less likely to have a successful outcome after treatment with SWL, Grasso and colleagues (1995a) reviewed a series of 121 patients whose initial SWL treatment session failed. **Several factors were found to be associated with poor stone clearance rates: large renal calculi (mean, 22.2 mm), stones within dependent or obstructed portions of the collecting system, stone composition (mostly calcium oxalate monohydrate and brushite), obesity or a body habitus that inhibits imaging, and unsatisfactory targeting of the stone.** For patients with these clinical characteristics, the authors suggest the consideration of alternative treatment modalities. The urologist, then, when treating a patient with a renal calculus, must ask himself or herself, **Is the patient an appropriate candidate for SWL or should other treatment modalities be used?**

Table 44–1. **Factors Affecting Management of Renal Stones**

Stone Factors	*Renal Anatomic Factors*	*Clinical (Patient) Factors*
Size	Obstruction or stasis	Infection
Number	Hydronephrosis	Obesity
Composition	Ureteropelvic junction obstruction	Body habitus deformity
	Calyceal diverticulum	Coagulopathy
	Horseshoe kidney	Juvenile
	Renal ectopia or fusion	Elderly
	Lower pole	Hypertension
		Renal failure

One must consider stone-related factors (size, number, location, composition), renal anatomy, and clinical factors of the patient (Table 44–1) as well as the morbidity inherent in each treatment modality and the availability of the requisite equipment before selecting the optimal therapy. Although treatment decisions are ultimately the result of an integrated analysis of a multiplicity of factors, for the sake of simplicity, these factors and considerations in management of kidney calculi are reviewed separately.

Preoperative Evaluation

The evaluation of patients with urolithiasis in the current era of minimally invasive therapies has not changed substantially from that of the previous era of open stone surgery. Although standard imaging of urinary tract calculi has previously used plain abdominal radiography and intravenous urography, recent evidence suggests that unenhanced helical computed tomography (CT) has gained widespread acceptance (Heidenreich et al, 2002). Nephrotomography, radionuclide studies, and retrograde contrast-enhanced studies are occasionally necessary to obtain more detailed anatomic and functional information.

Bacteriologic evaluation of the urine is mandatory for all patients. The composition of any previous stone material passed or removed from the patient is extremely important. If previous stones have contained significant amounts of calcium oxalate monohydrate (whewellite) or brushite, fragmentation with SWL may be expected to be more difficult. If a stone of such composition is of a large size, the patient may achieve a better outcome with a percutaneous or ureteroscopic procedure rather than with SWL. Cystinuria may be revealed by previous stone analysis or by the characteristic cystine crystals on urinalysis. Any patient whose stone or stones have radiographic features suggestive of cystine (low radiodensity, ground-glass appearance, smooth edges, bilateral stones) should be screened for cystinuria before treatment because these stones are often not well fragmented by SWL. Many stones may harbor bacteria even though bacteriuria is only intermittently present. This is particularly true in the patient who has received antibiotics in the past. Mariappan and associates (2005) have also reported that **the best predictor of post-PNL urosepsis is stone culture or renal pelvic urine culture results, rather than bladder urine culture results. The fragmentation of stones, despite sterile urine,** may

release preformed bacterial endotoxins and viable bacteria that place the patient at risk for septic complications (Scherz and Parsons, 1987; McAleer et al, 2002, 2003; Paterson et al, 2003). Therefore, patients who have radiographic or clinical features suggestive of struvite or in whom infection is suspected should receive a minimum of 2 weeks of broad-spectrum antibiotics before surgery to reduce the risk of sepsis. Parenteral antibiotics should be administered preoperatively in any patient in whom urinary infection is suspected.

Natural History

Calyceal Stones

Before the introduction of minimally invasive therapies, urologists were often reluctant to remove incidentally found, asymptomatic, or minimally symptomatic calyceal stones because of the high morbidity associated with open surgery. Although the traditional indications for intervention, including pain, infection, and obstruction, have not changed, the introduction of minimally invasive procedures has allowed patients with mild or no symptoms to consider these less morbid treatments. However, the decision for intervention should be based on a thorough understanding of the natural history of calyceal stones.

Hubner and Porpaczy (1990) reviewed the natural history of calyceal stones in 63 patients during an average of 7.4 years. They reported that of 80 stones, 6% were dissolved with alkali therapy, 16% passed spontaneously, 40% required surgical intervention, and 38% remained in situ. During the observation period, 45% of the stones increased in size, 68% of the patients experienced symptoms of infection, and 51% of the patients experienced pain. Thus, **most calyceal stones, in the absence of intervention, are likely to increase in size, causing symptoms of pain or infection.** Furthermore, as time progressed and stone size increased, the likelihood of spontaneous stone passage decreased. Glowacki and associates (1992) reviewed **the natural history of 107 patients with asymptomatic calyceal stones and found that the cumulative 5-year probability of a symptomatic event was 48.5%; half of these events required active intervention.** A linear association was identified between the development of a symptomatic event and the number of previous stones as well as the number of asymptomatic stones at presentation. Burgher and associates (2004) reported a series of 300 patients initially presenting with asymptomatic renal calculi who were observed for a mean of 3.26 years. **Seventy-seven percent of patients experienced progression of calculi, with 26% requiring surgical intervention.** Those **patients who initially presented with calculi larger than 4 mm were more likely to fail observation** than were patients with smaller solitary calculi. Keeley and colleagues (2001) reported the results of a randomized prospective trial of SWL versus observation for 200 patients with small asymptomatic calyceal calculi. Although the authors found little difference in the number of patients in each group requiring additional treatment, the **interventions in the observation group were more invasive. Patients in the SWL group required no invasive treatment** on follow-up and could be adequately managed with analgesia or antibiotics. In 1988, a National Institutes of Health Consensus Conference addressed the issue of small, asymptomatic calyceal stones and stated that the use of SWL for small (<5 mm), incidentally discovered, asymptomatic kidney calculi was controversial and that more data were required (Consensus conference. Prevention and treatment of kidney stones, 1988). Furthermore, although SWL, with its low morbidity, might be considered a good option for the prophylactic treatment of patients with small, asymptomatic calyceal stones, the targeting of stones smaller than 5 mm may be difficult because of focusing problems with either a fluoroscopic or an ultrasound-guided lithotripter (Motola and Smith, 1990). Collins and Keeley (2002) reported that they did not detect a benefit after treatment in a randomized controlled trial of prophylactic SWL for patients with asymptomatic calyceal stones. **The necessity of treating patients with small (<5 mm), nonobstructive, asymptomatic stones in a prophylactic fashion remains undetermined.** However, **patients must be advised about the need for regular follow-up; a significant proportion of these calculi will eventually become symptomatic and require intervention.** Treatment decisions in these situations should be based on the individual patient's risk factors and the patient's preference. In several groups of patients, including pediatric patients, patients with a solitary kidney, patients in high-risk professions (e.g., pilots), and women considering pregnancy, treatment of asymptomatic calyceal stones may be indicated.

Historically, simple calyceal stones documented to be immobile and not causing obstruction have been thought to be unlikely causes of flank pain. However, it has been reported that **the pain induced by nonobstructive calyceal stones is characterized by a dull, deep ache, different from the classic pain of renal colic** (Coury et al, 1988). Several groups have reported that patients experience excellent pain relief after the removal of small calyceal stones by SWL, PNL, or ureteroscopy (Andersson and Sylven, 1983; Brannen et al, 1986; Fernandez and Carson, 1989; Brandt et al, 1993; Andreassen et al, 1997). Therefore, **a patient who is thought to be symptomatic from a calyceal stone should be treated.**

Staghorn Calculi

Staghorn calculi are those stones that fill the major part of the renal collecting system. Typically, they occupy the renal pelvis and branch into most of the calyces, mimicking the horns of a deer or stag (Fig. 44–1). Most staghorn stones are composed of struvite (Segura et al, 1994). Until the early 1970s, some physicians believed that patients harboring staghorn calculi should not be treated (Segura, 1997). However, a better understanding of the natural history of staghorn stones has evolved.

Blandy and Singh (1976) compared untreated staghorn stones in 60 patients with operative removal of staghorn stones in 125 patients. **The 10-year mortality was 28% for patients with untreated staghorn stones versus 7% for patients treated by surgical intervention.** Koga and associates (1991) reported on 167 patients with staghorn stones, of whom 61 were treated conservatively and followed up for an average of 7.8 years. Chronic renal failure occurred in 36% of the patients treated conservatively, and this cohort also experienced higher morbidity and mortality. Teichman and coworkers (1995) reviewed the records of 177 consecutive patients with staghorn calculi for a mean follow-up of 7.7 years. In those patients managed surgically, they noted 28% and 17% overall rates of renal deterioration and mortality,

Figure 44–1. Three-dimensional computed tomographic reconstruction of a staghorn calculus.

respectively. Renal deterioration was more frequently associated with a solitary kidney (77% versus 21%), previous stones (39% versus 14%), stone burden (partial staghorn 13% versus complete staghorn 34%), urinary diversion (58% versus 18%), and neurogenic bladder (47% versus 28%). Of note, stone recurrence was a significant predictor of the patient's becoming dialysis dependent. No patient with complete stone clearance died of kidney-related causes, compared with 3% of those without clearance of fragments and 67% of those who refused treatment.

Thus, **untreated struvite staghorn calculi eventually destroy the kidney and pose a significant risk to the patient's life.** The American Urological Association (AUA) Nephrolithiasis Clinical Guidelines, released in 2005, recommended that in otherwise healthy individuals, **newly diagnosed struvite staghorn calculi should be treated surgically** (Preminger et al, 2005). Moreover, **struvite stones must be removed completely to minimize the risk of continued urea-splitting bacteriuria.**

Stone Factors

Stone factors to be considered in the treatment of patients with kidney calculi include **stone burden (size and number), stone composition, and stone location.** Because a significant issue in renal stone location is the treatment of a lower pole stone and the influence of renal anatomy on the treatment results of such calculi, further discussion of this topic is included in the section on renal anatomic factors.

Treatment Decisions by Stone Burden

Stone burden (size and number) is perhaps the single most important factor in determining the appropriate treatment modality for a patient with renal calculi (Motola and Smith, 1990). However, cutoff points for stone size that would categorize those who should be treated by SWL and those who should undergo other treatment modalities have yet to be definitively determined. For now, kidney calculi are conveniently divided into nonstaghorn and staghorn stones, and most controversy is in the area of nonstaghorn stones.

Nonstaghorn Calculi. In examining the efficacy of SWL in treatment of patients with renal calculi, passage of stone debris rather than fragmentation of the stone is the primary limiting factor (Renner et al, 1999). There is general agreement that **stone free is the most rigorous definition of successful outcome of any stone removal procedure, and complete stone clearance should be the preferred goal** (Psihramis et al, 1992). However, because SWL outcome is dependent on spontaneous stone clearance, treatment results are often reported in terms of "success rates," which may be defined as patients who are either stone free or who have asymptomatic, small, residual fragments. Various cutoff points between 2 and 5 mm are used in the literature to define the size of these fragments, making study comparisons difficult. A prospective analysis of 121 SWL treatment failures concluded that for almost half of the cases, treatment failure was due to a failure to clear stone fragments (Grasso et al, 1995a). The mean stone size before SWL therapy was 22.2 mm. Steinstrasse, a significant morbid complication, occurred in 8% of those patients who had a mean stone size of 33.7 mm. **Failure to clear stone fragments resulted in a higher retreatment rate as well as a higher number of ancillary procedures.** Clayman and associates (1989) suggested that in comparing the results of SWL and PNL or in comparing different lithotripters, the parameters of stone-free rate, retreatment rate, and number of auxiliary procedures should be combined into an effectiveness quotient that may better express treatment results and allow one to compare different treatment modalities:

$$\frac{\%\ \text{stone free}}{100\% + \%\ \text{re-treatment} + \%\ \text{auxiliary procedures}} \times 100$$

For example, Netto and associates (1991), in a study comparing PNL and SWL for patients with lower pole calculi, reported overall stone-free rates of 93.6% and 79.2% for PNL and SWL, respectively; these values were not significantly different. However, the effectiveness quotients of 93.7% and 55.9% for PNL and SWL did differ significantly as this incorporated the 41% re-treatment rate for the SWL group.

The negative effect of an increasing stone burden (size and number) on the results of SWL has been reported by many groups using a variety of lithotripters (Drach et al, 1986; Lingeman et al, 1986a; Politis and Griffith, 1987; el-Damanhoury et al, 1991). A now-axiomatic principle of SWL is that **as stone burden increases, the stone-free rate declines and the need for ancillary procedures and re-treatment rises.** Furthermore, larger stone burdens are associated with a higher rate of residual stones, a point of particular concern in the treatment of patients with struvite calculi (Segura, 1989). The presence of multiple stones also adversely affects the results of SWL treatment (Drach et al, 1986; Cass, 1995).

Figure 44–2 illustrates the effect of the size of solitary renal stones on the results of SWL. PNL, although more invasive and often associated with higher morbidity, achieves better

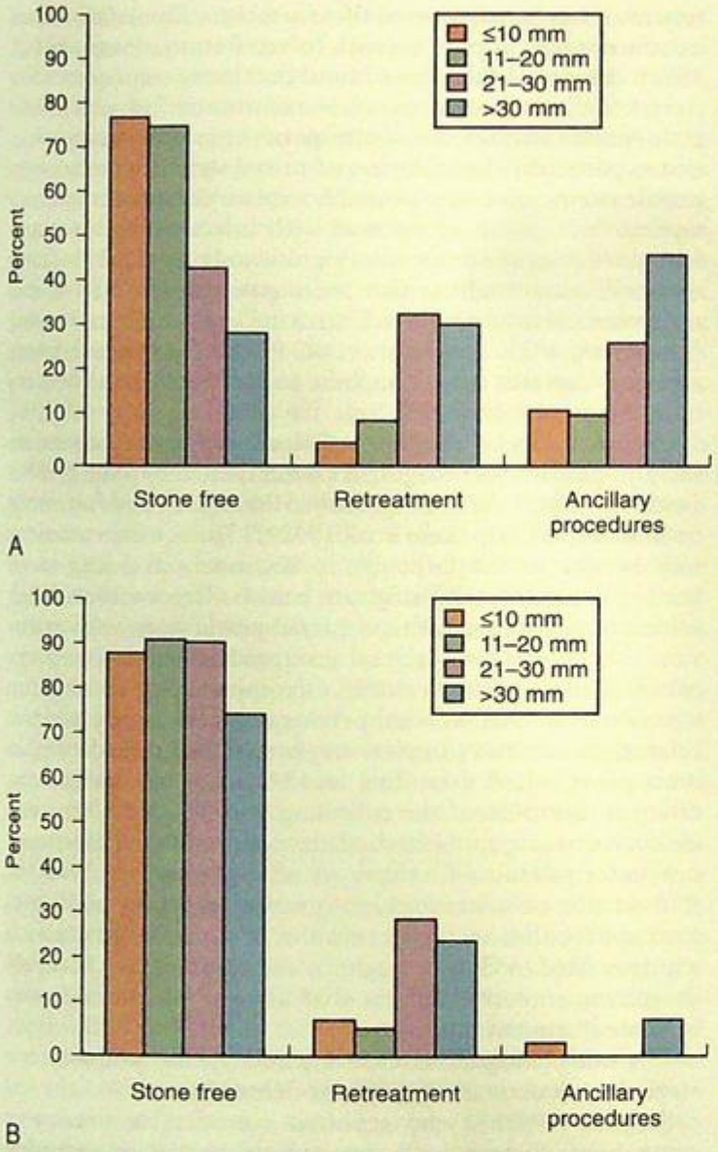

Figure 44–2. A, Solitary nonstaghorn calculi treated by SWL, stratified by size. B, Solitary nonstaghorn calculi treated by PNL, stratified by size.

stone-free rates than does SWL and is not affected by stone size (Lingeman et al, 1987b). Ureteroscopy, another treatment alternative for patients with renal calculi, is also negatively affected by increasing stone burden but possibly to a lesser degree than is SWL because stone fragments are often removed or vaporized. Fabrizio and colleagues (1998) evaluated the characteristics of residual calculi after ureteroscopy in a group of 100 patients and found that increased stone burden led to a higher percentage of patients with residual fragments. For patients with stones smaller than 10 mm, only 20% were found to have residual fragments, whereas more than 50% of patients with stones larger than 16 mm harbored residual fragments. Thus, as stone burden increases, PNL becomes more efficient than either SWL or ureteroscopy.

Treatment algorithms for patients with nonstaghorn calculi are commonly organized by stone size. The mean overall stone-free rates of SWL for the treatment of patients with solitary stones stratified by size are 79.9% (range, 63% to 90%), 64.1% (range, 50% to 82.7%), and 53.7% (range, 33.3% to 81.4%) for stones 10 mm or less, 11 to 20 mm, and larger than 20 mm, respectively (Clayman et al, 1989; Psihramis et al, 1992; Lingeman et al, 1994; Cass, 1995; Logarakis et al, 2000).

Approximately **50% to 60% of all solitary renal calculi are less than 10 mm in diameter** (Cass, 1995; Renner and Rassweiler, 1999; Logarakis et al, 2000). **Treatment results of SWL for this substantial group of patients are generally satisfactory** and independent of stone location or composition. Although better results can be achieved with PNL or ureteroscopy for patients with stones smaller than 10 mm, these procedures are more invasive, are associated with greater morbidity, and may be reserved for special circumstances (e.g., anatomic malformation causing obstruction, SWL failure).

Patients with calculi between 10 and 20 mm are often treated with SWL as first-line management. However, stone composition and location also affect the results of SWL for patients with calculi in this size range and should be carefully considered. For example, SWL results for patients with 10- to 20-mm stones in the lower pole are inferior (55%) to SWL results for patients with stones in the upper and middle pole calyces (71.8% and 76.5%, respectively) (Saw and Lingeman, 1999). Havel and associates (1998) compared stone-free rates for patients with a solitary lower pole stone managed with either SWL or PNL. For patients with stones smaller than 10 mm, both therapeutic modalities were equally effective. However, **for patients with 10- to 20-mm lower pole stones, significantly better clearance rates were achieved with PNL rather than with SWL** (73% versus 57%). Stone composition is also a factor to consider in treatment of patients with stones larger than 10 mm. Cystine calculi respond poorly to SWL treatment, particularly stones larger than 15 to 20 mm (Hockley et al, 1989; Kachel et al, 1991). Likewise, brushite calculi have demonstrated an in vitro and in vivo resistance to fragmentation that is surpassed only by cystine calculi (Dretler, 1988; Klee et al, 1991). Patients with renal stones of 10 to 20 mm and factors predicting poor treatment outcomes with SWL should be advised about alternative therapeutic modalities. Both PNL and ureteroscopy are less affected by stone location and composition, and good results may be attained with these modalities for patients with 10- to 20-mm renal stones (Lingeman et al, 1994; Grasso and Ficazzola, 1999).

Lingeman and associates (1987b) showed that the frequency of multiple treatments increased from 10% to 33% when SWL was used to treat patients with stones of 1 to 2 cm and 2 to 3 cm, respectively. In addition, the stone-free rate was only 34% compared with a 90% stone-free rate for those patients treated by PNL. Psihramis and colleagues (1992) described 94 patients with renal stones larger than 2 cm treated by SWL, with only 31 patients (33%) becoming stone free. Interestingly, patients with multiple stones had a similar stone-free rate of 32%. These high re-treatment rates and increased need for auxiliary procedures were the basis for the National Institutes of Health Consensus Conference recommendation that patients with stones larger than 2 cm be initially treated with PNL followed, if necessary, by SWL (Consensus conference. Prevention and treatment of kidney stones, 1988). However, because the stone-free rates for patients with renal stones of 2- to 3-cm range treated by SWL can have a wide variability (33% to 65%), SWL in combina-

tion with ureteral stent placement may still be considered an option, provided the patient is advised about the higher retreatment rate and the lower likelihood of achieving a stone-free state in comparison with PNL (Renner and Rassweiler, 1999).

Grasso and associates (1998) described 51 patients with 66 large (≥2 cm) upper urinary tract (45 renal, 21 ureteral) stones treated by ureteroscopy. One third of patients with renal stones required a second-look endoscopy; and in three patients with renal calculi, conversion to PNL was necessary. The overall success rate, defined as pulverization of the stone to dust or fragments smaller than 2 mm, after the second ureteroscopy procedure was 91%, which is comparable to PNL results. However, the 6-month follow-up data, which were available for 25 patients, demonstrated that only 60% of patients were stone free, whereas 24% had small lower pole debris and 16% had new stone growth.

Murray and coworkers (1995) reported on 65 treatments for renal calculi larger than 3 cm with SWL monotherapy. The overall success rate for SWL was only 27% at 3 months. The best stone-free rate (60%) was obtained for stones smaller than 500 mm^2 that were located primarily within the renal pelvis. The stone-free rate for stones with surface areas larger than 1000 mm^2 was a dismal 8%. Notably, steinstrasse occurred in 23% of patients. Likewise, Lingeman and colleagues (1987b) reported on 13 nonstaghorn stones larger than 3 cm treated with SWL monotherapy. Seventy-seven percent of the patients required further treatment, whereas only 29% were rendered stone free.

In summary, for patients harboring nonstaghorn stones smaller than 10 mm, SWL is usually the primary approach. For patients with stones between 10 and 20 mm, SWL can still be considered a first-line treatment unless factors of stone composition, location, or renal anatomy suggest that a more optimal outcome may be achieved with a more invasive treatment modality (PNL or ureteroscopy). Patients with stones larger than 20 mm should primarily be treated by PNL unless specific indications for ureteroscopy are present (e.g., bleeding diathesis, obesity).

Staghorn Calculi. Patients suffering from staghorn calculi remain a challenging problem for the practicing urologist. **Most staghorn stones are composed of struvite,** and factors that predispose to urinary tract infection and retained urine increase the likelihood of struvite stone formation (Gettman and Segura, 1999). However, other crystals, including cystine, calcium oxalate monohydrate, and uric acid, can assume a staghorn configuration (Segura, 1997).

The conservative treatment of patients with staghorn calculi exposes the patient to an increased risk of renal loss as well as a mortality rate of up to 30% (Blandy and Singh, 1976; Rous and Turner, 1977; Koga et al, 1991). Therefore, the ideal management of patients with staghorn calculi is composed of three stages. First, complete surgical removal of the entire stone burden is essential. **If all of the infected stone debris is not evacuated, urea-splitting bacteriuria may persist, which can ultimately lead to eventual stone regrowth.** The urologist should select the procedure or combination of procedures most likely to render the patient free of stone material while minimizing the risk of morbidity and mortality. Second, any metabolic abnormalities must be identified and appropriately treated. It has been reported that metabolic abnormalities are not uncommon in patients with infected stones (Segura et al, 1981). However, others have found that stone recurrence after complete elimination of calculi is uncommon (Silverman and Stamey, 1983). Different definitions of the term *infection stone*, and in particular the inclusion of mixed struvite and calcium oxalate stones in studies, probably explain these contradictory reports. In a group of patients with infection stones, those with pure struvite stones were significantly less likely to have metabolic abnormalities than were patients who had stones composed of a mixture of struvite and calcium oxalate (Lingeman, 1995; Lingeman et al, 1995c). Finally, anatomic abnormalities that may contribute to stasis within the urinary tract should be addressed.

Classification of Staghorn Calculi. Reported stone-free rates for patients with staghorn calculi treated by SWL or PNL (with or without SWL) range from 31% to 85% and from 23% to 86%, respectively (Lam et al, 1992a). These wide variations may be due to the difficulty in accurately assessing stone burden in patients with staghorn calculi. The traditional definition of staghorn calculus is a renal pelvic stone with extension into at least two calyceal groups. Historically, staghorn calculi were classified as partial or complete. Partial staghorn calculi were defined as renal pelvic calculi extending into two calyceal groups, and complete staghorn stones were defined as renal pelvic calculi extending into all major calyceal groups, filling at least 80% of the collecting system. At the time this definition was popularized, there was only one treatment option for patients with these calculi: open surgery. With the introduction of newer and less invasive treatment modalities such as SWL that are highly sensitive to stone burden, there is a greater need to classify staghorn calculi according to reproducible, quantitative criteria that allow clinicians to better evaluate treatment outcomes.

The morphologic classification into partial and complete staghorn calculi is inadequate, as demonstrated by Lam and colleagues (1992b), who reported considerable overlap in stone burdens of calculi grouped as partial or complete staghorn stones. When stone burden was assessed by stone surface area as measured on a kidney, ureter, bladder (KUB) radiographic image, for stones between 501 and 1500 mm^2, an overlap between partial and complete staghorn calculi occurred in 66% and 56.1% of cases, respectively. To remedy this limitation, several groups have proposed new classification schemes to better define staghorn calculi (Rocco et al, 1984; Griffith and Valiquette, 1987; Ackermann et al, 1989; Di Silverio et al, 1990). However, the cumbersome and subjective nature of these classification approaches has resulted in limited clinical use.

Currently, the most accurate method to estimate the volume of a staghorn calculus is CT imaging with three-dimensional reconstruction. This technique permits highly accurate determination of stone volume as well as the three linear dimensions of renal calculi (Olcott and Sommer, 1999). In addition, Hubert and associates (1997) reported that three-dimensional reconstructions of staghorn calculi assisted in the preoperative determination of the optimal routes for percutaneous access. This technique correlates well with the actual volume of the stone, as measured by water displacement (Lam et al, 1992b). However, three-dimensional CT reconstructions are costly, time-consuming, and not widely available, thus

limiting the utility of this technology. Nadler and associates (2004) have reported use of coronal reconstructions of axial CT images to calculate the craniocaudal length of stones, which can facilitate stone volume calculations.

Surgical Management of Staghorn Calculi. Overall, the stone-free rate after open surgery for patients with struvite stones is about 85%, with a 30% stone recurrence rate during 6 years (Griffith et al, 1978). In a comparison of the results of a combination treatment regimen of PNL and SWL with previously reported results of anatrophic nephrolithotomy, Lingeman and associates (1987b) demonstrated that the stone-free rates (191 of 224, or 85% of all staghorn cases treated with combination therapy) were similar. However, convalescence and hospital stay for the PNL cohort were shorter and blood loss was less. Similarly, Snyder and Smith (1986) compared PNL and anatrophic nephrolithotomy for patients with staghorn calculi and found that although patients undergoing PNL had a higher retained stone fragment rate (13% versus 0%, respectively), shorter procedure times, less need for blood transfusions and narcotics, and more rapid return to work ultimately favored PNL over the open surgical procedure.

Increasing experience with PNL (with or without SWL) has further improved treatment outcomes for patients with staghorn calculi. Lam and coworkers (1992c) compared 252 patients treated from 1984 to 1987 with 91 patients treated from 1988 to 1990. In the first group, renal access was performed by a radiologist; in the second group, access was established exclusively by the urologist. The authors noted a significant decrease in the proportion of cases managed by combination therapy (PNL plus SWL) in the second group (35%) compared with the first group (65%). Although the overall stone-free rates (83.3% and 86.8%) were not significantly different between the two groups, the second group had a greater proportion of staghorn stones and also had a greater use of multiple tracks. Of note, the pulmonary complication rate was greater in the second group (8.8% versus 2.8%), reflecting increased use of upper pole access.

When PNL was compared with SWL monotherapy in the treatment of patients with staghorn stones, the overall stone-free rate for PNL with or without SWL was 84.2% compared with 51.2% for SWL monotherapy (Lam et al, 1992a). Approximately **one third (30.5%) of patients in the SWL group required auxiliary procedures compared with 3.4% in the PNL group.** The success rate of PNL as initial therapy was independent of stone composition and superior to SWL for all types of stone material. SWL monotherapy was successful (stone-free rate, 92%) in only a small group of patients, those with 500 mm^2 or smaller stone burden in nondilated collecting systems. However, this subgroup represented only 3% of the staghorn stone cohort. In a prospective randomized study, Meretyk and associates (1997) compared 27 patients treated by SWL with 23 patients treated by PNL (with or without SWL). Stone-free rates were 74% and 22% in the PNL and SWL groups, respectively. They reported a significantly higher complication rate and number of ancillary procedures in the SWL group compared with the PNL group. The authors concluded that PNL followed by SWL, if needed, is superior to SWL monotherapy in the treatment of patients with staghorn stones. The use of SWL monotherapy in treating struvite stones may be particularly problematic because residual, "insignificant" fragments can prevent the sterilization of urine, increasing the risk of stone regrowth.

The use of multiple endourologic techniques for the treatment of patients with staghorn stones is referred to as combination therapy. The most frequently used regimen was described by Streem and colleagues (1997) as sandwich therapy, which consisted of primary percutaneous stone debulking followed by SWL of any inaccessible, residual infundibulocalyceal stone extensions or fragments. After SWL, a secondary percutaneous procedure was performed. These various stages are usually separated by 1 or 2 days. Stone-free rates for combined therapy are similar to those obtained by PNL alone or by open surgery (Lam et al, 1992c). **The management of patients with staghorn stones by a combined approach must be viewed as primarily percutaneous in nature, with SWL being used only as an adjunct to minimize the number of access tracks required.** Improved PNL techniques, incorporating the increasing use of flexible nephroscopy and providing complete or nearly complete clearance of stone material at the time of the primary procedure, may have decreased or eliminated the need for additional SWL treatment (Lam et al, 1992c; Beaghler et al, 1999).

The 2005 AUA Nephrolithiasis Committee has published recommendations for the management of patients with staghorn calculi based on a meta-analysis of outcome data from published, peer-reviewed articles. According to the committee, all treatment options (SWL, PNL, combined PNL and SWL, open surgery) must be discussed with the patient (Preminger et al, 2005). As a guideline, however, **PNL, followed by either SWL or repeated PNL, should be used for most patients with struvite staghorn calculi, with PNL being the initial element of the combination therapy.** SWL and open surgery should not be used for most of these patients as a first-line treatment. PNL and SWL are equally effective in treating patients with small-volume staghorn stones when the renal anatomy is normal or nearly normal. Open surgery may be an option in unusual situations in which a staghorn stone is not expected to be removed by a reasonable number of PNL or SWL procedures. Nephrectomy is an option for the patient with a poorly functioning kidney harboring a staghorn stone. Although there are limited data for the treatment of pediatric patients with staghorn calculi, PNL is a safe and effective therapy. Pediatric patients often experience better stone-free rates than do adults with treatment by SWL. The stone-free rate with SWL monotherapy, reported by studies including only pediatric patients, is 78%; an average of 2.9 procedures are performed, and complications are infrequent. However, the developing kidney may be more susceptible to the bioeffects of SWL (Lifshitz et al, 1998).

Treatment Decisions by Stone Composition

Dretler (1988) first introduced the concept of stone fragility. The readiness with which a stone is fragmented by SWL is variable among stones of different composition. Furthermore, even stones of the same composition may fragment differently (Bhatta et al, 1989; Sakamoto et al, 1991; Wang et al, 1993; Wu et al, 1993; Pittomvils et al, 1994). The efficacy of intracorporeal lithotripters, as well, is dependent on stone composition. Teichman and colleagues (1998b) reported that the holmium laser in vitro was the most effective lithotrite for fragmenting

struvite stones and the least effective lithotrite for calcium oxalate monohydrate stones. These results are consistent with the known thermal threshold for each stone composition. Saw and Lingeman (1999) reported that adjusted for size, cystine and brushite calculi are the most resistant to SWL, followed by calcium oxalate monohydrate; following, in descending order of resistance to fragmentation, are struvite, calcium oxalate dihydrate, and uric acid stones (Pittomvils et al, 1994; Saw and Lingeman, 1999). Stone composition affects not just resistance to fragmentation but also the type of fragments produced. Cystine and calcium oxalate monohydrate, in addition to being difficult to fragment, tend to produce relatively large pieces that may be difficult to clear from the collecting system (Pittomvils et al, 1994; Rutchik and Resnick, 1998). In general, **patients with such stones (i.e., brushite, cystine, calcium oxalate monohydrate) should be treated by SWL only when the stone burden is small** (i.e., <1.5 cm). Those patients with larger stones should preferentially be treated with PNL or ureteroscopy.

Patients suffering from cystinuria present a unique challenge to the urologist. Assimos and associates (2002) reported that **cystinuric patients have higher serum creatinine levels compared with a cohort of calcium oxalate stone formers.** Importantly, they also reported that **cystinuric patients are at greater risk for renal loss than are calcium oxalate stone formers** and that open stone surgery for these patients is associated with higher serum creatinine concentration and potential renal loss. Furthermore, patients with cystinuria have been reported to be poorly compliant with medical therapy, increasing the likelihood of recurrent stone events (Pietrow et al, 2003). Chow and Streem (1998) analyzed 31 cystinuric patients who underwent selected intervention for 61 stone events and reported that the probability of stone recurrence at 1 and 5 years was 27% and 73%, respectively. Achieving stone-free status prolonged the time to stone recurrence compared with patients left with residual fragments, a finding confirmed by Knoll and associates (1988). The high likelihood of repeated procedures underlines the need to select not just the least invasive treatment modality but also the most effective treatment modality. Treatment efficacy is of particular importance, as Barbey and associates (2000) reported that decreased renal function was more pronounced in cystinuric patients subjected to more stone removal procedures.

When stone removal is required, therefore, a minimally invasive approach is preferred. SWL, when it is used unselectively to treat patients with cystine stones, yields poor results. Hockley and colleagues (1989) described 43 cystinuric patients treated by SWL and PNL. Stone-free rates with use of SWL for calculi 20 mm or smaller and for calculi larger than 20 mm were 70.5% and 41%, respectively, whereas the stone-free rates for those who underwent PNL were 100% and 92%, respectively. Kachel and associates (1991) reviewed 18 patients with cystine stones and suggested a treatment algorithm based on their experience and the reported experience of others. They recommended SWL monotherapy for cystine renal calculi 15 mm or smaller and PNL for stones larger than 15 mm in diameter. Chow and Streem (1998) reported selective treatment, adjusted for stone size, in 31 cystinuric patients with an overall stone-free rate of 86.9%. Rudnick and colleagues (1999) reported success with retrograde ureterorenoscopic fragmentation in patients with 1.5- to 3.0-cm renal calculi. This approach is especially appealing as it has an inherently low morbidity.

Brushite calculi have a resistance to fragmentation that is surpassed only by that of cystine calculi (Dretler, 1988). Klee and associates (1991) described 30 patients with a total of 46 brushite stones. The overall success rate for patients treated by SWL monotherapy was 65% (success defined as fragments smaller than 4 mm), with a mean of 1.5 SWL sessions required per stone. However, only 11% of patients became stone free. PNL and ureteroscopy achieved 100% success rates and stone-free rates of 100% and 66%, respectively. Of 20 kidneys with residual fragments smaller than 4 mm, 12 had rapid regrowth to significant size within 3 to 12 months. Parks and associates (2004) found that SWL use was more frequent among brushite stone formers than among a similar cohort of calcium oxalate stone formers. Therefore, **when brushite calculi are suspected or confirmed, a surgical treatment algorithm similar to that for cystine stones should be applied.**

Although resistance to SWL is generally common for very hard stones, it also characterizes the rare and very soft **matrix** calculi that are composed of as much as 65% organic matter (compared with 2% to 3% organic matter in most noninfected urinary calculi). Matrix stones are radiolucent and are often associated with urea-splitting bacteriuria. SWL is not an effective treatment modality for patients with these stones. These situations are usually best treated with PNL (O'Connor et al, 1990). SWL is usually ineffective because of the stone's gelatinous nature, and ureteroscopy may be compromised by the large volume of stone material present (Bani-Hani et al, 2005).

Another soft radiolucent stone is composed of **indinavir,** a protease inhibitor commonly used in the treatment of human immunodeficiency virus infection (Daudon et al, 1997). A significant number of patients who receive this drug develop symptoms or signs of indinavir nephrolithiasis (Saltel et al, 2000; Nadler et al, 2003). Reiter and coworkers (1999) reported an incidence of symptomatic stone episodes in 12.4% of 105 patients treated with indinavir. The mean time from the initiation of indinavir therapy until the acute stone episode was 21.5 weeks. Twelve of 16 stones were passed spontaneously. Kohan and colleagues (1999) described 13 symptomatic patients with indinavir stones; conservative therapy was successful in 11 patients, and 2 patients were treated by stent placement. Pure indinavir stones are not detectable with standard radiography or CT. However, some patients form indinavir stones that contain a calcium component, which may be radiographically visible (Sundaram and Saltzman, 1999). Hydration and analgesic therapy are recommended for the initial treatment of patients with indinavir stones. Indinavir therapy may need to be temporarily or permanently discontinued, in which case another protease inhibitor may be substituted. Invasive intervention may be necessary for patients with prolonged renal obstruction, signs of sepsis, or unremitting symptoms.

The ability to predict stone composition and, consequently, the number of shockwaves required for complete stone fragmentation would be of great benefit in selecting appropriate treatment of patients with stone disease. If a stone is of a type not amenable to treatment by SWL, other modes of treatment can be pursued. However, except for cystinuric patients and patients who have had previous stone analysis, accurate prediction of stone composition based on imaging and the

patient's history is difficult. The ability of plain radiography to differentiate subtypes of calcium oxalate stones and possible relationships to stone fragility was first suggested by Dretler (Dretler, 1988; Dretler and Polykoff, 1996). Using x-ray patterns to predict stone fragility, Wang and colleagues (1993) found that smooth-edged stones with a homogeneous structure required significantly more shockwaves to be completely fragmented, compared with round, radially reticulated stones with spiculated edges or stones with an irregular margin and structure. In a retrospective study of 485 patients, Bon and colleagues (1996) found that smooth, uniform, bulging stones that appeared more dense than bone (with use of either the 12th rib or a transverse process as a reference point) responded poorly to SWL; the stone-free rates for patients with smooth, radiographically dense stones versus those harboring stones with irregular outlines were 34% and 79%, respectively. However, in a prospective study, the overall accuracy of predicting stone composition from plain radiographs was reported to be only 39% and therefore inadequate for clinical use (Ramakumar et al, 1999).

Non–contrast-enhanced helical CT, an increasingly popular method of evaluating patients with suspected renal colic, may be used to identify stone composition. Several in vitro investigations of this technology have been reported. Mostafavi and associates (1998b) performed an in vitro study that used the attenuation levels acquired by CT imaging to accurately predict the chemical composition of pure urinary calculi. Similarly, Saw and associates (2000) found that CT at 1-mm collimation (120 kV) was able to differentiate in vitro between stone groups (each containing at least 60% of one stone constituent) on the basis of absolute attenuation values. The authors noted that both stone size and beam collimation affected the attenuation measurements. Joseph and associates (2002) reported an in vivo study of 30 patients with renal calculi who underwent SWL treatment. They reported that the success rate was significantly lower for those calculi with attenuation values greater than 1000 Hounsfield units than for those calculi with attenuation values less than 1000 Hounsfield units.

Although CT attenuation values can distinguish some stone types in vivo, such as uric acid from calcium stones, the use of attenuation values alone results in considerable overlap; the range of values for calcium oxalate monohydrate and struvite stones does not allow these types to be confidently distinguished. Furthermore, it is not certain that the ease with which a stone is fragmented by SWL can be predicted by knowing only the major mineral composition of the stone. For example, cystine stones, which are considered difficult to break, have been shown in certain cases to break easily (Bhatta et al, 1989). Williams and associates (2003), too, reported that **the variability in stone fragility to shockwaves is large, even within groups defined by mineral composition.** It is likely that **this variability in fragility could be due to variation in stone composition or structure,** including variable amounts of secondary mineral in the stone, variation in the spatial arrangement of the secondary mineral within the stone, and variation in the layer structures of the primary and secondary minerals within a stone. Williams and associates (2002) also reported that displaying the data acquired by helical CT with use of bone windows can reveal remarkable internal structural detail of kidney calculi (Fig. 44–3). It is clear that CT provides a wealth of information about stone characteristics. However, additional work is needed to determine the utility of this powerful imaging tool in determining the susceptibility of a given stone to SWL.

Renal Anatomic Factors

There are certain anatomic factors, either congenital or acquired, that can hinder stone clearance after SWL. Congenital anomalies manifest not uncommonly in the upper urinary tract, and almost all that affect the drainage of the kidney are associated with increased incidence of calculous disease. Renal anatomic anomalies associated with an increased risk of stone formation include ureteropelvic junction obstruction, horseshoe kidney, and other ectopic or fusion anomalies as well as calyceal diverticula (Jones et al, 1991; Husmann et al, 1996; Cohen and Preminger, 1997). The dependent position of lower pole calyces may also affect stone clearance after SWL. In addition, stone-free rates after SWL for patients with hydronephrosis or obstruction are poor (Drach et al, 1986; Winfield et al, 1988). A retrospective study identified a significant association of hydronephrosis with the failure to clear residual fragments (Shigeta et al, 1999). Any patient with obstruction distal to the targeted stone should not undergo SWL treatment. If both obstruction and infection are present, SWL may result in life-threatening urosepsis (Meretyk et al, 1992a). Furthermore, the patient is unlikely to clear stone fragments unless the concomitant obstruction is alleviated.

Figure 44–3. Photographic and helical CT images show structural variability in stones of the same type. Note that although all stones depicted are calcium oxalate in type, some have a mottled structure and others have a lamellar structure.

Ureteropelvic Junction Obstruction

Ureteropelvic junction obstruction in adults is commonly associated with urinary calculi. Furthermore, a stone at the ureteropelvic junction can exacerbate the degree of preexisting obstruction and further compromise the renal unit (Rutchik and Resnick, 1998). The role of anatomic obstruction and associated urinary stasis in stone formation is not clearly established. Husmann and colleagues (1995) reviewed the records of 111 patients with simultaneous ureteropelvic junction obstruction and renal calculi. They found that 71% of patients with nonstruvite stones had significant metabolic abnormalities. Furthermore, more than 60% of recurrent calculi in the nonstruvite group occurred in the patient's contralateral kidney. Likewise, 68% of 22 pediatric patients treated for ureteropelvic junction obstruction associated with renal calculus had recurrent stones at a median follow-up of 9 years (Husmann et al, 1996). Thus, **in addition to anatomic obstruction, underlying metabolic abnormalities are commonly present in patients with ureteropelvic junction obstruction.**

Although patients with stones and concomitant ureteropelvic junction obstruction have traditionally been treated by open pyeloplasty and stone extraction, PNL with concomitant endopyelotomy can achieve good results with less morbidity. Endopyelotomy, defined as incision of the ureteropelvic junction obstruction intraluminally, has an overall success rate between 63% and 88% (Ramsay et al, 1984; Van Cangh et al, 1989, 1994; Motola et al, 1993; Kletscher et al, 1995; Nadler et al, 1996; Preminger et al, 1997; Albani et al, 2004; Knudsen et al, 2004). Percutaneous endopyelotomy can easily be combined with PNL, which permits efficient stone removal as well as careful endoscopic inspection of the ureteropelvic junction. Success rates for combined PNL and endopyelotomy have been reported to range from 64% to 85% (Cassis et al, 1991; Meretyk et al, 1992b; Motola et al, 1993). Although retrograde endopyelotomy can also be performed, the antegrade approach is preferable when renal calculi are present. Ramakumar and colleagues (2002) have reported that laparoscopic pyeloplasty with concomitant pyelolithotomy is a feasible technique for this population of patients as well. However, Ball and associates (2004) have observed that **laparoscopic pyeloplasty with concomitant pyelolithotomy is most efficacious when it is applied to patients with limited stone burdens.**

Calyceal Diverticula

Calyceal diverticula are congenitally derived, nonsecretory, urothelium-lined eventrations of the renal collecting system that are filled with urine. A narrow neck communicating with the collecting system is typically present, which permits the diverticulum to fill passively with urine. Calyceal diverticula are uncommon, having been reported as incidental findings in 0.2% to 0.6% of individuals undergoing renal imaging (Middleton and Pfister, 1974; Timmons et al, 1975; Wulfsohn, 1980; Michel et al, 1985). Stones have been reported to form in 9.5% to 50% of these cavities and can cause pain and hematuria or harbor bacteria (Yow and Bunts, 1955; Williams et al, 1969; Middleton and Pfister, 1974). The role of metabolic factors versus urinary stasis in the pathogenesis of stone formation in calyceal diverticula is controversial. Burns and coworkers (1984) suggested that particle retention time, especially in the setting of a diverticulum, could be the cause of stone formation. However, several studies examining metabolic data have drawn conflicting conclusions. Although Hsu and Streem (1998) have reported metabolic abnormalities in 50% of 14 patients with calyceal diverticular calculi, Liatsikos and associates (2000) found a low incidence of metabolic abnormalities in 49 patients with calyceal diverticular stones.

Historically, patients with calyceal diverticula were treated by open surgical nephrotomy with closure of the infundibulum, marsupialization and fulguration of the diverticular cavity, or partial nephrectomy. However, with the development of minimally invasive surgical therapies, including PNL, ureteroscopy, SWL, and laparoscopic surgery, open surgical treatments are uncommon. The use of SWL for the treatment of patients with diverticular calculi is controversial. Most investigators agree that **to prevent stone recurrence, eradication of the diverticulum should accompany stone removal,** a goal that is not achieved with SWL (Cohen and Preminger, 1997). Furthermore, **the stone-free rate for patients with calculi within calyceal diverticula who are treated by SWL averages only 21%** (range, 4% to 58%) (Renner and Rassweiler, 1999). However, an average of 60% (range, 36% to 86%) of patients will become symptom free after SWL. The follow-up in series showing the highest symptom-free rates is relatively short (3 to 6 months); on extended follow-up, Jones and associates (1991) demonstrated that some of the patients initially rendered symptom free will subsequently become symptomatic and require re-treatment. The highest success rate with SWL was reported by Streem and Yost (1992), who treated a series of 19 patients harboring calyceal diverticular calculi smaller than 1.5 cm and a functionally patent diverticular neck. An initial stone-free rate of 58% and a symptom-free rate of 86% were achieved, probably a result of careful selection of patients; all of the diverticula filled with contrast material on preoperative intravenous pyelography, and the ostia were well visualized. In addition, the aggregate stone size was smaller than 1.5 cm. However, recurrent stone growth was demonstrated in one patient during the follow-up period, and six of nine patients with infection presumed to be secondary to the diverticulum developed recurrent infections.

The percutaneous approach for the management of subjects with diverticular stones provides the patient with the best chance of becoming stone and symptom free, 88% and 91%, respectively (Hulbert et al, 1986; Hedelin et al, 1988; Kriegmair et al, 1990; Ellis et al, 1991; Jones et al, 1991; Lang, 1991; Hendrikx et al, 1992; Bellman et al, 1993; Shalhav et al, 1998; Donnellan et al, 1999; Al-Basam et al, 2000; Monga et al, 2000; Auge et al, 2002b). Furthermore, there is an excellent chance of ablating the diverticular cavity by this approach. **A direct percutaneous approach to the calyceal diverticulum is preferable because it allows use of a rigid nephroscope for stone extraction, dilation and incision of the diverticular neck, and fulguration of the diverticular epithelium.** Kim and associates (2005a) reported a novel, single-stage procedure that does not require ureteral catheter placement or entrance into the renal collecting system. Percutaneous access is directed onto the diverticular cavity harboring stone, two movable core J wires are coiled in the diverticular cavity, and the track is balloon dilated. Once the stone material is removed, the cavity is fulgurated.

Retrograde ureteroscopic management is a reasonable option for certain patients with diverticula in the upper and

middle portions of the kidney when the stone burden is less than 2 cm and the diverticular neck is short and accessible (Grasso et al, 1995c). Ureteroscopy also offers the ability to use a laser fiber or electrocautery probe to fulgurate the diverticular epithelium (Cohen and Preminger, 1997). Fuchs and David (1989) reported a stone-free rate of 73% and a symptom-free rate of 86%. Batter and Dretler (1997) attempted this approach in 26 patients. They were able to access the diverticular cavity in only 18, and 15 were rendered stone free. All of the 18 patients in whom the diverticulum could be entered were symptom free at a mean follow-up of 39 months. Auge and associates (2002b) reported a symptom-free rate of 35% and stone-free rate of 19% for this technique. For those patients harboring larger diverticular stones, a combined ureteroscopic and antegrade approach was reported to improve the outcome of PNL (Grasso et al, 1995c).

Laparoscopic management of patients with symptomatic calyceal diverticula has been described in several small series and case reports (Gluckman et al, 1993; Ruckle and Segura, 1994; Harewood et al, 1996; Hoznek et al, 1998; Curran et al, 1999). Miller and associates (2002) reported a series of five patients with symptomatic, stone-bearing calyceal diverticula who underwent retroperitoneoscopic surgical therapy. The authors concluded that the optimal candidates for this approach are those with a symptomatic calyceal diverticulum with thin overlying renal parenchyma, those with a large stone burden, and those with an anterior lesion inaccessible to or unsuccessfully managed by other approaches. However, the laparoscopic approach is more invasive than PNL and therefore is usually limited to diverticula in anterior calyces, which are otherwise difficult to access with a percutaneous approach.

Horseshoe Kidney and Renal Ectopia

Horseshoe kidney is the most common congenital renal anomaly, and patients with this condition are often affected by urolithiasis (Evans and Resnick, 1981). A horseshoe kidney is considered the result of a median fusion of metanephric tissue during early gestation. Subsequent entrapment of the fused lower pole isthmus by the inferior mesenteric artery results in an incomplete cephalad migration and an associated malrotation of the kidney (Hohenfellner et al, 1992). In many cases, the ureteropelvic junction is anomalous because of a high ureteral insertion into an elongated renal pelvis. This can cause impaired urine drainage, a likely reason that up to two thirds of such patients are found on evaluation to have hydronephrosis, infection, or urolithiasis (Lampel et al, 1996). Although SWL can be used to treat patients with calyceal stones in a horseshoe kidney, the anomalous orientation of the calyces makes localization of the calculi more difficult, especially for stones in the anteromedial calyces. Placement of the patient in a prone position may facilitate localization of the stone (Jenkins and Gillenwater, 1988). Alternatively, a "blast path" technique, which uses the observation that sufficient acoustic pressure for stone fragmentation exists beyond F2 along the axis of the shockwave in many lithotripters, may be employed (Locke et al, 1990). Reported results of SWL treatment of patients with horseshoe kidney stones are variable; stone-free rates between 28% and 78% have been reported (Esuvaranathan et al, 1991; Vandeursen and Baert, 1992; Theiss et al, 1993; Kirkali et al, 1996; Lampel et al, 1996; Kupeli et al, 1999). Much of the wide range of results can be explained by variability in stone size and location among the different studies. Theiss and colleagues (1993) stratified stones by location and found, as expected, that the clearance rate for lower calyceal stones was inferior to that of middle and upper calyceal stones (a stone-free rate of 53.8% versus 100%). Kirkali and associates (1996) studied a series of 18 patients with calculi larger than 10 mm and found a stone-free rate of 28%. Patients with renal calculi in horseshoe kidneys treated by SWL required a higher number of shockwaves per treatment and also experienced a higher re-treatment rate (30% versus 10%) than did patients with similar stones in orthotopic renal units (Chaussy and Schmiedt, 1984; Drach et al, 1986; Lingeman et al, 1986a). Lampel and associates (1996) reported a recurrence rate of 86% for patients harboring persistent fragments after SWL compared with a 14% recurrence rate for patients who were stone free. Despite the negative implications of these studies, **SWL can achieve satisfactory results in the properly selected patient with a stone burden smaller than 1.5 cm and nonobstructed urine drainage.**

For patients with larger calculi or for those who demonstrate evidence of poor urine drainage, PNL should be the primary approach. **The results of PNL for patients with calculi in a horseshoe kidney are generally superior to those achieved with SWL, with an average stone-free rate of 84%** (range, 75% to 100%) (Esuvaranathan et al, 1991; Jones et al, 1991; Al-Otaibi and Hosking, 1999; Raj et al, 2003; Shokeir et al, 2004). The **optimal point of entry for these kidneys is through a posterior calyx, which is typically more medial than in the normal kidney** because of the altered renal axis and rotation associated with the midline fusion. Except in the isthmus of the horseshoe kidney, where the vascular supply can be variable, **vessels tend to enter the kidney anteriorly. An upper pole collecting system puncture is often appealing as the entire kidney is usually subcostal.** In most cases, the lower pole calyces are anterior and inaccessible percutaneously. During PNL, the flexible nephroscope often aids in accessing stones within anteromedial calyces, which may be difficult to reach with a rigid nephroscope.

An ectopic kidney can be found in a pelvic, iliac, abdominal, thoracic, or crossed position. The most common site of ectopia is the pelvis, and the incidence of pelvic kidney is estimated to be 1 in 2200 to 1 in 3000 patients. See Chapter 113, "Anomalies of the Upper Urinary Tract." Although the ectopic location of the kidney can cause positioning problems during SWL treatment, calculi in these kidneys should be approached initially with SWL, if it is feasible (Harmon et al, 1996; Zafar and Lingeman, 1996). If the bony pelvis shields the targeted stone from the shockwave of the lithotripter, a prone position may be necessary. Kupeli and associates (1999) reported in a series of seven patients with calculi in pelvic kidneys that although successful fragmentation was achieved for most patients at the time of treatment, the stone-free rate at 3 months was only 54%.

For those situations in which SWL therapy is either unsuccessful or not possible, alternative modalities should be used. Laparoscopy-assisted percutaneous transperitoneal nephrolithotomy has been described (Fig. 44–4) (Eshghi et al, 1985; Figge, 1988; Lee and Smith, 1992; Toth et al, 1993). Holman and Toth (1998) described 15 patients treated by laparoscopy-assisted PNL with good results and no major

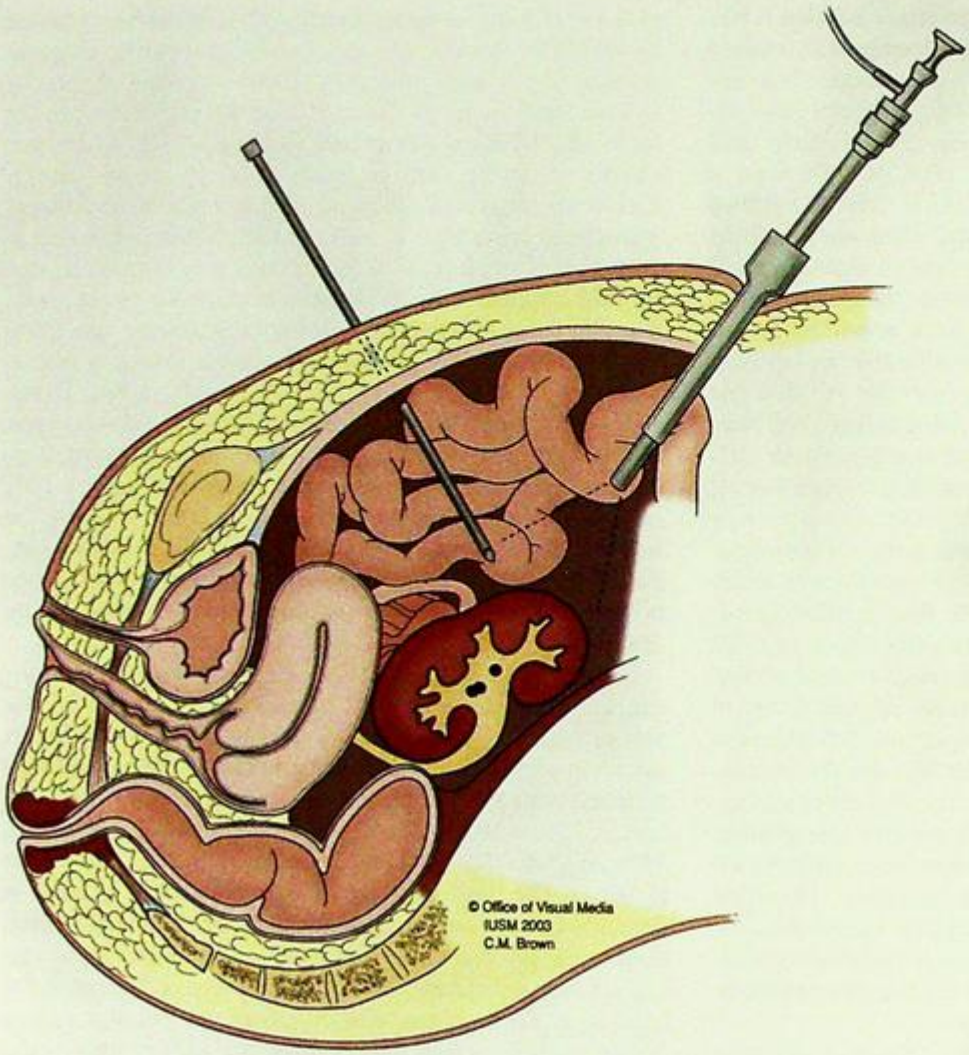

Figure 44–4. Laparoscopy-assisted PNL technique, in which the bowel is reflected off of the ectopic kidney before radiographically and laparoscopically guided percutaneous access.

complications. Alternatively, laparoscopic retroperitoneal pyelolithotomy in a pelvic kidney has been reported (Harmon et al, 1996). Flexible ureteroscopy is also an attractive alternative for this unusual problem if the stone burden is not large. Weizer and associates (2005) reported a series of eight patients with renal calculi in either a horseshoe kidney or an ectopic kidney who were treated successfully with ureteroscopy. Alternatively, CT guidance can permit percutaneous access into the ectopic renal collecting system without injury to adjacent organs (Matlaga et al, 2003b).

Lower Pole Calculi

Although SWL is the preferred method for treatment of most patients with symptomatic upper tract calculi, there is considerable controversy concerning the management of patients with lower pole calculi (Tolley and Downey, 1999). The limitations of SWL for treatment of patients with lower pole renal calculi were first noted in a meta-analytic study by Lingeman and associates (1994). These investigators reported that the stone-free results achieved with PNL were superior to those of SWL: **the overall stone-free rate for SWL applied to lower pole calculi was 60% compared with 90% for PNL.** Stratified according to stone size, patients with stones smaller than 10 mm had stone-free rates of 74% when they were treated by SWL compared with 100% by PNL. Among patients with stones of 10 to 20 mm, stone-free rates were 56% for the SWL group compared with 89% for the PNL group. A regression analysis demonstrated that increasing stone burden was associated with progressively less successful stone-free outcomes for patients treated with SWL, whereas for PNL-treated patients, stone-free rates were not different across categories of stone size. This study has prompted a number of groups to assess the impact of lower calyceal anatomy; studies reported stone-free rates for calculi 10 mm or smaller, 11 to 20 mm, and 20 mm or larger of 67.8%, 54.6%, and 28.8%, respectively (Havel et al, 1998; Kupeli et al, 1998; May and Chandhoke, 1998; Talic and El Faqih, 1998; Keeley et al, 1999b). Importantly, since the mid-1980s, a significant change in renal stone distribution has been noted, with an increase in the percentage of SWL treatments for patients with renal calculi being performed for lower calyceal stones (2% in 1984 to 48% in 1991) (Lingeman et al, 1994). This change in stone distribution may be explained by the tendency of small, radiographically undetectable fragments to gravitate to more dependent calyces after SWL therapy and to act as a nidus for new stone growth (Carr et al, 1996).

The reasons for poor clearance of fragments from the lower pole after SWL are unclear. Intuitively, the gravity-dependent position of the lower pole calyx may impede the passage of stone fragments (El-Nahas et al, 1998). However, several

investigators have proposed that in addition to the gravity-dependent positioning of the lower pole calyces, anatomic features may play an important role in the evacuation of stone fragments from this location. Anatomic factors were first suggested by Sampaio and Aragao (1992, 1994), who described the anatomy of the lower pole by use of polyester resin endocasts of the intrarenal collecting system obtained from adult cadavers. They examined 146 three-dimensional casts from 73 cadavers and noted that in many cases, the spatial anatomy of the lower pole region had peculiar features that were thought to be potentially important factors for the clearance of stone fragments. In 83 of 146 casts (56.8%), the inferior pole was drained by multiple infundibula. The authors hypothesized that an inferior pole with multiple infundibula might have poor drainage and consequently less possibility of eliminating stone fragments than would an inferior pole drained by a single infundibulum receiving fused calyces. In addition, the authors found that 39.7% of the kidneys had calyceal infundibular diameters of less than 4 mm. Again, the authors hypothesized that such a small diameter may hinder passage of stone fragments. The authors also examined the angle formed between the lower infundibulum and the renal pelvis, believing that an angle greater than 90 degrees should facilitate drainage of fragments from the lower pole. In 26% of the casts, the authors noted that this angle was less than 90 degrees and hypothesized that this could perhaps hinder stone clearance. In a prospective study, Sampaio and associates (1997) found that 39 of 52 patients (72%) became stone free when the lower pole infundibulopelvic angle was greater than 90 degrees, whereas only 5 of 22 patients (23%) were stone free when the angle was less than 90 degrees.

A number of other investigators have analyzed the impact of lower pole anatomy on SWL stone clearance (Table 44–2). Sabnis and colleagues (1997) reported that patients with favorable lower calyceal anatomy, as defined by Sampaio, had a post-SWL clearance rate of 70% or more, whereas those with unfavorable factors had a clearance rate of less than 20%. Elbahnasy and associates (1998) assessed the infundibulopelvic angle, infundibular length, and infundibular width in a retrospective study of 34 patients with solitary lower calyceal calculi treated with SWL. These anatomic features were measured by preoperative intravenous pyelography. Overall, the mean infundibulopelvic angle was significantly greater, 45 degrees versus 51 degrees, in SWL stone-free patients compared with those with residual stones after SWL. Furthermore, all patients with an infundibulopelvic angle greater than 90 degrees were stone free. The authors also found that there was a direct, statistically significant relationship between infundibular width and stone-free rate after SWL; only 33% of patients with an infundibular width of 5 mm or less became stone free after SWL compared with a 60% stone-free rate for patients with an infundibular width greater than 5 mm. Furthermore, there was a statistically significant inverse relationship between infundibular length and stone-free status after SWL; the infundibular length was 32 mm in stone-free cases versus 38 mm in cases with residual stone. They concluded that successful SWL is highly sensitive to lower pole anatomy. The combination of an infundibulopelvic angle of 90 degrees or greater, an infundibular length of less than 3 cm, and an infundibular width of more than 5 mm was associated with a successful outcome for lower pole calculi of 15 mm or less. The combination of an infundibulopelvic angle of less than 90 degrees, an infundibular length of more than 3 cm, and an infundibular width of 5 mm or less was associated with treatment failure. Keeley and associates (1999b) reported that collecting system anatomy affected the results in 116 patients with lower pole calculi measuring 11 to 20 mm treated with SWL. The overall stone-free rate was 52%. However, an obtuse infundibulopelvic angle was the only factor to attain significance in predicting stone-free status. Combining the three unfavorable factors (acute angle, distorted calyx, and narrow infundibulum), the stone-free rate was 9%; whereas with three favorable factors, the stone-free rate was 71%.

Others have not found collecting system anatomy to be predictive of lower pole stone clearance with SWL. Madbouly and colleagues (2001) employed the same methods to measure the three aforementioned anatomic parameters in 108 patients undergoing SWL treatment of lower pole stones. The mean infundibular length, the mean infundibular width, and the mean lower pole infundibulopelvic angle were not significant outcome predictors. However, the authors did find that patients with renal scarring had the least chance of becoming stone free.

Sorenson and Chandhoke (2002) reported a series of 190 patients with lower pole calculi who underwent SWL therapy. The patients were all evaluated with intravenous pyelography preoperatively, and these studies were used to measure the infundibular length, infundibular width, and infundibu-

lopelvic angle. Calyceal anatomy was not predictive of success, even when the stones were stratified by size. There was no difference in stone-free outcome when patients were grouped by favorable anatomy (infundibular angle greater than 70 degrees, infundibular length less than 30 mm, and infundibular width more than 5 mm) versus unfavorable anatomy (infundibular angle less than 70 degrees, infundibular length more than 30 mm, infundibular width less than 5 mm). Albala and associates (2001), of the Lower Pole I study group, reported on 38 cases in a randomized trial comparing SWL with PNL for the treatment of patients with lower pole calculi. In all of the SWL cases, infundibular length, infundibular width, and infundibulopelvic angle were calculated and recorded. In this study, there was no significant difference in mean lower pole infundibular width, lower pole infundibular length, and lower pole infundibulopelvic angle among patients undergoing SWL who had residual calculi and those rendered stone free.

One of the confounding issues in examining lower pole outcomes is the reproducibility of lower pole anatomic measurements. Pace and colleagues (2000) reported that there is wide variability in lower calyceal infundibular width between different intravenous pyelography phases. The authors found that the width was greatest on the compression film and smallest on the postvoid film, which prompted them to suggest the use of standardized timing when infundibular width is measured from an intravenous pyelogram. Likewise, Keeley and associates (1999b) suggested that because peristalsis changes the diameter of the infundibulum, measurement of this variable from a single x-ray film is imprecise. Although some of the disparity regarding the lower pole anatomic influences on stone-free status may be due to the techniques in which the parameters were measured, other sources of variability may be due to the type of lithotripter employed. In addition, stone composition, an important variable, is often neglected in these studies. However, it is likely that an obtuse versus an acute lower pole infundibulopelvic angle is important in fragment clearance after SWL. The most appropriate method for measuring lower pole infundibulopelvic angle and its relevant cutoff values as well as the significance of other lower pole anatomic features as predictive factors of stone clearance are yet to be determined.

Despite the lower stone-free rates achieved with SWL therapy, a number of clinicians advocate this modality for the treatment of patients with lower pole calculi. Elbahnasy and associates (1998b) compared the outcomes of patients with lower pole calculi treated by either SWL or PNL. The authors found that the stone-free rate with SWL was significantly lower compared with PNL (56% versus 85%). However, the clinical stone recurrence rates of the two groups at 20 months were similar (10% versus 11%). Cass (1996a) reviewed the results of 968 lower pole calculi treated by SWL and compared these results with four published series of PNL therapy for lower pole calculi. The author concluded that although the stone-free rate achieved with PNL is greater than that achieved with SWL, lower complication rates, lower repeated treatment and secondary procedure rates, shorter hospital stays, and similar recurrent stone rates make SWL more clinically effective as a primary therapy for patients with lower pole calculi less than 2 cm in diameter. Obek and associates (2001) reported a series of 455 patients with isolated lower pole calculi treated with SWL. After a single SWL treatment, the stone-free rate for patients with isolated lower pole calculi was 63%. However, the stone-free rate dropped to 49% for patients with calculi larger than 2 cm, leading the authors to recommend SWL for primary treatment of patients with lower calyceal stones smaller than 2 cm. Chen and Streem (1996) reported a series of 206 patients with isolated lower pole calculi in 220 renal units who were treated with SWL. The stone-free rate at 1 month of follow-up was 48%, with another 6.3% of patients becoming stone-free during extended follow-up. Of those patients with residual stones, 9% required secondary intervention.

The poor stone clearance rates for patients with lower pole calculi treated by SWL have prompted investigators to examine techniques to facilitate fragment passage. McCullough (1989) anecdotally reported that postural drainage may assist in the elimination of retained fragments from dependent calyces. Brownlee and associates (1990) subsequently treated patients with residual lower pole fragments with controlled inversion therapy, using intravenous hydration, inversion, and percussion. D'A Honey and associates (2000) reported a pilot study to determine whether mechanical percussion with inversion therapy and furosemide-induced diuresis can move stone fragments out of the lower pole of the kidney. At a mean time of 63 days after SWL, this group reported an 83% stone passage rate. In a subsequent study, Pace and associates (2001) compared the effectiveness of mechanical percussion, inversion, and furosemide-induced diuresis with observation for elimination of lower calyceal fragments after SWL. They reported that 40% of patients with residual lower pole fragments treated with this regimen became stone free compared with 3% in the observation group; the observation group was then treated with this regimen as part of a crossover design, and 43% were rendered stone free. Other authors have reported lower pole irrigation techniques as adjuncts to SWL. Nicely and associates (1992) performed retrograde irrigation of the lower pole with a cobra angiographic catheter during SWL and found that the irrigation group had a 71% stone-free rate at 1 month of follow-up compared with 33% in the control group. Graham and Nelson (1994) placed a small percutaneous nephrostomy tube into the lower pole collecting system before SWL and performed a continuous saline irrigation of the collecting system. All patients became stone free with this therapy. None of these techniques, however, has gained widespread acceptance.

As previously described retrospective studies have indicated, **the results of SWL of lower pole calculi are inferior to those of PNL and depend on stone size.** Albala and associates (2001) have performed a multicenter, randomized, prospective study (Lower Pole I) that compared the treatment outcomes for patients with lower pole calculi after either PNL or SWL. The stone-free rate at 3 months after treatment, as measured by nephrotomograms, was 95% for those undergoing PNL and 37% for those undergoing SWL. Of note, **stone clearance from the lower pole after SWL was especially poor as stone size increased above 10 mm.** For patients with stones smaller than 10 mm, 20 of 20 (100%) patients treated with PNL were stone free, whereas 12 of 19 (63%) treated with SWL were stone free. For those patients with calculi of 11 to 20 mm, 26 of 28 (93%) treated with PNL were stone free, whereas 6 of 26 (23%) treated with SWL were stone free. Finally, for

patients with calculi of 21 to 30 mm, 6 of 7 (86%) treated with PNL were stone free, whereas 1 of 7 (14%) treated with SWL was stone free. The main advantage of SWL was the lower associated morbidity.

A number of significant advances in endourologic technology have facilitated the treatment of lower pole calculi through a retrograde endoscopic technique. Grasso and Ficazzola (1999) reviewed a series of 79 patients with 90 lower pole calculi treated through a retrograde approach by small-diameter, actively deflectable, flexible ureteroscopes and holmium laser intracorporeal lithotripsy. In this series, the overall stone-free rate was 76%. Stratified by stone size, the stone-free rates were 82%, 71%, and 65% for patients with stones 1 to 10 mm, 11 to 20 mm, and more than 20 mm, respectively. A long lower pole infundibulum and infundibular stenosis were associated with treatment failures. Hollenbeck and associates (2001) reviewed 61 patients who underwent 68 ureteroscopic procedures for the treatment of lower pole calculi. Laser lithotripsy was performed in situ, without displacement of the stone from the lower pole. After a single procedure, 62% were stone free, and after a second procedure, 69% were stone free. Stratified by size, 71% of patients with stones smaller than 10 mm and 75% of patients with calculi of 10 to 20 mm were stone free.

Recognizing the technologic advances in ureteroscopy, the **Lower Pole Stone Study Group compared ureteroscopy and PNL for patients with 10- to 25-mm lower pole stones and found a significant difference in stone clearance, with only 31% of the ureteroscopy cohort stone free at 3 months versus 76% of the PNL cohort.** The definition of stone free was strict, based on CT imaging. If the definition is broadened to include fragments smaller than 4 mm, the stone-free rate improved to 80% for the ureteroscopy cohort and to 100% for the PNL cohort (Kuo et al, 2003). Thus, **ureteroscopy for patients with a large renal stone burden is probably inferior to PNL and should be used only for those patients who are poor candidates for PNL.** The Lower Pole Stone Study Group also performed a prospective, randomized study of SWL and ureteroscopy for lower pole stones smaller than 10 mm and reported that there was no significant difference in stone-free rates between the two techniques (Pearle et al, 2005).

Placement of an instrument through a flexible ureteroscope impedes scope deflection, which may make it difficult or impossible to perform laser lithotripsy of lower pole calculi. Nitinol baskets and flexible grasping devices have less of a negative effect on deflection than laser fibers do and can be used to displace the targeted stone to the mid or upper portions of the collecting system, facilitating laser lithotripsy (Auge et al, 2001). Kourambas and associates (2000a) reviewed a series of 34 patients with 36 lower pole calculi treated through a retrograde approach. Twenty-six stones were fragmented in situ in the lower pole, whereas 10 calculi were moved to a more favorable position in the collecting system. The stone-free rate of patients who were treated with stone displacement before fragmentation was 90% compared with a stone-free rate of 83% for those patients who underwent in situ fragmentation. Schuster and associates (2002) similarly reported a 77% stone-free rate for patients with lower pole calculi smaller than 1 cm treated in situ versus an 89% stone-free rate for those treated with displacement first. For patients with calculi larger than 1 cm, 100% of those undergoing displacement first were treated successfully compared with 29% of those treated in situ.

The optimal approach for management of patients with lower pole stones is still evolving. SWL is a reasonable consideration for individuals with lower pole stones of 1 cm or less in aggregate size. There is a reasonable chance of achieving a stone-free state with minimal attendant morbidity with this technique. Patients with lower pole stones of 2 cm or more are still best served with PNL as this offers them the best chance of being rendered stone free with one procedure. Much of the controversy regarding treatment of lower pole stones is limited to stones of 10 to 20 mm in diameter. PNL, ureteroscopy, and SWL are all acceptable options. Stone composition and lower pole anatomy should be considered in recommending a treatment modality for these patients. Patients with an acute lower pole infundibulopelvic angle (with or without other unfavorable anatomic features), patients whose SWL treatment has failed, and patients known to have stones resistant to SWL should be treated with PNL or ureteroscopy. In the future, it may be possible to predict which patients among this group will have good results with the different treatment modalities.

Clinical Factors

The treatment of urinary tract calculi must be viewed in the context of the patient as a whole. Any coexisting clinical factors that may affect the safety and the efficacy of the selected treatment must be considered.

Urinary Tract Infection

Urinary tract infection, in the presence of renal calculi, can be difficult to eradicate unless the offending stones are completely removed. For these patients, then, PNL or ureteroscopy, both of which permit the complete removal of stone fragments, may be preferable to SWL. The reported incidence of sepsis after SWL is less than 1%, although a staghorn calculus increases this rate substantially to 2.7% to 56% (Lam et al, 1992a; Meretyk et al, 1997). The risk of sepsis increases if the urine culture demonstrates bacterial growth before SWL (Zink, 1988). Furthermore, the risk of sepsis is also greater in the presence of obstruction (Meretyk et al, 1992a). Therefore, **SWL should be performed only if the urine is sterile and there is no distal obstruction.** In general, prophylactic antibiotics are not required before SWL but should be considered in high-risk patients (Kattan et al, 1993; Bierkens et al, 1997).

Morbid Obesity

Morbid obesity, which may be defined as more than 100 pounds overweight, greater than 200% of ideal body weight, or a body mass index (a value obtained by weight in kilograms divided by height in meters^2) greater than 40, poses a number of physiologic and technical challenges to the successful treatment of kidney stones (Giblin et al, 1995; Freedman et al, 2002). The respiratory and cardiovascular morbidities inherent in a morbidly obese state can significantly increase the perioperative risk associated with even a minimally invasive procedure. Morbid obesity may make SWL impractical or technically impossible because of weight limitations on the lithotripter table or gantry, inability to target the stone radiographically, or skin to stone distance that exceeds the

maximum allowable focal distance of the lithotripter. When the increased distance from the skin surface to the stone renders positioning of the stone at the focus of the shockwave impossible, a blast path technique that relies on high pressures produced at a point located coaxially beyond F2 may be required (Whelan et al, 1988; Locke et al, 1990). Although the successful treatment of obese patients with SWL has been reported, with an overall stone-free rate of 68% at 3 months, high-energy settings of the lithotripter were required (Thomas and Cass, 1993). Should the urologist treating a morbidly obese patient have a choice among different SWL machines, the machine with the greatest focal length and highest peak pressure should be selected (Hofmann and Stoller, 1992).

Despite these potential maneuvers, the morbidly obese may still achieve a suboptimal outcome after SWL. Ackermann and associates (1994) reported a multivariate analysis that found body mass index to be a significant negative predictor of a stone-free outcome after SWL. Portis and associates (2003) have reported similar findings. In many cases, PNL is the only effective treatment option for the morbidly obese patient with a complex renal calculus. The judicious use of an extralong working sheath, along with extralong rigid nephroscopes, flexible nephroscopes, and longer instruments, can overcome the increased distance between skin surface and stone in these patients. Pearle and associates (1998) described 57 obese patients (body mass index greater than 30) who underwent PNL. The overall stone-free rate (88.3%) and the complication and transfusion rates (12.8% and 5%, respectively) were comparable to the results of PNL in an unselected population of patients. Koo and associates (2004) similarly reported that **the outcome of PNL is independent of the patient's body mass index.**

Significant alterations in technique are not required when a ureteroscopic approach is selected for the morbidly obese patient with a renal calculus. **For morbidly obese patients who do not harbor an excessively large stone burden, the ureteroscopic approach may be preferable** (Fabrizio et al, 1998; Nguyen and Belis, 1998).

Spinal Deformity or Limb Contractures

Patients with spinal deformity or limb contractures may also be difficult to position within the lithotripter. Alternative treatment modalities, including PNL and ureteroscopy with flexible instruments, may be preferable in these patients. Owing to the unusual anatomy that is often present, **a preoperative CT scan can help in planning percutaneous access.** In certain cases, CT guidance may be necessary to safely obtain percutaneous access into the renal collecting system (Matlaga et al, 2003b).

Uncorrected Coagulopathy

Although **SWL or PNL treatment of patients with uncorrected coagulopathy can result in life-threatening hemorrhage,** such patients can be safely treated once the bleeding diathesis has been corrected (Streem and Yost, 1990). However, **if the patient's coagulopathy is the result of a pharmacologic therapy that cannot be safely discontinued, ureteroscopy with holmium:yttrium-aluminum-garnet (holmium:YAG) laser lithotripsy is the preferable approach.** Grasso and Chalik (1998) have reported that this is a safe and effective technique for patients with uncorrected coagulopathies. Watterson and associates (2002b) conducted a multicenter retrospective analysis and also reported that upper tract calculi in patients with uncorrected bleeding diathesis can be safely managed by a ureteroscopic approach.

Other Groups

The management of renal calculi in children is discussed in Chapter 131. However, when children as well as the elderly, the hypertensive, and those with impaired renal function are treated with SWL, enhancement of the adverse effects of the shockwaves may occur. Care should be taken to limit the number and energy of shockwaves applied in such circumstances (Janetschek et al, 1997; Evan et al, 1998; Lifshitz et al, 1998).

Assessment and Fate of Residual Fragments

In the era of open stone surgery, residual fragments of any size suggested a failed procedure. However, the increasing popularity of SWL as the treatment of choice for most patients with upper tract urinary calculi has changed the definition of a successful outcome, introducing the concept of **clinically insignificant residual fragments** (Newman et al, 1988). Newer definitions of treatment success were required after the observation that **although many patients had successful stone fragmentation, not all patients completely and spontaneously passed all of the stone fragments.** Furthermore, the clearance of stone fragments produced by shockwaves is not immediate; as many as 85% of patients have radiologic evidence of residual fragments in the kidney several days after SWL (Drach et al, 1986). Although most fragments will pass spontaneously during the first 3 months after SWL, continued clearance of fragments can occur for more than 24 months after treatment (Chaussy and Schmiedt, 1984; Graff et al, 1988; Kohrmann et al, 1993). Therefore, since the introduction of SWL, treatment outcomes for patients with renal calculi have been reported by two different terms: stone-free rate and success rate. The stone-free rate is self-explanatory, but the success rate includes patients who are stone free as well as those with clinically insignificant residual fragments. These different methods of reporting treatment results, the lack of consensus regarding the definition of clinically insignificant residual fragments, and the various modalities used for assessing postprocedural stone-free status (KUB radiography, nephrotomography, ultrasonography, CT) make the comparison of endourologic stone removal procedures with SWL difficult.

Clinically insignificant residual fragments were initially defined as residual fragments 4 mm or smaller in diameter associated with sterile urine in an otherwise asymptomatic patient (Newman et al, 1988). However, **small residual stones often become clinically symptomatic** (Streem et al, 1996; Zanetti et al, 1997; Candau et al, 2000). Streem and colleagues (1996) reported on a prospective, long-term follow-up study of 160 patients after SWL who had small, residual, asymptomatic, calcium oxalate or calcium phosphate stones (4 mm or smaller). At a mean follow-up of 23 months, 43% of patients had suffered a significant symptomatic episode or required intervention. Likewise, Zanetti and associates (1997) followed up 129 patients with residual stones smaller than 4

mm after SWL and noted that 22% became symptomatic or required intervention.

Residual fragments not only may become symptomatic but also can act as a nidus for new stone growth. Complete stone removal will decrease the risk of stone recurrence and regrowth (Singh et al, 1975; Patterson et al, 1987; Newman et al, 1988). Stone recurrence rates of 6% to 15% have been reported for patients who were rendered stone free after SWL compared with rates of 17% to 80% when residual fragments were present (Graff et al, 1988; Newman et al, 1988; Nijman et al, 1989; Beck and Riehle, 1991; Fuchs et al, 1991; Zanetti et al, 1991; Nakamoto et al, 1993). In a long-term prospective study, residual fragments (<4 mm) after SWL were found to pass spontaneously in 24% of patients, whereas increased, decreased, and stable amounts of residual fragments were noted in 18%, 16%, and 42% of patients, respectively (Streem et al, 1996). Similarly, a retrospective study of 83 patients with residual fragments (<4 mm) after SWL found complete stone clearance or a decreased, stable, or increased amount of residual stone at a mean follow-up of 40 months in 33%, 1%, 29%, and 37% of the patients, respectively (Candau et al, 2000). Furthermore, the size of the residual fragment (2 mm or smaller versus 2 to 4 mm) influences the risk of its becoming symptomatic (Candau et al, 2000).

Many investigators have noted that **after SWL, residual fragments are commonly localized to lower pole calyces, no matter where the stone was treated in the kidney** (Drach et al, 1986; Graff et al, 1988; Liedle et al, 1988; Zanetti et al, 1991; Kohrmann et al, 1993). As well, the incidence of stone recurrence is higher in the lower pole calyces (Zanetti et al, 1991; Kohrmann et al, 1993). Carr and associates (1996) compared SWL with PNL and at 1-year follow-up reported a significantly greater rate of new stone formation in the SWL group. They also demonstrated a greater likelihood of stone recurrence in lower and middle calyces. A plausible explanation for these results is that fine debris, undetectable by KUB radiography, persists after SWL and, because of gravity, tends to settle in the most dependent calyces, serving as a nidus for new stone formation.

In patients with infection-related calculi, the consequence of residual fragments is particularly harmful. Residual fragments may harbor the offending bacteria and thus perpetuate postoperative bacteriuria and persistent infection. Furthermore, stone regrowth has been reported in up to 75% of such patients after SWL, compared with 10% of patients who experienced complete stone removal (Beck and Riehle, 1991; Zanetti et al, 1991).

For patients with metabolic stone disease (such as those with cystinuria), complete stone removal does not prevent stone recurrence, but it does prolong treatment intervals (Chow and Streem, 1998). Thus, residual stones, including small stones, may not have an immediate clinical relevance but are likely to affect the patient's well-being in the long term. In these situations, it is important to select a treatment approach that is most likely to render the patient stone free.

The sensitivity of the method used to detect residual stones after a stone removal procedure has important effects on the incidence and size of residual fragments. In early studies investigating stone clearance after SWL, plain radiography was commonly used to determine stone-free status. A plain radiograph can detect an opaque stone fragment as small as 2 mm (Thornbury and Parker, 1982). However, Denstedt and coworkers (1991) reported that in 29 patients with large renal calculi treated with a combination of PNL and SWL, plain radiography and renal tomography, overestimated stone-free rates by 35% and 17%, respectively, compared with flexible nephroscopy, leading the authors to conclude that plain radiography is inadequate to accurately determine stone-free status after SWL. Several groups have reported that nephrotomography is superior to plain radiography in evaluating stone-free status; additional residual stone fragments are detected in 12% to 47% of patients (Hjollund Madsen, 1972; Schwartz et al, 1984; Goldwasser et al, 1989). Sonography is inferior to plain radiography and is particularly inadequate in detecting ureteral stones, with a sensitivity of only 19% (Yilmaz et al, 1998; Older and Jenkins, 2000). Although ultrasonography should not be used as a single modality for detecting residual stones, it is effective in diagnosing hydronephrosis and should be considered following all ureteroscopic procedures, as silent obstruction has been reported to occur in certain, albeit rare, instances (Weizer et al, 2002). A prospective study comparing the relative efficacy of abdominal radiography and renal ultrasonography with excretory urography for the evaluation of asymptomatic patients 1 month after SWL treatment demonstrated that the combination of ultrasonography and abdominal radiography was as good as or better than intravenous urography in identifying residual stone fragments and renal abnormalities, including hydronephrosis (Coughlin et al, 1989). The authors suggested that **routine radiologic evaluation of asymptomatic patients after SWL could be limited to abdominal radiography and ultrasonography.**

Although plain films of the abdomen and nephrotomograms were at one time commonly used to identify retained fragments after PNL, antegrade nephrostograms and second-look nephroscopy have now became commonplace (Waldmann et al, 1999). Although flexible nephroscopy may be considered the "gold standard" for assessment of residual stones after PNL, its routine use has been challenged by studies showing the high sensitivity of CT in detecting residual stones after PNL. Pearle and coworkers (1999) noted that CT had 100% sensitivity for detecting residual stones after PNL in 36 patients evaluated with both CT and flexible nephroscopy. Selective use of flexible nephroscopy based on positive CT findings would have avoided an unnecessary procedure in 20% of patients. In a retrospective study of 121 patients who underwent CT after PNL (including 59% stone-free patients and 16% patients with fragments of 1 to 3 mm), Waldmann and associates (1999) reported that routine nephroscopy would not have been required in 75% of cases. Given its wide availability and high sensitivity, non–contrast-enhanced CT is likely to become the primary method for evaluation of patients after PNL.

Adjunctive Medical Treatment

Any patient who requires surgical stone removal should be offered a metabolic evaluation and stone analysis. **Appropriate medical therapy can decrease the risk of stone recurrence and stone regrowth** (Lifshitz et al, 1999a).

In a retrospective study, Fine and associates (1995) examined the effect of medical management on residual fragments and recurrent stone formation after SWL; they reported that selective medical therapy decreased the stone formation rate

compared with the control group by 91% versus 35%, respectively, if the patient was stone free and by 81% versus 17%, respectively, in the presence of residual fragments. Likewise, Lee and colleagues (1999) conducted a retrospective study of patients with upper urinary tract calculi observed for 24 to 60 months and found a significant decrease in the stone recurrence rate in patients who received medical prophylaxis compared with those who were managed expectantly (7.8% versus 46.2%, respectively). In a prospective study, Cicerello and coworkers (1994) found that for patients with either calcium oxalate or struvite stones, alkaline citrate therapy improved stone clearance at 6 and 12 months and also decreased stone regrowth after SWL. The use of long-term (for more than 3 months) antibiotics was reported to decrease the risk of stone recurrence from 90% to 15% after open surgery for struvite stones, suggesting that a prolonged course of antibiotic treatment may also be beneficial after PNL, SWL, and ureteroscopy (Husmann et al, 1995).

Mardis and associates (2004) emphasized the importance of the administration of validated medical therapies, guided by metabolic evaluation, in reducing stone recurrence rates after treatment. Medical therapy in patients with hypercalciuria confers a secondary advantage, as Pak and associates (2003) have reported that appropriate treatment can increase bone density in these patients. However, any postprocedural medical management should not supercede the choice of a treatment approach that gives the patient the best chance to achieve a stone-free status with minimal morbidity.

KEY POINTS: RENAL CALCULI

- The majority of patients with renal calculi have a normal kidney and a small stone burden, and can be managed best with SWL. Patients with lower pole calculi larger than 10 mm will experience significantly better stone-free rates after PNL than after SWL.
- The procedure of choice for patients with staghorn calculi is PNL. When they are left untreated, staghorn calculi are associated with the loss of renal function and increased mortality.
- Patients harboring stones that are resistant to fragmentation (cystine, brushite, calcium oxalate monohydrate) should undergo SWL only when the stone burden is small.
- The percutaneous approach to patients with calculi in calyceal diverticula provides the best chance for a stone- and symptom-free outcome.
- The outcome of PNL is independent of the patient's body mass index, and therefore PNL is a good treatment option for the morbidly obese with a large stone burden. For the morbidly obese with a small stone burden, ureteroscopy is the optimal approach.

URETERAL CALCULI

The goal of the surgical treatment of patients suffering from ureteral calculi is to achieve complete stone clearance with minimal attendant morbidity. Improvements in surgical technology, such as SWL, rigid and flexible ureteroscopes, the holmium:YAG laser, and basket devices, have greatly augmented the urologist's ability to efficiently treat such patients, regardless of the size or location of the ureteral calculus. Although the treatment options available to the urologist are greater now than they have ever been, most patients with ureteral calculi do not require intervention. Ureteral calculi 4 mm or smaller will usually pass spontaneously, although in some cases with discomfort and expense to the patient. Ureteral calculi of any size may be associated with renal obstruction, and care must be taken to prevent irreversible damage to the kidney, whether the patient selects expectant or active treatment.

Perhaps the greatest dilemma facing the urologist today is "to blast or not to blast" (i.e., to choose between the two most frequently used modalities in ureteral stone treatment—SWL and ureteroscopy). PNL is a less commonly used treatment option and is usually reserved for a limited group of patients with large, proximal ureteral stones. Open ureterolithotomy is rarely indicated, although it may be an option as a salvage procedure. Laparoscopic ureterolithotomy has been described both as a salvage procedure in lieu of an open ureterolithotomy and as a first-line therapy (Turk et al, 1998; Keeley et al, 1999a; Gaur et al, 2002). The ultimate role of this procedure in the urologic armamentarium is yet to be determined, although it is effective for a select group of patients.

The factors that the urologist must consider when recommending treatment to patients with ureteral calculi may be grouped into three broad categories: stone-related factors (location, size, composition, duration, and degree of obstruction), clinical factors (the patient's tolerance of symptomatic events, the patient's expectation, associated infection, single kidney, abnormal ureteral anatomy, and clinical factors previously mentioned in the treatment of renal calculi), and technical factors (equipment available for treatment, costs) (Table 44–3). These factors may be thought of as treatment modifiers; the presence or absence of one or more of these factors may shift the balance toward a certain treatment modality.

Natural History

The indications for intervention in the management of patients with ureteral calculi have clearly been affected by the increased efficiency and lower morbidity of minimally invasive treatment modalities. Although the traditional indications for intervention (intolerable or intractable symptoms, infection, obstruction, and a stone that is unlikely to pass spontaneously) have not changed, the array of technologies currently available allows almost any symptomatic patient to be considered a candidate for stone removal. Lingeman and

Table 44–3. Factors Affecting Management of Ureteral Stones

Stone Factors	*Clinical Factors*	*Technical Factors*
Location	Symptom severity	Available equipment
Size	Patient's expectations	Cost
Composition	Associated infection	
Degree of obstruction	Solitary kidney	
	Abnormal ureteral anatomy	

associates (1986b) reported that when a patient requires hospitalization, it is less costly to remove the patient's stone with either SWL or ureteroscopy than to attempt to control the patient's symptoms with pharmacotherapy only. However, many patients will pass the stone spontaneously. A thorough knowledge, then, of the natural history of ureteral stones permits a well-informed judgment of when conservative measures (e.g., observation), rather than intervention, are indicated. Furthermore, such data help the patient consider the spectrum of options and decide whether to try to endure further symptoms or to elect immediate stone removal.

In the absence of external ureteral compression or internal narrowing, **the width of the stone is the most significant measurement affecting the likelihood of stone passage** (Ueno et al, 1977). However, the measurement of stone size from a plain radiograph can be misleading. Otnes and Sandnes (1978) reported that stone size was overestimated in 59% of cases, was underestimated in 15%, and correlated accurately with the actual size in only 26%. Ueno and colleagues (1977) reported that in a series of 520 patients with ureteral stones, **those with stones smaller than 4 mm, 4 to 6 mm, and larger than 6 mm experienced rates of spontaneous passage of 80%, 59%, and 21%, respectively.** Morse and Resnick (1991) showed that **the rate of spontaneous passage is highly dependent on stone location; passage rates from the proximal, middle, and distal ureter were 22%, 46%, and 71%, respectively.** Hubner and associates (1993) also reported that the likelihood of spontaneous stone passage was directly related to stone size and location at the time of presentation. The rate of spontaneous passage for stones smaller than 4 mm was 38% compared with 1.2% for those larger than 6 mm, irrespective of their position in the ureter at the time of presentation. Calculi discovered in the distal third of the ureter had a spontaneous passage rate of 45%, compared with 22% for the middle third and 12% for the proximal third. Two thirds of all stones that passed did so within 4 weeks after the onset of symptoms. Segura and associates (1997) reported in the AUA guidelines on the management of patients with ureteral calculi that for stones smaller than 5 mm, the spontaneous passage rate in the distal ureter and proximal ureter ranged from 71% to 98% and from 29% to 98%, respectively, whereas stones larger than 5 mm had a lower spontaneous passage rate, ranging from 10% to 53% and 25% to 53% for proximal and distal ureteral calculi, respectively. These rates have been affirmed by a more recent review of CT imaging of ureteral calculi (Coll et al, 2002). Therefore, **for patients with stones of 5 mm or less, conservative management should be considered,** whereas the chance of spontaneous passage for larger stones diminishes considerably, and intervention should be more readily contemplated.

Miller and Kane (1999) analyzed 75 patients with ureteral calculi and found that the interval to stone passage was highly variable and dependent on stone size, location, and side: for 95% of stones to pass, 31 days were required for stones 2 mm or less, and about 40 days were required for stones 2 to 6 mm. Furthermore, only 4.8% of patients with stones smaller than 2 mm required intervention compared with 50% of patients with stones 4 to 6 mm. Cummings and coworkers (2000) trained an artificial neural network to predict outcome in patients with ureteral stones with 76% accuracy. The duration of symptoms before initial presentation was the most influential factor, followed by degree of hydronephrosis. The importance of symptom duration was reported by several other authors, who concluded that if significant progress has not occurred after 1 month of observation, intervention is usually required (Ibrahim et al, 1991; Hubner et al, 1993; Singal and Denstedt, 1997).

Several groups have investigated the role of pharmacologic therapy to facilitate spontaneous stone passage. Borghi and associates (1994) reported a randomized, double-blind, placebo-controlled study that compared the effectiveness of nifedipine plus methylprednisolone with the effectiveness of the steroid alone in hastening stone passage. The authors found that the combination treatment of calcium channel blocker and steroid increased the rate of spontaneous stone passage over the steroid alone. Porpiglia and associates (2000) and Cooper and associates (2000) investigated the efficacy of a calcium channel blocker and steroid combination in the management of patients with distal ureteral stones, comparing this treatment regimen with a control arm that did not receive any medical therapy beyond analgesia. Both of these studies found that the medical treatment arms had a significantly reduced stone expulsion time and a significantly increased stone expulsion rate. Dellabella and colleagues (2003), in a study performed to investigate the efficacy of tamsulosin in facilitating ureteral stone passage, randomized 60 patients to receive either tamsulosin or floroglucine-trimetossibenzene, a spasmolytic. Both groups received deflazacort, a steroid. The authors found that tamsulosin therapy was associated with an increased stone expulsion rate and a decreased time to stone expulsion. Porpiglia and associates (2004), in a similar study, compared tamsulosin with nifedipine and found that tamsulosin treatment was associated with a reduced time to stone expulsion; as in the preceding studies, both groups of patients were also treated with steroids.

Factors Affecting Treatment Decisions

Stone Factors

Location. The location at which the passage of a ureteral stone is arrested is an important factor in assessing the likelihood of spontaneous passage as well as in determining the optimal treatment options and their relative successes. The statistical **probability of spontaneous ureteral stone passage is directly related to the distance of the ureter to be traversed and inversely related to stone size.**

Ureteral stones usually become impacted at three distinct sites where the caliber of the ureter narrows: the ureteropelvic junction, the iliac vessels, and the ureterovesical junction. Historically, the ureter was divided into thirds: the proximal ureter, from the ureteropelvic junction to the upper edge of the sacrum; the middle ureter, from the superior to the inferior margin of the sacroiliac joint; and the distal ureter, from the inferior margin of the sacrum to the ureterovesical junction. This three-part division was based on the different open surgical approaches to stones in the ureter. However, with the development of minimally invasive techniques, open surgery is rarely indicated, and the ureter is more often now divided into two segments, proximal and distal; the point of division is the narrow part of the ureter where it crosses the iliac vessels, reflecting a technical impediment for rigid

ureteroscopy (Segura et al, 1997). Anatomic location has an important effect on what treatment modality has a higher stone-free rate. In the 1980s, proximal ureteral stones were commonly treated with SWL, whereas distal ureteral stones were treated with ureteroscopy (Sosa et al, 1987). Since that time, the treatment paradigms for ureteral stones have evolved; they are defined further in the sections on proximal and distal ureteral stones.

Stone Burden. The stone burden, in terms of both size and number, may affect what form of therapy will be the most efficient and confer the highest stone-free rate. The majority of ureteral stones pass spontaneously, especially stones less than 5 mm in diameter, and thus can be treated with expectant management (Kinder et al, 1987; Segura et al, 1997). Stones larger than 8 mm, however, are unlikely to pass spontaneously in a timely fashion without causing significant symptoms and possible renal damage from obstruction (Ueno et al, 1977). Experience with various treatment modalities has demonstrated differences in efficacy when they are applied to large ureteral stones. In the meta-analysis performed by the AUA, SWL for the in situ treatment of large (>1 cm) ureteral stones achieved a stone-free rate of 76%, independent of initial stone location (Segura et al, 1997). However, if the same stones are manipulated into the renal pelvis before SWL treatment, the stone-free rate increases to 82% (Drach et al, 1986). Some investigators have reported that patients with stones larger than 50 mm^2 treated by SWL have a higher likelihood of requiring more than one SWL treatment session (Bierkens et al, 1998; Mattelaer et al, 1994).

For patients with proximal ureteral calculi, ureteroscopy will produce a stone-free rate of 90% to 97%, and this modality is less affected by stone size than is SWL (Erhard et al, 1996; Grasso et al, 1998). Therefore, ureteroscopy may be more efficient for patients with larger stones in the ureter. SWL efficiency also decreases with very small stones because they are more difficult to locate radiographically. Fortunately, such small stones usually pass spontaneously or are easily retrieved with the ureteroscope.

Composition. Stone composition, if it is known, is useful information to help discern which treatment strategy may be favored (e.g., SWL for fragile calcium oxalate dihydrate stones or ureteroscopy and intracorporeal lithotripsy for cystine or brushite stones that are relatively resistant to SWL). In general, most ureteral stones are resistant to medical therapy. However, in the moderately symptomatic or asymptomatic patient with an incomplete obstruction caused by a uric acid stone, urine pH manipulation may be attempted as part of a conservative treatment approach. Urine pH manipulation should also be considered for the patient who does not desire or cannot medically tolerate anesthesia for SWL or ureteroscopy and who is thought to harbor a uric acid stone.

Duration of Presence. The management of patients with ureteral stones may be affected by the duration of a stone's presence or the patient's symptoms. The length of time a stone has been in the ureter is significant because of the potential for irreversible loss of renal function. However, even with complete ureteral obstruction, irreversible loss of renal function does not occur before 2 weeks, although it can progress to total renal unit loss at up to 6 weeks (Vaughan and Gillenwater, 1971).

Andren-Sandberg (1983) reported that in 358 patients with ureteral stones, nuclear renography detected impaired renal function in 27% of patients who were asymptomatic. Furthermore, 7% of these patients had persistent renal impairment up to 17 months after stone passage. Holm-Nielsen and associates (1981) reported that of 134 patients with unilateral ureteral stones, one third of the patients with obstruction lasting more than 4 weeks suffered irreversible renal damage. Similarly, Kelleher and associates (1991) found that sequential renal scintigraphy performed on 76 patients with obstructive ureteral calculi demonstrated an 18% incidence of reduced renal function (defined as a decrease in relative function greater than 7%). Two of the 14 patients had persistent loss of renal function after treatment. These two patients had undergone previous unsuccessful attempts at stone removal, emphasizing the importance of achieving stone-free status at the time of the initial procedure. Irving and associates (2000) studied 54 patients with ureteral calculi and reported that 28% of patients had silent loss of renal function at presentation. Interestingly, small calculi were as likely to be associated with diminished renal function as were larger stones, and patients who underwent early intervention (before 7 days) for diminished renal function had a better outcome than did patients with delayed intervention. **Because the patient's symptoms and stone size do not predict loss of renal function, and because there is no clear time threshold for irreversible damage, intervention should be considered in any patient with ureteral obstruction unless the ability to closely monitor renal function is available.**

Clinical Factors

Pain. Pain (renal or ureteral colic) is the primary presenting symptom of most patients with ureteral obstruction and is the source of considerable morbidity. The pain of ureteral colic is mediated by prostaglandins released by the ureter in response to obstruction. Prostaglandins act to increase ureteral peristalsis to aid in stone passage and also to sensitize nociceptors to stimuli such as bradykinins that induce pain and visceral responses (nausea, vomiting) (Selmy et al, 1994). For these reasons, prostaglandin inhibitors such as indomethacin and ketorolac are particularly effective in relieving the pain and nausea of ureteral obstruction (Cordell, 1996). However, **prostaglandins must be used with caution or avoided altogether in patients with compromised renal function; infusion of ketorolac in an acute unilateral ureteral obstruction model decreased ipsilateral renal blood flow by 35%** (Perlmutter et al, 1993).

Management of ureteral obstruction on the basis of symptoms should be tailored to the amount of time the symptoms have persisted. Patients presenting with early symptoms of renal colic may be managed expectantly for stone passage as long as their symptoms are controllable with oral medical therapy. Patients with symptoms of longer duration may be more appropriately managed by relieving the ureteral obstruction through either the placement of a ureteral stent or definitive stone treatment. Patients with ureteral stones causing severe symptoms refractory to conservative and medical therapy require prompt treatment.

Infection. Infection associated with ureteral stones, or obstructed pyelonephritis, is a not uncommon and poten-

tially life-threatening urologic emergency. Such patients are typically febrile and may present with signs of septic shock, such as hypotension. Urgent drainage of the obstructed portion of the urinary tract by either ureteral catheter or percutaneous nephrostomy is essential. A urine culture specimen from the obstructed segment will aid in directing antibiotic therapy. Definitive stone therapy should be delayed until urine cultures are negative and the patient has recovered completely.

Patient's Expectations. The patient's expectations must be considered in recommending different treatment modalities. For ureteral stones with low probability of spontaneous passage, the patient must be informed of the available treatments, including the relative benefits and risks associated with each. Although ureteroscopy is more invasive than SWL, the patient may achieve immediate or nearly immediate stone-free status with a single procedure. Although SWL is less invasive, a patient may be reluctant to select this modality because it entails an often lengthy follow-up until fragment clearance as well as the risk of unplanned additional invasive procedures and re-treatments (Wolf et al, 1995; Peschel et al, 1999). Conversely, patients may select SWL as a consequence of apprehension of the anesthesia associated with ureteroscopy or the possibility of a temporary ureteral stent.

Solitary Kidney. Patients with ureteral stones in either surgically or functionally solitary kidneys require a modification of standard treatment algorithms. **A ureteral stone obstructing a solitary kidney demands prompt attention,** usually with internal drainage and definitive stone treatment (SWL or ureteroscopy).

Aberrant Anatomy. Ureteral stones in patients with abnormal anatomy (ureteral ectopia, ureteroceles, megaureters) may have impaired egress because of obstructive or functional factors (Kajikawa et al, 1985; Diamond et al, 1994; Dretler, 1995). These patients may not respond to therapies such as SWL with the same level of success as do those with normal ureteral anatomy. The anatomic abnormality may need to be corrected or circumvented to permit successful treatment of ureteral stones. For example, patients with recurrent stones that become lodged and obstruct the ureter in a ureterocele should have the ureterocele treated (by either endoscopic incision or open excision with reimplantation) simultaneously with ureteral stone removal.

Technical Factors

The treatment of patients with ureteral calculi depends on multiple surgical technologies, and the availability of certain equipment will affect the possible options for treatment. Few operating environments will have all possible lithotripters, ureteroscopes, lithotrites, or stone retrieval devices immediately available. In addition, the surgeon's preference and technical expertise will also affect the technique chosen. The majority of urologists and patients with stone disease in the United States do not have direct access to a fixed lithotripter on an unlimited basis. Therefore, treatment decisions may need to be modified according to lithotripter availability. Patients with symptomatic ureteral stones and no immediate lithotripter access have several options: they may be clinically observed with pain and emetic control; they can undergo placement of an internal ureteral stent to relieve the symptoms of renal colic (but then may suffer stent-related morbidities); or they may have primary ureteroscopic removal of the stone, provided the requisite endoscopic equipment is available.

Because of recent pressures to decrease resource use, there is increasing emphasis in the modern medical environment on the reduction of cost. Economic pressures have promoted the movement toward less invasive, more cost-effective therapy for patients with ureteral stones. Grasso and colleagues (1995b) analyzed the cost of ureteroscopy and SWL for 112 patients with ureteral calculi. When they compared outpatient ureteroscopic lithotripsy with SWL monotherapy, treatment costs were similar. However, the addition of re-treatments and auxiliary procedures after SWL more than doubled the costs and weighed heavily against this modality's cost-effectiveness. Wolf and associates (1995) used a literature-based probability decision tree to determine the more effective and cost-efficient therapy for patients with distal ureteral calculi and found that although initial SWL was only slightly more expensive than ureteroscopy, the cost differential increased when additional complications and re-treatments were calculated. Kapoor and associates (1992) compared the treatment costs of 20 patients treated by SWL and 32 patients treated by ureteroscopy, with success rates of 75% and 97%, respectively, recorded. They reported that ureteroscopy was 60% less costly than SWL.

In contradistinction to these studies, Bierkens and associates (1998) reported that ureteroscopy was more expensive than SWL for the treatment of patients with middle and distal ureteral stones. However, the average hospital stay for patients who underwent ureteroscopy was more than 3 days, whereas SWL was performed as an outpatient procedure. When ureteroscopy was performed on an outpatient basis, the cost of SWL was greater than that of ureteroscopy. Lotan and associates (2002) performed a decision tree model to identify the most cost-effective treatment option for patients with ureteral calculi. On the basis of a comprehensive literature review to determine the average success rate of observation, SWL, and ureteroscopy, they found that **ureteroscopy is the most cost-effective treatment strategy for ureteral stones at all locations, after observation fails.**

Proximal Ureteral Stones

The surgical treatment options for patients with proximal ureteral stones include SWL with or without stone manipulation, ureteroscopy, PNL, and, rarely, open or laparoscopic stone surgery. The AUA Ureteral Stones Clinical Guidelines Panel performed a meta-analysis of all articles on ureteral calculi published during a 30-year period from 1966 to 1996 (Segura et al, 1997). The results were analyzed for SWL in situ, SWL after "pushback," SWL after stent insertion, PNL, ureteroscopy, and open surgical stone removal. The stone-free rates of SWL and ureteroscopy were 84% and 56%, respectively, for stones smaller than 1 cm and 72% and 44%, respectively, for stones larger than 1 cm. The risks of significant complications after SWL and ureteroscopy were 4% and 11%, respectively. Although open stone surgery had a median stone-free rate of 97%, it was associated with longer hospitalization and greater postoperative morbidity and therefore was not recommended as a first-line intervention. As a guideline, because of its greater efficacy and lower morbidity, the panel suggested that SWL, either in situ or after pushback, should be the

primary approach for stones smaller than 1 cm in the proximal ureter. For stones larger than 1 cm in diameter, SWL, PNL, and ureteroscopy are all acceptable choices. Initial experience with SWL suggested that placement of a ureteral stent before treatment facilitated stone fragmentation and passage (Liong et al, 1989). However, the AUA meta-analysis demonstrated no improvement in stone fragmentation for these patients, so this practice was discouraged. Placement of a ureteral stent may be appropriate for other indications, such as in the management of pain, for the relief of obstruction, and in the treatment of difficult-to-visualize stones. Stent placement is mandatory in patients who have a solitary obstructed kidney.

Since the publication of the AUA guidelines, significant improvements have been made in ureteroscopic technology. In 2001, the European Association of Urology published "Guidelines on Urolithiasis," in which they performed an analysis of the relevant literature for the 3 years after the AUA publication (Tiselius et al, 2001). They detected a significant improvement in stone-free rates; **semirigid and flexible ureteroscopes provided a 90% to 100% stone-free rate for distal ureteral calculi and a 74% stone-free rate for proximal ureteral calculi.** These results are considerably better than those reported by the AUA panel. In addition, 95% of patients could be successfully treated with only one endoscopic procedure, and the best results were reported with holmium:YAG laser lithotripsy in the proximal ureter.

Currently available flexible ureteroscopes are easily accommodated by even unstented ureteral orifices and allow immediate access to ureteral calculi. As well, the introduction of increasingly efficient lithotrites, such as the holmium:YAG laser, facilitates the endoscopic treatment of ureteral calculi of any size, composition, and location. Several investigators have demonstrated excellent outcomes for patients with proximal as well as distal ureteral calculi. Mean stone-free rates of 95%, with a less than 1% incidence of complications such as stricture or perforation, have been reported for patients with proximal as well as distal calculi treated ureteroscopically. Park and associates (1998) analyzed the outcomes of patients with proximal or distal ureteral calculi treated by either SWL or ureteroscopy and found that the efficacy of SWL worsened significantly for stones larger than 1 cm (83.6% versus 42.1%), whereas the stone-free rate for ureteroscopic treatment was unaffected by size (88.9% versus 86.6%).

An impacted stone may be defined as a stone that cannot be bypassed by a wire or catheter or a stone that remains at the same site in the ureter for more than 2 months (Morgentaler et al, 1990; Roberts et al, 1998). **Impacted stones are often more resistant to fragmentation by SWL** (Green and Lytton, 1985; Farsi et al, 1994). Both Mueller and associates (1986) and Park and colleagues (1998) have performed in vitro studies demonstrating that the confinement of a model stone is associated with substantial reduction in fragmentation, which may be due to the lack of a liquid interface surrounding the stone, thus reducing cavitation activity. Mugiya and colleagues (2000) reported a series of 104 patients with impacted ureteral stones, including 83 in the proximal ureter, of which 100 (96.2%) were completely fragmented by a single endoscopic procedure. At 1 month, the stone-free rate was 100%, and there were no significant complications.

Although these reports suggest that ureteroscopy may be the optimal approach to the impacted ureteral stone, some urologists still favor SWL as the initial approach for stones smaller than 1 cm in the proximal ureter. However, flexible ureteroscopy may be the treatment of choice for patients whose SWL treatment failed, for patients with cystinuria, for patients with distal obstruction, for patients with impacted stones, for obese patients, for patients with bleeding diathesis, and when SWL is not readily available (Tawfiek and Bagley, 1999). If a ureteral stent is required for SWL, a pushback technique of manipulating the stone into the intrarenal collecting system may provide a greater likelihood of complete stone fragmentation (Mueller et al, 1986; Riehle and Naslund, 1987; Liong et al, 1989; Bolton et al, 1991). Gross and coworkers (1998) compared 105 patients who underwent pre-SWL ureteral stone manipulation with 93 patients undergoing SWL of ureteral stones in situ and found that the practice of stone manipulation was successful in 91.4% of patients; the mean number of SWL treatments was 1.4 in the pushback group and 2.1 in the in situ group. Other prospective studies have failed to demonstrate an improved stone-free rate with pushback technique versus in situ SWL, although stones treated in situ did require significantly more shockwaves, administered at higher voltages, than did those treated with pre-SWL manipulation (Rassweiler et al, 1986; Hendrikx et al, 1990; Danuser et al, 1993). When stone manipulation is planned under regional or general anesthesia or when a ureteral stent is to be placed before SWL, consideration should be given to immediate flexible ureteroscopy as it is more definitive and associated with a higher success rate (Grasso, 1999). For patients with proximal ureteral stones larger than 1 cm, a better outcome may be achieved with flexible ureteroscopic lithotripsy as the primary approach.

Alternatively, PNL is a reasonable option for select patients with proximal ureteral calculi. A dilated proximal ureter facilitates access to these stones with large-caliber instruments that can fragment and remove stone burden efficiently (Srivastava et al, 1992). Stone-free rates of 86% have been reported (Segura et al, 1997). Although PNL permits rapid stone removal, it does require general anesthesia and can be associated with longer convalescence and higher complication rates. Therefore, **PNL is usually reserved for the patient with complex, proximal ureteral stones.** Particularly good candidates for this approach include those with impacted calculi that are refractory to other modes of stone removal, those with dilated renal collecting systems, those with large stone burdens, and those with distal ureteral strictures (Preminger, 1992).

Distal Ureteral Stones

The optimal therapy for patients requiring removal of distal ureteral calculi is controversial. SWL and ureteroscopy are both effective treatments associated with high success rates and limited morbidity. A 1997 meta-analysis performed by the AUA Ureteral Stones Clinical Guidelines Panel established that both ureteroscopy and SWL are acceptable treatment options for patients with distal ureteral stones. This recommendation was based on the stone-free results, morbidity, and re-treatment rates for each respective therapy. However, this report used data that were derived from older lithotripsy and endoscopic technology; in addition, costs and patients' satisfaction or preferences were not addressed. Although blind basket

extraction (without fluoroscopy and a safety wire) had an overall success rate of 73%, the panel's expert opinion was that "guided stone manipulation (concomitant use of fluoroscopy and safety guide wire) or ureteroscopic basketing would be safer and more efficacious treatment options." Therefore, the panel recommended that blind basketing of ureteral stones not be encouraged as a treatment option. In addition, the panel also recommended (as a standard) that open stone surgery not be used as a primary approach for distal ureteral stones.

Both recommended treatment options, SWL and ureteroscopy, have valid advantages and disadvantages. The primary goal in treating patients with ureteral calculi is a stone-free state, and the AUA guidelines panel's meta-analytic study reported that 85% of 9422 patients subjected to SWL were rendered stone free compared with 89% of 3978 patients undergoing ureteroscopy. There have been two randomized prospective studies comparing ureteroscopy and SWL for treatment of patients with distal ureteral stones subsequent to the guidelines document. Peschel and associates (1999) randomized 80 patients and found that those undergoing ureteroscopy achieved stone-free status more rapidly, regardless of initial stone size, than did those treated by SWL. All of the patients undergoing ureteroscopy were rendered stone free, whereas 10% of the SWL cohort required subsequent ureteroscopy to achieve a stone-free status. Pearle and associates (2001) randomized 64 patients and reported that 100% of individuals who completed radiographic follow-up subsequent to either SWL or ureteroscopy became stone free. One possible reason for the difference in this outcome compared with the prior study is that an unmodified Dornier HM3 lithotripter, which is known to fragment stones more efficiently, was used in Pearle's study rather than the Dornier MFL5000 used in Peschel's study.

There is no validated instrument available to assess the satisfaction of patients for either of these procedures, although this is an important concern. Peschel and associates (1999) measured patients' satisfaction after ureteroscopy or SWL. They found that for patients with stones smaller than 5 mm, all patients undergoing ureteroscopy reported complete satisfaction, compared with 75% of those undergoing SWL. For those with stones larger than 5 mm, all patients undergoing ureteroscopy were satisfied, compared with 95% of those undergoing SWL. Pearle and associates (2001) also measured patients' satisfaction and found no significant difference between SWL (96%) and ureteroscopy (89%). Neither of these studies used a validated questionnaire, and the divergent conclusions of these two analyses emphasize the need for the development of such a device.

Supporters of SWL claim that it is effective and noninvasive, is associated with less morbidity, requires less anesthesia than ureteroscopy, and seldom requires ureteral stents. Critics argue that the success rates are not as high as those of ureteroscopy, equipment availability may be limited, visualization of the stone is often difficult, attainment of a stone-free state requires a longer time and follow-up, retreatment rates are higher, and costs are higher. Supporters of ureteroscopy claim that it is highly successful and minimally invasive, is associated with minimal morbidity, can be used with larger and multiple stones, and has high immediate stone-free rates. Critics argue that it requires specialized training, requires more anesthesia, and more often requires ureteral stent placement. Continued studies are warranted to better define the roles of each in the management of patients with distal ureteral calculi because both are highly effective.

Laparoscopic Ureterolithotomy

Laparoscopy should be considered whenever one contemplates the open surgical removal of a ureteral calculus. Although the indications for this surgery are not common, there are certain patients for whom this may be an acceptable approach, such as those with concomitant upper tract abnormalities (e.g., ureteral stricture, ureteropelvic junction obstruction) requiring surgical repair.

Both transperitoneal and retroperitoneal approaches have been described for laparoscopic ureterolithotomy (Wuernschimmel and Lipsky, 1993; Gaur et al, 1994). Keeley and associates (1999a) reported on a series of 14 patients undergoing transperitoneal laparoscopic ureterolithotomy, which represented 1.1% of the 1240 patients with stone disease treated in a 5-year period. The authors considered stones that could not be accessed ureteroscopically or did not fragment with other treatment modalities as well as large (>1.5 cm) proximal ureteral stones as indications for the procedure. Three patients with associated ureteral strictures underwent laparoscopic incision of the stricture at the time of ureterotomy; two of these patients subsequently required further dilation but ultimately had a successful result. Turk and colleagues (1998) described 26 patients who underwent laparoscopic ureterolithotomy for stones ranging from 20 to 45 mm. A transperitoneal approach was performed in 21 patients, and a retroperitoneal approach was performed in 5 patients. In two cases, the calculus could not be located, necessitating conversion to open surgery. No intraoperative complications were encountered, and patients were discharged between 2 and 5 days after surgery. Gaur and associates (2002) reported long-term follow-up of a series of 101 patients undergoing laparoscopic ureterolithotomy, performed through a retroperitoneal approach in all but one patient. The procedure was successful in 93 patients. The duration of urine leakage was 5.5 days in those patients whose ureter was neither stented nor sutured

KEY POINTS: URETERAL CALCULI

- Conservative management for a patient with a ureteral stone smaller than 5 mm is appropriate as there is a high likelihood of stone passage. Ureteral stones larger than 5 mm are unlikely to pass spontaneously.
- Obstructed pyelonephritis due to a ureteral calculus is a not uncommon and potentially life-threatening emergency that is best treated by urgent decompression of the urinary tract.
- Both SWL and ureteroscopy are highly effective for patients with ureteral calculi.
- Medical expulsive therapies with agents such as tamsulosin may promote spontaneous stone passage.

after ureterolithotomy and 3.2 days for those patients whose ureter was both stented and sutured. Although the authors suggest that laparoscopic ureterolithotomy may be used as a primary procedure, it is more likely that this operation will be reserved for those patients who require a salvage procedure after failed ureteroscopy or SWL or who have another indication for a laparoscopic procedure.

URINARY CALCULI DURING PREGNANCY

Urolithiasis is an infrequent complication of pregnancy. However, pain from renal colic is the most common nonobstetric reason for hospital admission during pregnancy (Rodriguez and Klein, 1988). Furthermore, the occurrence of urinary calculi during pregnancy presents danger not only to the mother but also to the fetus as renal colic, infection, and obstruction are all associated with premature labor (Maikranz et al, 1987; Hendricks et al, 1991). The reported incidence of symptomatic urinary calculi during pregnancy ranges from 1 in 200 to 1 in 2500 pregnancies; the wide variation in reported incidence may be due to the small numbers of patients in these studies (Gorton and Whitfield, 1997). However, **the incidence of symptomatic urinary calculi has been calculated to be the same for pregnant women as for nonpregnant women of childbearing age** (Coe et al, 1978; Hendricks et al, 1991). Multiparous women have been reported to be affected more often than primiparous women, in some cases by a ratio of about 3:1 (Horowitz and Schmidt, 1985; Rodriguez and Klein, 1988). However, when it is adjusted for age, the incidence for multiparous women is no greater than that for primiparous women (Swanson et al, 1995). Calculi present with equal frequency on the left and right sides, although ureteral calculi occur almost twice as frequently as renal calculi (Stothers and Lee, 1992; Parulkar et al, 1998). The majority of patients with symptomatic calculi present during the second or third trimesters but rarely during the first trimester (Denstedt and Razvi, 1992; Stothers and Lee, 1992; Swanson et al, 1995).

Pregnancy induces significant physiologic alterations, some of which affect the urinary system. The most remarkable anatomic change is the dilation of the renal calyces, pelvis, and ureters, which is usually evident by the first 6 to 10 weeks of gestation. Pregnancy-induced hydronephrosis is the most common cause of dilation of the urinary tract in pregnancy and may cause flank discomfort or even mimic renal colic. **Upper tract dilation is seen in up to 90% of pregnant women by the third trimester** and may persist for as long as 12 weeks post partum (Boridy et al, 1996). The **right ureter tends to be more dilated than the left,** and the dilation rarely is observed distal to the pelvic brim (Schulman and Herlinger, 1975). Rarely, spontaneous rupture of the kidney may occur, and if it does, it more commonly happens on the right side (MacNeily et al, 1991; Loughlin, 1994). Both **humoral as well as mechanical factors have been implicated in the etiology of hydronephrosis in pregnant women.** Circulating progesterone, a humoral factor that is increased in pregnancy, causes relaxation of ureteral smooth muscle, reducing ureteral peristalsis. Paller and Ferris (1996) have reported that dilation of the urinary collecting system can be reproduced in an animal model by the administration of estrogen and progesterone. However, recent evidence suggests that mechanical factors, in particular the gravid uterus directly compressing the ureters, are likely to be primary in the pathogenesis of this condition; women with an altered upper urinary tract in whom the ureter does not cross the pelvic brim, such as those with ileal conduit or renal ectopia, do not experience hydronephrosis during pregnancy (Rasmussen and Nielsen, 1988; Dafnis and Sabatini, 1992; Swanson et al, 1995). Although the exact etiology of hydronephrosis of pregnancy is not yet well defined, most would agree that both mechanical and humoral factors play a role in the pathogenesis of this condition.

Other important physiologic changes in pregnancy include an increase in renal plasma flow, which induces a 30% to 50% increase in glomerular filtration rate. As a result of this physiologic alteration, **the normal ranges of serum creatinine and blood urea nitrogen are approximately 25% lower for the pregnant patient.** Importantly then, a serum creatinine value that is in the normal range for the nonpregnant population may actually represent a decrease in renal function for the pregnant patient (Paller and Ferris, 1996). **The increase in renal plasma flow and glomerular filtration rate also increases the filtered loads of sodium, calcium, and uric acid, causing a state of hypercalciuria and hyperuricosuria** (Boyle et al, 1966; Howarth et al, 1977; Gertner et al, 1986). Hypercalciuria is further exacerbated by the suppression of parathyroid hormone and the increase in circulating 1,25-dihydroxycholecalciferol produced by the placenta, which increases intestinal absorption of calcium. However, **these potentially lithogenic physiologic changes are offset by an increase in the excretion of urinary inhibitors, such as citrate and magnesium, as well as an increase in urine output** (Biyani and Joyce, 2002). It has been postulated that metabolic alterations in the urine may contribute to the accelerated encrustation of ureteral stents during pregnancy (Denstedt and Razvi, 1992; Loughlin, 1994).

Although renal colic is the most common nonobstetric cause of abdominal pain in hospitalized pregnant women, the diagnosis of urolithiasis in the pregnant patient can be challenging; many of the usual presenting signs and symptoms may be masked by the patient's gravid status. As gestation progresses, the perception and localization of pain may be altered. Stothers and Lee (1992) reported that 28% of pregnant patients ultimately diagnosed with an obstructing stone were initially, and incorrectly, diagnosed with appendicitis, diverticulitis, or placental abruption. For most patients, though, **the most common presenting symptom is flank pain, usually accompanied by either macroscopic or microscopic hematuria** and, in some cases, urinary tract infection (Stothers and Lee, 1992). Hematuria can occasionally occur in the normal course of pregnancy; however, hematuria without discomfort is unusual in a patient with stone disease (Swanson et al, 1995). It is particularly important to obtain a urine specimen for culture from these patients because pyuria may commonly be seen in the urinalysis of a pregnant patient, which diminishes the sensitivity of this test in detecting urinary tract infection (Hendricks et al, 1991; Houshiar and Ercole, 1996; Parulkar et al, 1998). A diagnosis of urinary calculi should be considered in evaluation of a pregnant patient who suffers from persistent urinary tract infection or infection with a urea-splitting organism. Other symptoms that may indicate urolithiasis include irritative voiding symptoms, chills,

nausea, and vomiting. However, these symptoms may also occur with other intra-abdominal conditions, so the urologist must maintain a high index of suspicion when examining these patients.

An important factor in the radiographic evaluation of pregnant patients suffering from stone disease is the risk of ionizing radiation exposure to the fetus. The principal effects of irradiation on the fetus include teratogenesis, carcinogenesis, and mutagenesis. However, the risk associated with radiation depends critically on the gestational age and the amount of radiation delivered (Biyani and Joyce, 2002). **During the first trimester, the period of early organogenesis and rapid cell division, the embryo is sensitive to the effects of radiation** (Swartz and Reichling, 1978). Although the fetus has diminished sensitivity to the teratogenic effects of radiation in the second and third trimesters, such exposure may increase the risk for development of childhood malignant neoplasia (Harvey et al, 1985).

As the radiation dose below which no deleterious effects on the fetus may occur has not been defined with certainty, it may be presumed that exposure to any level of radiation will carry some degree of risk. For this reason, **ultrasonography has become the standard initial study in evaluation of the pregnant patient thought to be experiencing renal colic.** Unfortunately, it can be difficult to adequately visualize the ureter with ultrasound examination as well as to distinguish dilation of the ureter that may be associated with a normal pregnancy from ureteral obstruction due to calculus. Stothers and Lee (1992) reported that renal ultrasonography for the detection of calculi had a sensitivity of 34% and a specificity of 86%. Butler and associates (2000) similarly reported that ultrasonography diagnosed 60% of 35 women who were later proven to have nephrolithiasis. Several techniques have been recommended to improve the diagnostic capability of this technology. Color Doppler imaging allows the sonographer to differentiate the iliac artery and vein from the dilated ureter. MacNeily and associates (1991) reported that the use of this technique can distinguish a dilated infrailiac ureter, which was strongly correlated with ureteral obstruction. Color Doppler imaging can also demonstrate jets of urine expelled from the ureter into the bladder. Deyoe and associates (1995) reported that if there are no ureteral jets on the suspected side of obstruction, ureteral obstruction can be diagnosed with a sensitivity of 100% and a specificity of 91%. However, Burke and Washowich (1998) reported that there is variation in ureteral jet symmetry in later pregnancy and recommended the use of this technique with caution. Renal vascular resistance increases in the presence of acute obstruction, and duplex ultrasonography allows the quantification of this alteration by calculating the kidney's resistive index (Ulrich et al, 1995). Shokeir and Abdulmaaboud (1999) prospectively evaluated 117 nonpregnant patients with ultrasonography; they reported that resistive index measurements had 77% sensitivity and 83% specificity in diagnosis of ureteral calculi and that change in resistive index had 88% sensitivity and 98% specificity. Horrigan and associates (1996) reported that **renal resistive index remains unchanged from the nonpregnant state throughout the course of pregnancy and also is unaffected by the physiologic hydronephrosis of pregnancy, which suggests that this imaging modality may be useful in detecting acute obstruction in this population.** Shokeir and associates (2000) evaluated pregnant women in a manner similar to their initial study and found that resistive index had a sensitivity of 45% and a specificity of 91% in detecting an obstructing ureteral calculus; change in resistive index had a sensitivity of 95% and a specificity of 100%. If an obstructing calculus cannot be visualized by conventional renal sonography, **transvaginal ultrasonography can provide imaging of the distal ureter.** In a series of 13 women, 6 of whom were pregnant, Laing and associates (1994) identified distal ureteral stones in all 13 patients with transvaginal ultrasonography and in only 2 by transabdominal ultrasonography.

If the clinician determines that ultrasound evaluation is inadequate, other imaging studies may be considered. **If intravenous pyelography is required, a limited study is recommended.** Stothers and Lee (1992) were able to visualize calculi in 16 of 17 pregnant patients with a three-film study, obtaining a scout, a 30-second, and a 20-minute film. Nuclear renography is a technique that can provide a functional assessment of pregnant patients with suspected ureteral obstruction while exposing them to a limited amount of radiation. However, the radioisotope is excreted in the urine, and the bladder reservoir can provide a significant source of radiation exposure to the fetus, necessitating high fluid intake and frequent voiding for these patients (Biyani and Joyce, 2002). This radiographic technique unfortunately does not provide good anatomic detail or visualization of calculi. Magnetic resonance imaging (MRI) does not rely on ionizing radiation or contrast medium, making it a potentially attractive tool to evaluate pregnant patients. Because MRI does not visualize calcium, stones are seen as filling defects overlying the high signal intensity of urine. The visualization of smaller stones with this technique is difficult (Hattery and King, 1995; Roy et al, 1995). Spencer and associates (2004) reported on the use of MRI to evaluate pregnant women with hydronephrosis and flank pain. The authors reported that this technique enabled the accurate distinguishing of physiologic hydronephrosis of pregnancy from hydronephrosis due to an obstructing ureteral calculus. **CT imaging should be avoided during pregnancy because the radiation dose is particularly high.**

Approximately **50% to 80% of pregnant patients with symptomatic calculi will pass their stones spontaneously when treated conservatively with hydration and analgesia** (Denstedt and Razvi, 1992; Stothers and Lee, 1992; Gorton and Whitfield, 1997; Parulkar et al, 1998). Intervention is required in approximately one third of patients, usually for pain uncontrolled by analgesia or signs of persistent obstruction and infection. Once intervention is elected, some advocate temporary measures, such as ureteral stent placement or percutaneous nephrostomy, with definitive management deferred until after delivery. One rationale for this paradigm is that ureteral stents can be placed with local anesthesia under sonographic or minimal radiographic monitoring (Jarrard et al, 1993; Loughlin, 1994; Swanson et al, 1995). However, accelerated encrustation and stent occlusion that may be encountered during pregnancy can necessitate frequent stent replacement, and the optimal indwelling time for a ureteral stent in a pregnant patient is not known and is likely to be highly variable; Kavoussi and associates (1992) have recommended that stents be changed at least every 6 to 8 weeks. Because patients subjected to ureteral stent placement in early pregnancy will probably require multiple stent exchanges,

Denstedt and Razvi (1992) have suggested limiting ureteral stent placements to the later stages of pregnancy (after 22 weeks) and placing a nephrostomy tube in early pregnancy. However, obstruction of the nephrostomy tube may occur as well, requiring frequent tube irrigation and changes (Kavoussi et al, 1992).

Improvements in ureteroscopic technology and intracorporeal lithotripters have made it possible to access and to treat any stone in the upper urinary tract successfully, even in the pregnant patient. Since Rittenberg and Bagley (1988) first described the safe and successful use of flexible ureteroscopy in pregnant patients, several groups have published their experiences with larger series of patients. Scarpa and associates (1996) reported a series of 15 pregnant patients who underwent rigid ureteroscopy for renal colic. In all cases, ureteroscopy was performed successfully, and there were no pregnancy-related complications. Lifshitz and Lingeman (2002) reported a series of pregnant patients with renal colic who underwent ureteroscopy, including one who underwent a bilateral procedure. No complications related to the surgery or the pregnancy occurred. Similarly, Watterson and associates (2002a) conducted a retrospective analysis of eight patients who underwent ureteroscopy with holmium:YAG laser lithotripsy. No obstetric or urologic complications occurred, and the overall success rate of the procedures was 91%. With the currently available rigid and flexible ureteroscopes, these procedures can be performed with minimal anesthesia. Although ureteral dilatation is usually unnecessary, in the event it is required, tactile sensation from sequential ureteral dilators, rather than radiographic imaging, can be used to guide the process. Although the use of a rigid ureteroscope in the latter stages of gestation is possible, the flexible ureteroscope is easier to manipulate in a tortuous ureter and reduces the risk of perforation. Most calculi can be extracted intact with a basket or grasper device. If lithotripsy is required, both the holmium:YAG laser and the pneumatic lithotrite devices are safe. Ultrasonic lithotripters should be avoided as the high-pitched audible sound may induce hearing injury in the fetus, although investigation in this area is ongoing and definitive data are not available (Ulvik et al, 1995; Karlsen et al, 2001). In all cases of ureteroscopic exploration of the pregnant patient, **it is important to minimize radiation exposure to the patient by use of a below-the-patient x-ray source and placement of a lead apron under the patient's pelvis and lower abdomen.**

Other treatment modalities that are effective in the nonpregnant patient are not appropriate for this population. Although there have been reports of the inadvertent treatment of pregnant patients with SWL, with no adverse sequelae to the fetus, pregnancy remains a contraindication to this treatment modality (Chaussy and Fuchs, 1989; Frankenschmidt and Sommerkamp, 1998). PNL should be deferred until after birth because this procedure often requires prolonged anesthesia and radiation exposure.

KEY POINTS: URINARY CALCULI DURING PREGNANCY

- Ultrasonography is the standard initial imaging study in evaluation of a pregnant patient.
- Improvements in ureteroscopy technology now permit ureteroscopic access to and treatment of stones at any location in the collecting system of the pregnant patient.
- It is important to minimize ionizing radiation exposure to the pregnant patient during ureteroscopy by use of a below-table x-ray source and to shield the fetus with a lead apron placed below the patient.

STONE REMOVAL: SURGICAL TECHNIQUES AND TECHNOLOGY

Intracorporeal Lithotripters

Ureteroscopy and PNL occupy an essential place in the treatment of urinary calculi as increasing technologic advancements allow easier access to stones in all parts of the kidney and ureter. In particular, improvements in ureteroscopic equipment emphasize the need for appropriate and effective miniaturized intracorporeal lithotripsy devices. Smaller ureteral stones can be extracted intact with endoscopic baskets or grasping devices after ureteral dilation, if necessary. However, larger ureteral stones require lithotripsy to permit the safe extraction of calculus fragments. The fragmentation of renal stones during PNL requires an approach different from that applied to ureteral intracorporeal lithotripsy. Although small and flexible endoscopic lithotrites are essential for the occasional difficult-to-approach kidney stone, renal stones can be visualized with a rigid nephroscope in most cases. In these situations, with a large kidney stone burden, the efficiency of the lithotrite is the most important requirement, and size and flexibility are of secondary importance. The urologist who treats patients suffering from urolithiasis, then, requires an armamentarium of intracorporeal lithotripsy devices, each maximizing a different quality (e.g., size, flexibility, efficiency).

Four techniques are available for intracorporeal lithotripsy: electrohydraulic lithotripsy (EHL), laser lithotripsy, ultrasonic lithotripsy, and ballistic lithotripsy. These techniques can be divided into those lithotrites that are flexible (laser lithotripsy and EHL) and those that are rigid (ultrasonic and ballistic lithotripsy). Herein, the mechanisms, advantages, disadvantages, and surgical techniques of the various flexible and rigid intracorporeal lithotripters are reviewed.

Flexible Lithotripters

Electrohydraulic Lithotripsy. EHL was invented in 1955 by Yutkin, an engineer at the University of Kiev, and was the first technique developed for intracorporeal lithotripsy (Grocela and Dretler, 1997). The first reported use of EHL outside the Eastern bloc was in 1960, when a modified version of Yutkin's invention, the Urat-1, was used to fragment bladder calculi (Rouvalis, 1970). EHL was first applied to renal calculi during an open surgical lithotomy in 1975 (Raney and Handler, 1975). In 1985, Lytton reported the first experience treating patients with ureteral stones with a rigid ureteroscope and a 5 French EHL probe; no immediate or long-term complications were encountered (Green and Lytton, 1985). The use of

smaller EHL probes through a flexible ureteroscope was first reported in 1988 (Begun et al, 1988).

The EHL probe is essentially an underwater spark plug composed of two concentric electrodes of different voltage polarities, separated by insulation. When a current sufficient to overcome the insulative gap is applied, a spark is produced. The spark discharge causes the explosive formation of a plasma channel and vaporization of the water surrounding the electrode. The rapidly expanding plasma causes a hydraulic shockwave followed by formation of a cavitation bubble (Fig. 44–5). Depending on the proximity of the probe to the stone surface, the collapse of the cavitation bubble may be symmetrical (at a distance of about 1 mm from the stone), resulting in a strong secondary shockwave, or asymmetrical (at a distance equivalent to a maximum bubble radius of about 3 mm), leading to the formation of high-speed microjets (Vorreuther et al, 1995; Zhong et al, 1997). **Unlike in SWL, the shockwave is not focused, so the stone must be placed where the shockwave is generated.** The first EHL probes developed were of larger diameters (9 French), which, because of their size, had a narrow margin of safety. Later improvements in technology allowed the development of smaller probes, from 1.6 to 5 French, that were safer and had the ability to be passed through small-diameter, flexible ureteroscopes without occluding the irrigation or working channel. There is little difference in fragmentation ability among the different-sized probes, but the larger probes tended to be more durable (Segura, 1999). Subsequent improvements in the EHL generator allowed the surgeon more control over energy discharge, pulse, and duration. Although it was originally hypothesized to function optimally in a $^1/_6$ to $^1/_7$ normal saline solution, Denstedt and Clayman (1990) demonstrated that EHL works equally well in a normal saline solution, eliminating the hazard of irrigating the upper urinary tract with a hypotonic solution.

Advantages and Disadvantages. **The major disadvantage of EHL is its propensity to damage the ureteral mucosa and its association with ureteral perforation.** Raney (1978) reported that with a 9 French probe, 90% of ureteral stones could be successfully fragmented, but there was a 40% incidence of ureteral extravasation. Ureteral perforation remained an issue of concern with EHL in the ureter despite advancements in technology and technique. Hofbauer and coworkers (1995), in a prospective study of 72 patients, reported a perforation rate of 17.6% with EHL versus 2.6% with pneumatic lithotripsy. However, others have reported a lower rate of perforation, with a mean incidence of 8.5% recorded. Vorreuther and associates (1995) suggested that the mechanism of damage is the expansion of the cavitation bubble, and thus injury may occur even when the probe is not in direct contact with the mucosa. The diameter of the cavitation bubble depends on the energy used and can expand to more than 1.5 cm when energies greater than 1300 mJ are employed. Therefore, **the risk of perforation is greater with higher energies, such as in treatment of a hard stone.** Even with smaller probes and lower energy settings, perforation may occur if repeated pulses are applied close to the mucosa. Santa-Cruz and colleagues (1998), in a comparative in vitro study, reported that the holmium laser and EHL were associated with a higher risk of perforation compared with the coumarin pulsed-dye laser and pneumatic lithotripter. When the authors placed a 3 French probe 0.5 mm from the ureteral wall, perforation was induced with an average of 24 pulses. The **risk of perforation may be higher for impacted stones** associated with significant mucosal edema or if vision is impaired by the minor hemorrhage that commonly occurs during EHL (Hofbauer et al, 1995).

As with most lithotrites, **retrograde propulsion of calculi and fragments can occur during EHL and is more pronounced than with holmium:YAG lithotripsy** (Teichman et al, 1997). In a series of 43 patients treated for proximal ureteral calculi, 14% required subsequent SWL for stones that migrated into the kidney (Yang and Hong, 1996). Placement of a basket or other retention device above the stone may prevent stone retropulsion. However, care should be taken not to activate the EHL device directly on the basket wires or the guide wire. Another disadvantage of EHL compared with holmium:YAG lithotripsy is the larger number and size of fragments produced, especially for stones larger than 15 mm. The repeated passage of the ureteroscope to extract the multiple stone fragments produced during EHL may exacerbate mucosal irritation (Teichman et al, 1997).

EHL will successfully fragment 90% of stones. However, treatment failures may be due to a variety of stone compositions. Stone surface characteristics may also play a role in fragmentation efficiency; rough calculi have been reported to fragment more readily than smooth calculi (Basar et al, 1997). Although EHL successfully fragments most ureteral stones, the average 3-month stone-free rate is only 84% because some of the fragments created during lithotripsy and not removed may be retained in the ureter (Table 44–4). Stone-free rates decrease with ureteral stones larger than 15 mm and are significantly lower than those reported for holmium:YAG lithotripsy (67% versus 100%) (Teichman et al, 1997).

The advantages of EHL include probe flexibility, especially the smaller probes such as the 1.9 French, which allows intracorporeal lithotripsy throughout the entire upper urinary tract through rigid or flexible ureteroscopes. Only the holmium:YAG laser, configured with the 200-μm fiber, offers comparable size and flexibility advantages (Elashry et al, 1996). The 1.6 French EHL probe may be even more flexible than the 200-μm laser fiber (Poon et al, 1997).

Weighted average	**465**		**8.5**	**90**	**84**

EHL is also the least costly intracorporeal device, requiring the purchase of a comparatively inexpensive generator and probes. An average of 1 to 1.3 probes are used per case, except in instances of harder stones (e.g., calcium oxalate monohydrate stones), when two or more EHL probes may be needed (Elashry et al, 1996; Huang et al, 1998).

Technique. For intraureteral lithotripsy, the smaller 1.6 and 1.9 French probes should be used. **The EHL fiber tip should be positioned approximately 2 to 5 mm distal to the end of the ureteroscope** to protect the lens system from being damaged when the probe is discharged. Before the EHL generator is activated, the stone must be clearly visible. **The probe is placed about 1 mm from the stone surface,** a distance allowing maximum shockwave emission (Zhong et al, 1997). Initially, low voltage (50 to 60 V) and short intermittent or single pulses are used to enhance safety. The generator output is increased as needed to fragment the stone. However, it is recommended that the treating physician limit the maximum output used in treating ureteral stones to minimize the risk of perforation. The goal of the treatment is to create fragments that can be removed with grasping forceps or a basket device or fragments that are likely to pass spontaneously. Attempts to reduce the stone to fragments smaller than 2 mm are not recommended because damage to the urothelium may occur (Denstedt and Clayman, 1990). After 50 to 60 seconds of firing, the insulation at the tip of the probe may peel away, and at this point, a new probe should be used (Segura, 1999).

Laser Lithotripsy. Laser is an acronym for light amplification by stimulated emission of radiation, which is a concise description of how a laser works. Laser energy is produced when an atom is stimulated by an external energy source, which creates a population of electrons in an excited state. These excited or higher energy electrons can release their excess energy in the form of photons or light energy. Laser light differs from natural light in that it is coherent (all photons are in phase with one another), collimated (photons travel parallel to each other), and monochromatic (all photons have the same wavelength (Floratos and de la Rosette, 1999). These unique features of laser light allow considerable energy to be transmitted in a highly concentrated manner. Lasers are named after the laser medium generating a specific wavelength. The laser was developed in 1960, and the first medium used was the ruby. In 1968, Mulvaney and Beck reported that although the ruby laser could effectively fragment urinary calculi, the ruby laser generated excessive heat and was not appropriate for clinical use. This continuous-wave laser simply heats the stone until vaporization occurs, which requires the laser to generate heat greater than the melting point of the stone.

A solution for this problem came with the development of pulsed lasers. The application of pulsed energy results in high power density at the stone's surface but little heat dissipation. As the pulse duration decreases, the power density increases proportionally. When it is applied to the stone surface, the pulsed laser causes release of electrons and formation of a "plasma" bubble (Floratos and de la Rosette, 1999). The expansion followed by the subsequent collapse of the plasma bubble generates a shockwave that is responsible for the stone fragmentation effect of most pulsed lasers (except the holmium laser, which is reviewed separately), a mechanism defined as photoacoustic (Watson and Wickham, 1986). The first widely available laser lithotrite was the pulsed-dye laser, which employed a coumarin green dye as the liquid laser medium. When the coumarin dye was excited with a flash lamp, pulses of green light 1 μs in duration with a wavelength of 504 nm were emitted and delivered through optical quartz fibers. **The coumarin wavelength was chosen because it is absorbed by all stone materials except cystine but not by surrounding tissues,** thus maximizing its margin of safety (Grocela and Dretler, 1997). Ureteral perforation induced by the pulsed-dye coumarin laser was noted only after multiple high-energy pulses were applied directly to the ureteral wall (Santa-Cruz et al, 1998). The coumarin pulsed-dye laser represented a major advancement in intracorporeal lithotripsy. The 200-μm fiber allowed the use of small-diameter semirigid and flexible ureteroscopes, although only a limited amount of energy (60 mJ) could be delivered through the small-diameter fiber. Calculi throughout the urinary system were fragmented, with success rates of 80% to 95% reported (Floratos and de la Rosette, 1999). However, the degree of stone fragmentation with the coumarin laser was related to stone composition; calcium oxalate monohydrate stones were reported to be more difficult to treat and often yielded larger, sharp-edged fragments (Coptcoat et al, 1988a; Grasso and Chalik, 1998). Furthermore, cystine calculi do not absorb the 504-nm laser light and cannot be fragmented with the coumarin pulsed-dye laser. Other limitations of the coumarin pulsed-dye laser include the initial high cost of the device and the cost of toxic disposables (coumarin dye). In addition, the coumarin laser requires about 20 minutes before it is ready to function, and the required eye protection (amber glass) makes visualization of the stone and laser fiber difficult (Segura, 1999).

Technologic advancements eventually led to the development of the holmium:YAG laser. The holmium laser is a solid-

state laser system that operates at a wavelength of 2140 nm in the pulsed mode. Pulse duration of the holmium laser ranges from 250 to 350 μs and is substantially longer than the pulse duration in pulsed-dye lasers. The holmium laser is highly absorbed by water, and as tissues are composed mainly of water, the majority of the holmium laser energy is absorbed superficially, which results in superficial cutting or ablation. **The zone of thermal injury associated with laser ablation ranges from 0.5 to 1.0 mm** (Wollin and Denstedt, 1998). The mechanism of stone fragmentation of the holmium:YAG laser is different from that of the pulsed-dye lasers. **The long holmium:YAG pulse duration produces an elongated cavitation bubble that generates only a weak shockwave,** in contradistinction to the strong shockwave produced by short-pulse lasers. Vassar and associates (1999) demonstrated that during holmium lithotripsy, stone fragmentation began before bubble collapse and shockwave production. Furthermore, no stone fragmentation occurred when the fiber was discharged at an incident angle of 90 degrees. Lithotripsy was more efficient for dry stones in air, indicating that the holmium laser requires direct absorption of laser energy. These data as well as the presence of thermal products after holmium irradiation, such as glowing hot stone fragments, indicate that **holmium laser lithotripsy occurs primarily through a photothermal mechanism that causes stone vaporization** (Dushinski and Lingeman, 1998; Wollin and Denstedt, 1998; Vassar et al, 1999).

Advantages and Disadvantages. The holmium:YAG laser can transmit its energy through a flexible fiber, which facilitates intracorporeal lithotripsy throughout the entire collecting system. However, compared with EHL, the holmium:YAG laser is safer and more efficient. Whereas EHL may cause injury to the ureter even when the probe is activated several millimeters away from the ureteral wall, the holmium laser may be safely activated at a distance of 0.5 to 1 mm from the ureteral wall (Santa-Cruz et al, 1998). **The ability of the holmium laser to fragment all stones regardless of composition is a clear advantage** over the coumarin pulsed-dye laser. Successful fragmentation of ureteral stones of all compositions has been reported in 91% to 100% of cases, with a mean stone-free rate of 95%. Failures are due mostly to stone migration. Mean perforation and stricture rates are 1.1% and 1.2%, respectively (Table 44–5). During PNL, the holmium laser is most helpful in clearing smaller stones (<2 cm) when the use of flexible instruments is required for access to stones in a calyx remote from the nephrostomy track (Wollin and Denstedt, 1998). The **holmium laser is one of the safest, most effective, and most versatile intracorporeal lithotripters.** Further advantages of the holmium laser include its production of significantly smaller fragments compared with other lithotrites. Holmium laser lithotripsy results in small stone debris, which is easily irrigated, reducing the need for extraction of the fragments with basket or grasping devices (Teichman et al, 1998a). **The holmium laser produces a weak shockwave, which reduces the likelihood of retropulsion of the stone** or stone fragments compared with EHL or pneumatic lithotrites (Teichman et al, 1998a; Vassar et al, 1999; Sofer and Denstedt, 2000). However, the 365-μm and 550-μm laser fibers will cause significantly more retropulsion than the 200-μm fiber (White et al, 1998). The holmium laser has several distinct operating advantages compared with the coumarin pulsed-dye laser. The required eye protection for the holmium laser does not compromise the ureteroscopic view of the stone or the fiber (Segura, 1999). In fact, the holmium laser properties are such that with use of energy levels applied for stone disease (i.e., less than 15 watts), the operator's cornea would be damaged only if it were positioned at a distance of 10 cm or less from the fiber (Scarpa et al, 1999). The holmium laser machine is more compact than the coumarin laser, requires minimal maintenance, and is ready for use 1 minute after it is turned on.

The major disadvantage of the holmium laser is the initial high cost of the device and the cost of the laser fibers. Elashry and coworkers (1996) noted an advantage of EHL over holmium laser lithotripsy in capital and service contract cost and lithotripter cost per case. However, **the holmium laser has multiple soft tissue applications and can be used to treat patients with benign prostatic hyperplasia, strictures, and urothelial tumors.** In addition, the laser fibers are reusable, so that the effective cost of the holmium laser device and reusable fibers may be lower than that of EHL (Teichman et al, 1998a).

A potential side effect of holmium laser lithotripsy is the production of cyanide when uric acid stones are treated, which has been reported in vitro. However, a **review of clinical experience suggests no significant cyanide toxicity from holmium laser lithotripsy** (Teichman et al, 1998c).

Technique. The technique of holmium laser lithotripsy is relatively straightforward and involves placement of the fiber on the stone surface before the laser is activated (Table 44–6). Clear vision is essential at all times to avoid mucosal perforation. After initiation of holmium laser lithotripsy, a short pause is often required because of the "snowstorm effect" created by the scattering of minute stone fragments, which can be cleared by endoscopic irrigation (Scarpa et al, 1999).

Table 44–6. Holmium Laser Lithotripsy Points of Technique

Do

Keep the fiber tip in view at all times.
Start at low settings and increase only as necessary.
Work from the inside of the stone outward.
Keep the fiber tip at least 2 mm from the urothelium.

Don't

Do not have one person controlling the fiber and another the foot pedal.
Do not discharge the laser fiber inside the working channel or on guide wires and baskets.
Do not pass the fiber tip through the back wall of stones.
Do not get impatient—holmium:YAG laser lithotripsy is not necessarily fast.

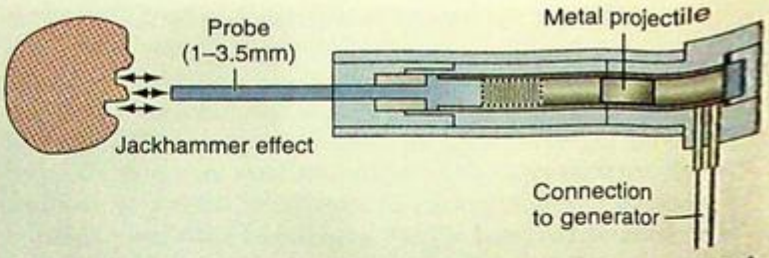

Figure 44–6. Schematic illustration of the LithoClast (Electromedical Systems, Kaufering, Germany) handpiece mechanism. An oscillating pellet provides ballistic energy to the probe, resulting in a jackhammer-like effect on calculi. (Courtesy of Dr. John Denstedt.)

Caution must be exercised in operating the holmium laser near a guide wire or a basket as **the holmium laser is capable of cutting through metal** (Freiha et al, 1997). Furthermore, the laser fiber should extend at least 2 mm beyond the tip of the endoscope to avoid destroying the lens system or the working channel of the endoscope. Baskets used to stabilize calculi during laser lithotripsy should be the preformed type and not the type manufactured by bending of the wire, so if they are inadvertently transected by the holmium laser, they will retain the basket shape and will not cause a sharp barbed effect (Grasso and Chalik, 1998).

Holmium laser fibers are available in 200-, 365-, 550-, and 1000-μm diameters as well as end- or side-firing fibers. However, only the 200- and 365-μm-diameter fibers are used for flexible intracorporeal lithotripsy. Teichman and colleagues (1998b) reported that the 550-μm side-firing fiber is more effective than the end-firing fiber during PNL, suggesting that the more nearly normal (perpendicular) laser-to-calculus incident angle provided by the side-firing fiber enhances lithotripsy. However, in treatment of ureteral stones, the end-firing fiber may produce a better angle of attack. **Lithotripsy with the holmium laser depends on the pulse energy output and the diameter of the optical delivery fiber, suggesting that lithotripsy efficiency correlates with energy density** (Vassar et al, 1998). Energy density increases with decreasing fiber diameter, although Calvano and associates (1999) demonstrated, in vitro, that peak lithotripsy occurred with 365- and 550-μm fibers, whereas the 200-μm fiber can act as a fine drill, which is less effective. Compared with some of the soft tissue applications of the holmium laser, the power used for stone fragmentation is considerably lower. In general, pulse energies of 0.6 to 1.2 J and pulse rates of 5 to 15 Hz are used (Wollin and Denstedt, 1998; Spore et al, 1999). Because high-pulse energy narrows the safety margin and may increase stone retropulsion as well as fiber damage, **it is recommended that treatment be commenced with low-pulse energy (e.g., 0.6 J) with a pulse rate of 6 Hz and that pulse frequency be increased (in preference to increasing pulse energy) as needed to speed fragmentation** (Spore et al, 1999). To maximize lithotripsy efficiency, the treating physician should move the laser fiber over the stone surface in a "painting" fashion, vaporizing the stone rather than fragmenting it, and avoid drilling into the stone, fracturing the fiber tip, or drilling past the stone, damaging the urothelium (Segura, 1999). The laser fiber should be kept at least 1 mm from the urothelium, and lithotripsy should proceed until the stone fragments are small enough to be passed spontaneously or can be safely retrieved with a basket or grasping device.

Rigid Lithotripters

Ballistic Lithotripsy. Ballistic lithotripsy relies on energy generated by the movement of a projectile (Fig. 44–6). The initial movement of the projectile can be induced by a variety of stimuli, but once the projectile is in contact with another object, the ballistic energy is transferred to the object. Flexible objects preserve the momentum of the energy, but inflexible objects, such as a stone, fragment on impact (a "jackhammer" effect).

The Swiss LithoClast, introduced in the early 1990s, was the first ballistic lithotrite. The metal projectile in the handpiece of the LithoClast is propelled by measured bursts of compressed air against the head of a metal probe at a frequency of 12 cycles per second. The probe tip is placed against the stone, and the LithoClast is activated by a foot pedal (Denstedt et al, 1992). In the mid-1990s, the electrokinetic lithotripter was introduced (Menezes et al, 2000). The electrokinetic lithotripter consists of a rheostat and a handset containing an electric coil that generates an electromagnetic field, which then vibrates the probe at 15 to 30 cycles per second. Whereas the LithoClast is connected to the hospital central air supply or to a compressed air tank, the electrokinetic lithotripter requires electrical power. In both instruments, the discharged probe is brought back into its former position by a rubber bushing around the base of the probe (Vorreuther et al, 1998). Studies comparing the LithoClast and the electrokinetic lithotripter, using the same stone fragmentation mechanism, showed no significant difference in stone fragmentation, proximal stone migration, and safety margin. However, the handpiece of the electrokinetic lithotripter is heavier than that of the LithoClast (Vorreuther et al, 1998; Menezes et al, 2000). Probes for the ballistic lithotrites range from 0.8 to 2.5 mm.

Two potential improvements to the ballistic lithotripter have been introduced. A suction device connecting to the LithoClast probe allows evacuation of stone particles, and a flexible nickel-titanium (nitinol) probe allows use of the LithoClast through a flexible ureteroscope (Tawfiek et al, 1997; Delvecchio et al, 2000).

Advantages and Disadvantages. **The ballistic lithotrites provide an effective means for stone fragmentation in the entire urinary tract with a wide margin of safety.** Successful

Table 44–7. Ureteroscopic Ballistic Lithotripsy

Author	Patients	Stone Migration (%)	Ureteral Perforation (%)	Successful Fragmentation with Ballistic Device Only (%)

fragmentation of ureteral stones of all compositions has been reported in 73% to 100% of cases (Table 44–7), a success rate similar to that of EHL. The lower success rate of 73.7% reported by Knispel and associates (1998) suggests reduced efficiency of the LithoClast when it is applied through the deflected working channel (30 degrees) of the 6.9 French semirigid ureteroscope. As well, a significant decrease in the maximum tip displacement and velocity of the LithoClast 0.89-mm flexible probe occurs when it is used through a flexible ureteroscope deflected more than 24 degrees (Zhu et al, 2000). Grocela and Dretler (1997) also reported that for the current ballistic devices, **bowing of the probe during lithotripsy results in significant power loss.** Ballistic devices may be especially advantageous when large or hard stones are encountered during PNL or endoscopic lithotripsy of bladder calculi. In contrast to ureteral stones, **kidney stones are easily "pinned down" against the urothelium during ballistic lithotripsy, allowing a rapid and more efficient fragmentation method than ultrasonic lithotripsy.** Once the bulk of the calculus is fragmented, lithotripsy can be completed with the ultrasonic lithotripter, which can also aspirate minute stone fragments (Denstedt, 1993; Teh et al, 1998; Yavascaoglu et al, 1999). Compared with EHL, ultrasonic lithotripsy, and laser lithotripsy, ballistic devices have a significantly lower risk of ureteral perforation (Piergiovanni et al, 1994). In an animal model, despite 6 minutes of activation in direct contact with the ureteral wall, a ballistic lithotripter was unable to cause perforation (Santa-Cruz et al, 1998). The average risk of ureteral perforation during ureteroscopic ballistic lithotripsy is less than 1%. Furthermore, because no heat is produced during lithotripsy, the risk of thermal injury to the urothelium is eliminated.

One of the advantages of ballistic lithotrites is their relatively low cost and low maintenance. Although the devices are more expensive than EHL, there are no disposable costs and the probes have an extremely long life span (Hofbauer et al, 1995).

Disadvantages of ballistic devices include the rigid nature of the technology, which requires ureteroscopes or nephroscopes with straight working channels. In addition, **ballistic lithotripsy is associated with a relatively high rate of stone retropulsion,** reported in 2% to 17% of ureteral stone treatments. Often, failure to fragment a stone is related to an inability to trap a ureteral stone in a capacious ureter (Denstedt et al, 1992). The migration rate depends on the initial stone location; there is a higher chance of stone migration for proximal ureteral stones compared with distal ureteral stones (Knispel et al, 1998). Limited data are available on the beneficial effects of suction devices, such as the LithoVac, in limiting stone migration. Delvecchio and colleagues (2000) reported the use of the 0.8-mm pneumatic lithotripsy probe placed through a 4.8 French hollow LithoVac suction probe in 21 patients with ureteral stones. Overall stone-free rate at 3 months was 95%, and the suction device reportedly facilitated lithotripsy by preventing stone migration and maintaining a clear endoscopic view.

Teichman and associates (1998a) reported that fragments larger than 4 mm are produced by all types of endoscopic lithotrites, with the exception of the holmium:YAG laser. Fragmenting a stone into pieces smaller than 4 mm with a ballistic lithotripter can be challenging, especially a hard stone in a dilated ureter. Fragments larger than 4 mm are associated with a higher rate of repeated ureteroscopy and therefore should be removed with baskets or stone graspers during the initial procedure (Keeley et al, 1999c).

Technique. Like other lithotrites, the ballistic lithotripter should be activated only when there is a clear view of the stone and the probe position can be identified. Fixation of the stone is rarely difficult in the kidney or the bladder but may be a problem in the ureter. Fixation of ureteral stones with a basket or proximal placement of a ureteral occlusion balloon is sometimes necessary. The goal of ballistic lithotripsy in the ureter is to generate fragments that are small enough to permit spontaneous passage (<2 mm). However, more often, larger fragments have to be removed with a basket or grasping device. The relatively atraumatic nature of ballistic lithotripsy may allow the avoidance of stent placement after ureteroscopy. Tan and colleagues (1998) reported the use of stent in only 9 of 68 patients undergoing ballistic lithotripsy. In this series, difficult ureteral access and severe edema and trauma at the site of stone impaction were indications for stent placement.

Ultrasonic Lithotripsy. Mulvaney first reported the use of ultrasound vibrations to break renal calculi in 1953. Since then, ultrasonic lithotripsy has become a commonly used modality for the treatment of renal calculi during PNL as well as for the fragmentation of bladder and ureteral stones. The ultrasound probe works by applying electrical energy to excite a piezoceramic plate in the ultrasound transducer (Fig. 44–7). The plate resonates at a specific frequency and generates

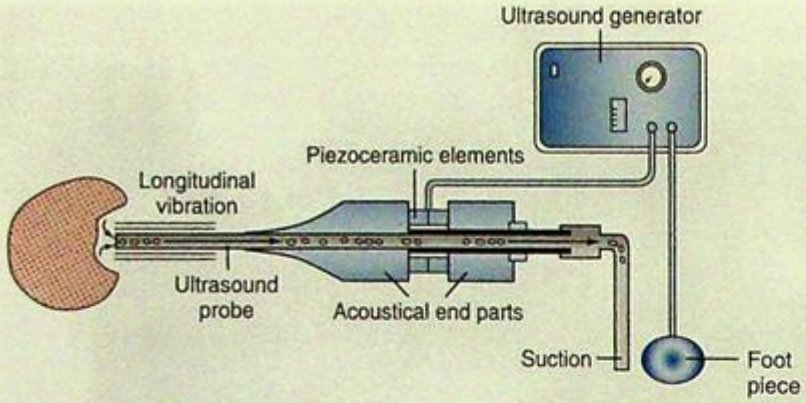

Figure 44–7. Ultrasound lithotripsy generator and handpiece.

ultrasonic waves at a frequency of approximately 23,000 to 25,000 Hz. At operating frequencies, there is no audible sound, although 98 dB of ultrasonic inaudible noise levels have been measured (Segura and LeRoy, 1984).

Ultrasound energy is transformed into longitudinal and transverse vibrations of the hollow steel probe, which then transmits the energy to the calculus. The probe tip causes the stone to resonate at high frequency and to break; but when the probe is placed on compliant tissue, such as urothelium, damage is minimal because the tissue does not resonate with the vibrational energy (Grocela and Dretler, 1997). Although some heat may develop at the end of the probe during lithotripsy, with an irrigation rate of 30 mL per minute, the temperature increase at the tip of the probe can be reduced to a maximum of 1.4° C (Marberger, 1983). Because irrigation may be limited during ureteroscopy, **ultrasonic lithotripsy is more efficient during PNL owing to the greater flow of irrigant through the larger diameter ultrasonic probes that can be used.** The ultrasonic lithotripter system is connected to suction so that debris from the stone is removed continuously with the irrigating fluid during lithotripsy. In addition, the flow of fluid through the hollow probe serves to cool the instrument. Heating of the ultrasound transducer should alert the surgeon to possible occlusion in the probe lumen, an occurrence more commonly encountered with small-diameter probes that are used in the ureter. Although many manufacturers provide an integrated power and suction foot switch for the ultrasonic unit, wall suction with intermittent clamping of the suction tubing by an assistant is a simple and inexpensive alternative. In general, suction is applied only when the ultrasonic lithotripter is activated, and suction pressures in the range of 60 to 80 cm H_2O are sufficient to maintain adequate flow of irrigant during lithotripsy. Higher suction pressures tend to draw air bubbles into the system, impeding vision. Ultrasonic probes are available at sizes ranging from 2.5 to 12 French. The 2.5 French probe is solid and contains no hollow center for suction. Therefore, when it is used in the ureter, heat dissipation is slow. Bending the probe results in energy loss at the convexity of the bend, with the energy being transformed to heat (Marberger, 1983).

Stones vary in their susceptibility to destruction with ultrasound. Although the chemical composition of the stone influences the time required for complete disintegration (cystine, calcium oxalate monohydrate, and uric acid being the most resistant to fragmentation), the size, density, and surface structure of the calculus appear to be more important. Smaller stones are more rapidly destroyed, as are rough stones. Smooth-surfaced large stones may be more difficult to fragment (Marberger, 1983; Segura and LeRoy, 1984).

Auge and associates (2002a) have reported on a new combination intracorporeal lithotripter that incorporates ballistic lithotripsy and ultrasonic lithotripsy modalities (LithoClast Ultra). In their in vitro study of this device, it was found to more efficiently fragment and clear phantom stones compared with a standard ultrasonic or ballistic device. These findings were confirmed in a subsequent in vitro study by Kuo and associates (2004).

Advantages and Disadvantages. The major advantage of ultrasonic lithotripsy is the efficient combination of stone fragmentation and simultaneous fragment removal. Fragments smaller than 2 mm are aspirated through the hollow lithotrite along with the irrigation fluid. Larger fragments may be removed with forceps or baskets. The efficiency of this technique coupled with the minimal risk of serious tissue damage has made this technology popular. Ultrasonic lithotripsy is often the first modality used for stone fragmentation during PNL.

However, the rigid nature of ultrasonic probes and their small diameter limit the appeal of this technology in treatment of ureteral stones. A ureteroscope with a straight working channel is required. Furthermore, a relatively large 5 French working channel is needed to accommodate the 4.5 French hollow probe. However, success rates between 69% and 100% have been reported (Denstedt, 1996; Gur et al, 2004). The technology may be particularly useful for patients with large ureteral stones as well as for those suffering from steinstrasse because removal of stone debris is facilitated. Excellent results have also been reported for distal ureteral stones easily accessible to the rigid ureteroscope (Grocela and Dretler, 1997; Segura, 1999). Chaussy and colleagues (1987) reported a 96.6% complete fragmentation rate in 118 patients with a 2.5 French solid probe that can be used with smaller ureteroscopes, and Fuchs (1988) has reported similar results. However, in a later report, Murthy and associates (1997) compared a group of 25 patients treated by a rigid ureteroscope and the 3 French ultrasonic solid probe with a group of 122 patients treated by the LithoClast ballistic device, and the overall success rate was significantly higher for the LithoClast group than for the ultrasonic group (97.3% versus 84%, respectively).

Technique. When ultrasonic lithotripsy is applied during PNL, the stone should first be trapped between the probe and the urothelium. The application of gentle pressure to the stone enhances fragmentation, but the temptation to push too hard

should be avoided as calculi can easily be pushed through the urothelium. The risk of perforation increases with smaller or more ruggedly surfaced stones as the force applied to the stone is transferred to a smaller surface area of the urothelium. The risk of perforation is particularly high in the thin-walled renal pelvis or ureter rather than in a calyx that is backed by renal parenchyma.

When ureteral stones are treated, the ureter may need to be dilated to allow passage of the offset rigid ureteroscope. The ultrasonic probe is passed through the working channel and placed directly on the stone. If necessary, the stone can be engaged in a stone basket to prevent proximal migration. As with other intracorporeal lithotripsy devices, the goal of treatment is either to fragment the stone completely or to generate fragments that are small enough to be extracted or passed spontaneously.

Conclusion

The current technology of intracorporeal lithotripsy provides the urologist with several effective options, depending on the type of endoscope used (rigid or flexible) and the location and accessibility of the stone. **The holmium laser has become the mainstay of ureterorenoscopic lithotripsy by virtue of its ability to fragment all stones. As well, the use of small-diameter fibers allows access to all areas of the ureter and intrarenal collecting system. However, for patients with complex, large-volume calculi undergoing PNL, the ultrasonic or pneumatic lithotripters will permit more efficient fragmentation of the stone.** When selecting a lithotripter for purchase, the institution must take into account the number and nature of stone-related procedures performed to maximize the utility and cost-effectiveness of the device.

Extracorporeal Shockwave Lithotripsy

Methods and Physical Principles of SWL

In extracorporeal SWL, shockwaves are generated by a source external to the patient's body and are then propagated into the body and focused on a kidney stone. **The uniqueness of this device is in its exploitation of shockwave focusing. Relatively weak, nonintrusive waves are generated externally and transmitted through the body. The shockwaves build to sufficient strength only at the target, where they generate enough force to fragment a stone.**

When energy is deposited rapidly into a fluid, a shockwave invariably results. **Shockwaves are surfaces that divide material ahead, not yet affected by the disturbance, from that behind, which has been compressed as a consequence of energy input at the source** (Sturtevant, 1996). These waves move faster than the speed of sound, and the stronger the initial shock, the faster the shockwave moves. Their behavior is characteristic of the propagation of nonlinear waves. Although the shockwaves in lithotripters generate large pressures, they are relatively weak in that they induce only slight compression and deformation of a material.

Generator Type. There are three primary types of shockwave generators: electrohydraulic (spark gap), electromagnetic, and piezoelectric.

Electrohydraulic (Spark Gap) Generator. **In the electrohydraulic shockwave lithotripter** (Table 44–8), **a spherically expanding shockwave is generated by an underwater spark discharge** (Cleveland et al, 2000). High voltage is applied to two opposing electrodes positioned about 1 mm apart. The high-voltage spark discharge causes the explosive vaporization of water at the electrode tip. **For the spherically expanding shockwave to be focused onto a calculus, the electrode is placed at one focus (termed F1) of an ellipsoid, and the target (the kidney stone) is placed at the other focus (termed F2).** Figure 44–8 shows a hemiellipsoid reflector and a spark gap typical of those used in the older electrohydraulic machines. This arrangement allows the projection of the majority of the original shockwave energy from the electrode tip to the stone, provided the electrode tip is precisely at F1. The body of the electrode varies in orientation among machines in that it is positioned within the ellipsoid to provide an easy means of replacement as it deteriorates.

The clear advantage of this generator is its effectiveness in breaking kidney stones (Lingeman, 1997). **Disadvantages are the substantial pressure fluctuations from shock to shock and a relatively short electrode life.** New longer life electrodes (like the NewTrode by HMT) have been developed to overcome these drawbacks. Another issue to consider is that as the electrode deteriorates, it wears down, and a 1-mm displacement of the electrode tip off of F1 can shift F2 up to 1 cm off of the initial target.

Electromagnetic Generator. Whereas the electrohydraulic lithotripter produces focused shockwaves by bouncing spherically expanding shocks off of an ellipsoid reflector, **the electromagnetic** (see Table 44–8) **generators produce either plane or cylindrical shockwaves.** The plane waves are focused by an acoustic lens (Fig. 44–9); the cylindrical waves are

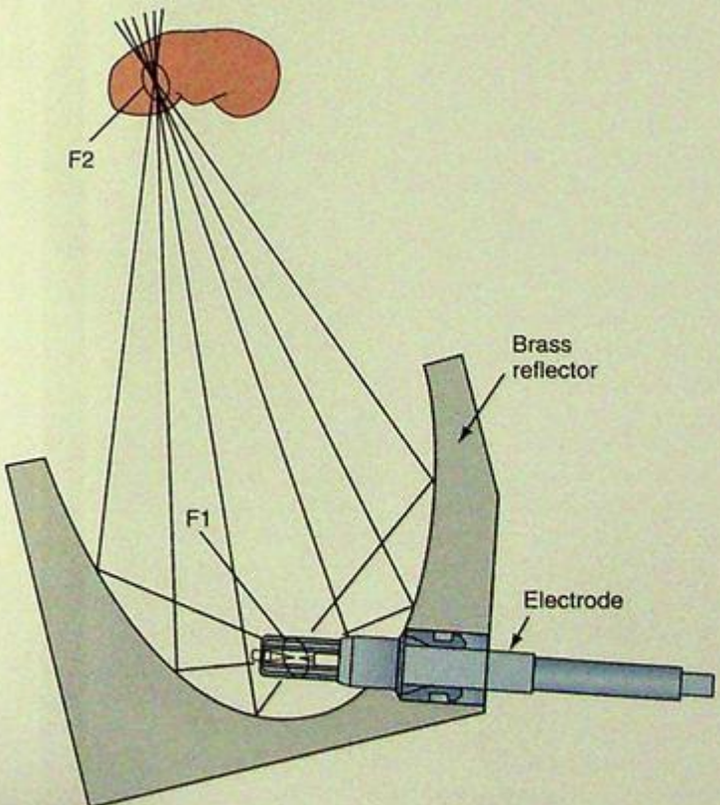

Figure 44–8. Schematic view of an electrohydraulic shockwave generator. An electrode is used to generate a shockwave.

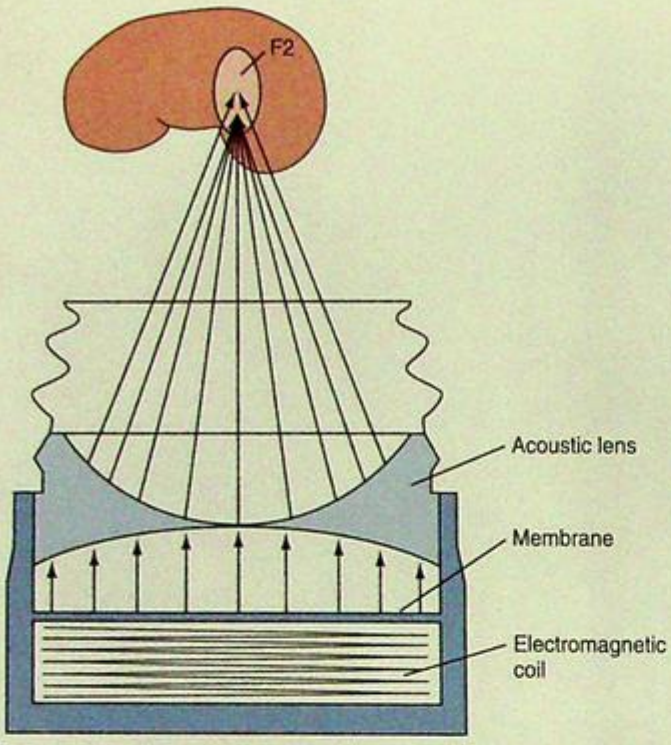

Figure 44–9. Schematic view of an electromagnetic shockwave generator that uses an acoustic lens to focus the shockwave. An electromagnetic coil is used to generate the shockwave.

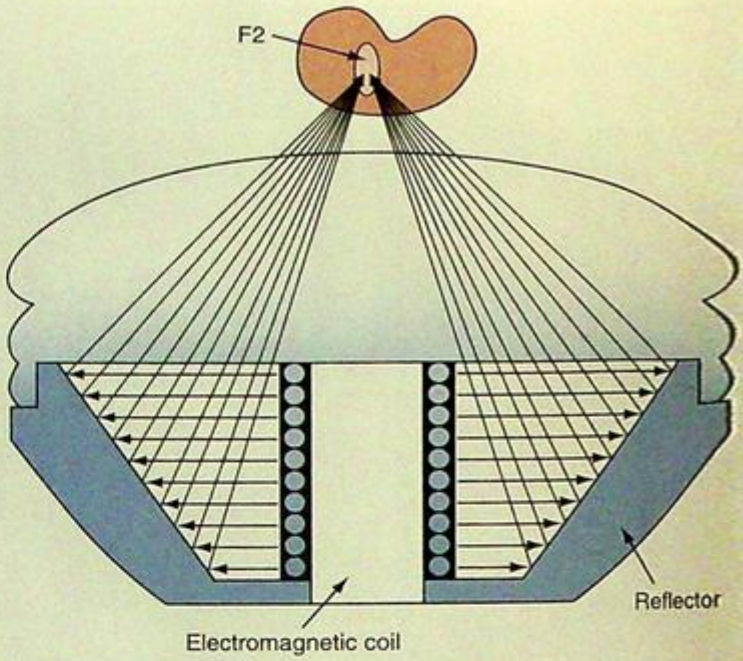

Figure 44–10. Schematic view of an electromagnetic shockwave generator that uses a parabolic reflector to focus the shockwave. An electromagnetic coil is used to generate the shockwave.

reflected by a parabolic reflector (Fig. 44–10) and transformed into a spherical wave. The basic design of an electromagnetic generator is simple. Figure 44–9 shows a system that uses a water-filled shock tube containing two conducting cylindrical plates separated by a thin insulating sheet. When an electrical current is sent through one or both of the conductors, a strong magnetic field is produced between the conductors, moving the plate against the water and thereby generating a pressure wave. The electromagnetic force that is generated, termed magnetic pressure, causes a corresponding pressure (shockwave) in the water. The shock front produced is a plane wave that is of the same diameter as the current-carrying plates. **The energy in the shockwave is concentrated onto the target by focusing it with an acoustic lens.** The electromagnetic system that uses a cylindrical source (see Fig. 44–10) also has a coil (cylindrical in shape) surrounded by a cylindrical membrane that is pushed away from the coil by the induction of a magnetic field between the two components. In both systems, the pressure pulse has only one focal point (F2) that is positioned on the target.

Electromagnetic generators are more controllable and reproducible than electrohydraulic generators because they do not incorporate a variable in their design such as the underwater spark discharge. Other advantages include the introduction of energy into the patient's body over a large skin area, which may cause less pain. In addition, a small focal point can be achieved with high-energy densities, which may increase its effectiveness in breaking stones. This generator will deliver several hundred thousand shockwaves before servicing, thereby eliminating the need for frequent electrode replacement, which is required with most electrohydraulic machines. **A disadvantage of this design may be that the small focal region of high energy results in an increased rate of subcapsular hematoma formation.** The rate of subcapsular hematoma formation for the Storz Modulith has been suggested to be 3.1 to 3.7% (Dhar et al, 2004). Piper and associates (2001) suggested that perinephric hematomas may occur in up to 12% of patients treated with a DoLi S. In contrast, perinephric hematomas were reported to occur in approximately 0.6% of patients undergoing SWL with the unmodified Dornier HM3 (Chaussy and Schmiedt, 1984; Knapp et al, 1987).

Piezoelectric Generator. The **piezoelectric lithotripter** (see Table 44–8) **also produces plane shockwaves with directly converging shock fronts.** These generators are made of a mosaic of small, polarized, polycrystalline, ceramic elements (barium titanate), each of which can be induced to rapidly expand by the application of a high-voltage pulse (Fig. 44–11). Owing to the limited power of a single piezoelectric element, 300 to 3000 crystals are necessary for the generation of a sufficiently large shock pressure. The piezoelectric elements are usually placed on the inside of a spherical dish to permit convergence of the shock front. The focus of the system is at the geometric center of the spherical dish.

The advantages of this generator include the focusing accuracy, a long service life, and the possibility of an anesthetic-free treatment because of the relatively low energy density at the skin entry point of the shockwave. For this reason, piezoelectric lithotripters in general tend to produce less discomfort than do lithotripters with other energy sources. **A major disadvantage of this system is the insufficient power it delivers, which hampers its ability to effectively break renal stones.** The piezoelectric energy sources produce some of the highest peak pressures of any lithotripter, but the actual energy delivered to the stone per shockwave pulse is several orders of magnitude lower than that delivered by an electrohydraulic machine because of the extremely tiny volume of F2.

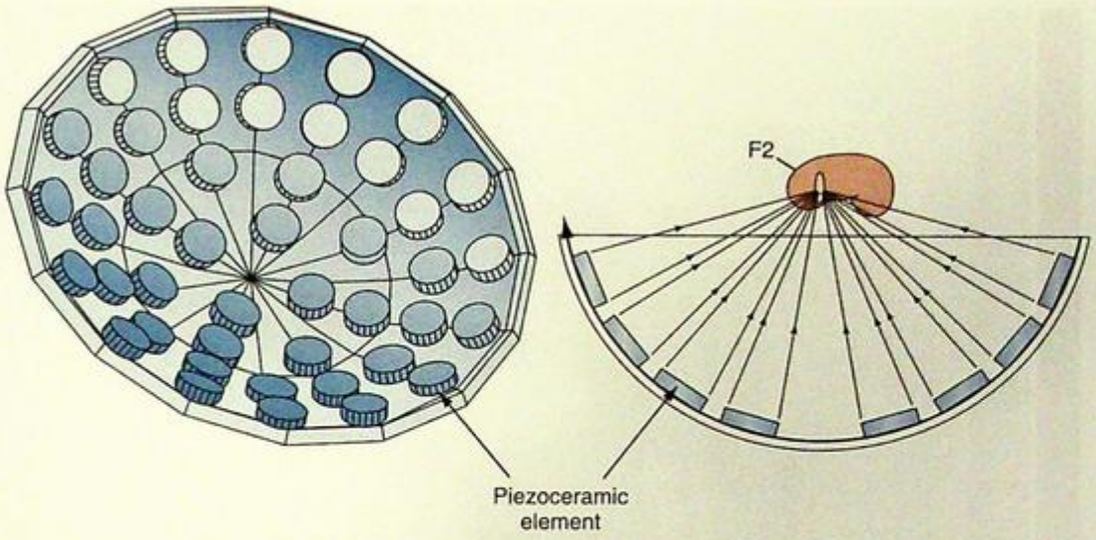

Figure 44–11. Schematic view of a piezoelectric shockwave generator. Numerous polarized polycrystalline ceramic elements are positioned on the inside of a spherical dish.

Other Generators. Microexplosive generators have also been produced but have not gained widespread acceptance. The explosion of tiny lead azide pellets within a parabolic reflector generates the device's shockwave (Kuwahara et al, 1987). Despite the effectiveness of this type of generator in producing shockwaves, this technology has not met with commercial success because of concerns about the storage and handling of the volatile lead azide pellets. Still other methods of shockwave generation use a laser beam or a multistage light gas gun, but these too have not been well received commercially.

Imaging Systems. There are **three basic designs** used by lithotripter manufacturers for stone localization (Table 44–9). They are **ultrasonography alone, fluoroscopy alone, and the combination of ultrasonography and fluoroscopy.**

Fluoroscopy Alone. The original Dornier HM3 lithotripter used two x-ray converters arranged at oblique angles to the patient and 90 degrees from each other to localize the stone effectively at F2. To reduce the cost of lithotripters, an adjustable C-arm has been subsequently introduced on many devices. There is presently a remarkable similarity in the fluoroscopic systems used among manufacturers. This appears to be primarily the result of a common theme in the industry to develop multifunctional tables around these machines. The fluoroscopic system typically consists of a high-quality digitized x-ray imaging system mounted on a rotatable C-arm with isocentrically integrated shockwave source. Because the shockwave head can be rotated out of the field of the fluoroscopic system, the table can be used for routine urologic fluoroscopic applications.

The primary advantages of fluoroscopy still include its familiarity to most urologists, the ability to visualize radiopaque calculi throughout the urinary tract, the ability to use iodinated contrast agents to aid in stone localization, and the ability to display anatomic detail. The disadvantages include the exposure of the staff and patient to ionizing radiation, the high maintenance demands of the equipment, and the inability to visualize radiolucent calculi without the use of radiographic contrast agents.

Ultrasonography Alone. Ultrasonic localization was initially designed to aid multifunctional lithotripters for treatment of both urinary and biliary stones. It is presently used in several low-cost machines because it is inexpensive to manufacture and to maintain compared with fluoroscopic systems. Another major advantage of this technology is in the treatment of children and infants when one is concerned about the dose of ionizing radiation. In addition, ultrasonography can localize slightly opaque or nonopaque calculi.

Despite its advantages, there are a number of significant disadvantages of ultrasound imaging. Sonographic localization of a kidney stone requires a highly trained operator. To complicate the issue of stone detection is the fact that it is almost impossible to view a kidney stone in areas such as the middle third of the ureter or when there is an indwelling ureteral catheter. Once a stone is fragmented, it is difficult to identify each individual stone piece. Unfortunately, these disadvantages tend to overshadow the advantages of ultrasound imaging.

Combination of Ultrasonography and Fluoroscopy. As the demand for interdisciplinary lithotripters has increased, the lithotripsy industry has responded, in some cases combining ultrasonography and fluoroscopy for stone localization. Table 44–9 lists a number of the variations that exist for these two imaging systems. There are clearly advantages to these setups, but each system has a drawback that limits one of the functions of the system.

Anesthesia. The approach to anesthesia for lithotripsy has changed considerably since clinical SWL began in 1980. At that time, regional or general anesthesia was used in all instances because the unmodified HM3 device (15.6-cm ellipsoid; 80 nF generator) produced a powerful shockwave and treatment at recommended energy levels caused intolerable pain. Subsequently, urologists and lithotripter manufacturers recognized that the HM3 is considerably more powerful at the recommended energy setting than is necessary for the fragmentation of most renal calculi, an observation that spawned interest in less powerful lithotripters with lessened anesthesia requirements (Marberger et al, 1988; Wilbert et al, 1987). Several researchers have noted that the original HM3 lithotripter without modification produces excellent clinical results when it is used at lower energy settings (Pettersson et al, 1989; Tiselius, 1991; Tolley et al, 1991). In addition, such

settings create a smaller lesion at F2 in experimental animals (Connors et al, 2000).

The discomfort experienced during SWL is related directly to the energy density of the shockwave as it passes through the skin as well as the size of the focal point. The last decade has produced many new and useful anesthetic techniques adaptable to SWL that were not available at the time SWL was introduced:

- Short-acting parenteral sedative-narcotics: alfentanil, midazolam, propofol
- Topical agents: EMLA cream

Short-acting agents, such as the narcotic alfentanil and the sedative-hypnotics midazolam and propofol, have been used in various combinations to allow most SWL treatments with any lithotripter (including the unmodified Dornier HM3) to be accomplished comfortably for the patient without the need for general or regional anesthesia, if the patient so desires. For this reason, anesthesia considerations have not been included in the technical data on lithotripters in Tables 44-8 and 44-9. Monk and associates (1991) compared two sedative-analgesic techniques (midazolam-alfentanil versus fentanyl-propofol) and found that both techniques provided adequate anesthesia for SWL with use of an unmodified Dornier HM3. Anesthesia and recovery times were significantly shorter than those recorded for epidural anesthesia techniques. These findings have been confirmed by others (Nelson et al, 2001; Burmeister et al, 2002; Ozcan et al, 2002).

Another approach to minimize anesthesia requirements during SWL has been the use of topical agents. EMLA cream, a eutectic mixture of lidocaine and prilocaine, has been shown significantly to reduce anesthesia requirements during SWL (Pettersson et al, 1989; Tiselius, 1989; Basar et al, 2003). A topical agent, EMLA cream should be applied at least 45 minutes before SWL. The combination of topical agents and short-acting intravenous agents is likely to minimize the amount of these agents required and to shorten recovery times (Monk et al, 1991).

Not all patients are well served by treatment with a low-energy SWL technique, and therefore a variety of factors need to be considered in choosing the preferred approach for SWL. Calculi composed of cystine, calcium oxalate monohydrate, or brushite are known to be resistant to fragmentation; if their presence is anticipated, delivery of higher levels of shockwave energy with attendant increased anesthesia requirements should be expected (Dretler, 1988; Klee et al, 1991). Thin patients have more pain during SWL because the converging shockwave is more concentrated at the point of skin penetration. Children and extremely anxious individuals may be served best by general anesthesia. If a lengthy treatment session is anticipated (i.e., bilateral SWL or treatment of ureteral and renal stones), the larger amount of topical and intravenous agents required lessens their appeal.

One important observation regarding the issue of general anesthesia versus intravenous sedation was reported by Sorensen and colleagues (2002). In a comparison of patients treated with the DoLi 50 lithotripter, those patients who received general anesthesia experienced a significantly greater stone-free rate than did those patients who underwent intravenous sedation. One possible explanation for this finding is the more controlled respiratory excursion that is conferred by the general anesthetic.

Lithotripter Comparisons

Information about currently available extracorporeal shock wave lithotripters marketed by several manufacturers is presented in Tables 44-8 and 44-9. Lithotripters that were no commercially viable and are no longer produced have not been included (i.e., Diasonics Therasonic LTS, Northgate SD and Yachioda microexplosion lithotripter). Furthermore, although there are a large number of Chinese lithotripters, no reliable technical or clinical information is available and these devices were not included.

Although there was a surge in publications in the urologic literature in the mid-1980s addressing lithotripsy, few if any appropriately designed comparative trials of lithotripters have been published. In addition, **there are no validated standards within the lithotripsy industry regarding a method of quantification of the power and efficiency of lithotripters, a problem further compounded by a lack of knowledge of the number of shockwaves that can be safely administered to a kidney during any single SWL session with any lithotripter.** Although there is a general consensus that re-treatment rates are an appropriate indicator of lithotripter effectiveness, the lack of clinical agreement about the appropriate outcome of lithotripsy (i.e., stone free versus residual fragments of various size) further hampers comparisons of lithotripters (Tolley et al, 1991).

Only a small part of the literature published to date on the outcomes of SWL presents data that are stratified sufficiently to permit a meaningful comparative analysis, but there is a significant amount of reasonably well stratified data regarding two early lithotripters, the unmodified Dornier HM3 and the Siemens Lithostar (Lingeman et al, 1989b; Tolley et al, 1991). The HM3 and Lithostar were compared by integration of stone-free rates stratified by size into a regression model (Fig. 44–12). The stone-free rate achieved with the unmodified HM3 lithotripter was significantly better than that with the less powerful Lithostar. To date, despite the proliferation of lithotripters and the variety of solutions devised for stone targeting and shockwave delivery, no other lithotripter system has convincingly equaled or surpassed the results produced by the unmodified Dornier HM3 device. That the most effective

lithotripter was invented first is a remarkable achievement for Dornier. In general, the less powerful lithotripters with smaller focal points result in lower stone-free rates or higher re-treatment rates (Table 44–10).

Several comparative trials of lithotripters have been reported, most of which involve studies of second-generation machines (the modified HM3 is considered a second-generation device). Tan and associates (1991) from Singapore reported a small nonrandomized series comparing an unmodified Dornier HM3 with an EDAP LT.01 and Sonolith 2000 (an earlier version of the Sonolith 3000) in which they found 3-month stone-free rates of 66%, 67%, and 58%, respectively, with re-treatment rates of 4%, 42%, and 26%, respectively. **This is the only direct (albeit nonrandomized) trial reported in the literature noting equivalent stone-free rates between the unmodified Dornier HM3 and second-generation lithotripters.** In the only other study comparing first- and second-generation lithotripters, Sofras and associates (1991) found that the unmodified Dornier HM3 achieved significantly higher stone-free rates overall than did the EDAP LT.01. However, for small renal calculi (<1 cm), the machines achieved equivalent stone-free rates. The re-treatment rates and running costs were higher for the EDAP LT.01. No other comparative trials have been reported that included an unmodified HM3 device.

Rassweiler and colleagues (1989) compared a modified (low-pressure generator and small F2) Dornier HM3 and Wolf Piezolith 2200 (predecessor of the Piezolith 2300). Stone-free rates were not reported, but stone fragmentation rates were equivalent. Re-treatment was necessary in 12% of the modified Dornier HM3 patients and 54% of the Wolf Piezolith cases. In addition, this was one of the first reports to note problems with sonographic stone localization of ureteral calculi; 5% of ureteral stones failed to be localized with ultrasound. Siebold and associates (1988) also compared a modified Dornier HM3 with another Dornier device, the MPL 9000, once again noting problems with ultrasound for stone localization and assessment of stone fragmentation. Fragmentation rates were lower for the MPL 9000 than for the modified HM3 (73% versus 95% successful disintegration). In addition, 18% of patients initially starting therapy with the MPL 9000 eventually crossed over to complete their lithotripsy therapy in the modified HM3 device, whereas only 3% of patients being treated with the modified HM3 crossed over to the MPL 9000. The Dornier HM4 lithotripter with a low-pressure generator was compared with the Dornier MPL 9000 in a study by Tailly (1990). Tailly noted that the MPL 9000 appeared to be a more efficient machine, with a slightly lower re-treatment rate than the modified Dornier HM4 (1.11 versus 1.17), but he also noted problems with sonographic stone localization for both ureteral stones and obese patients. The MPL 9000 device was initially produced only with ultrasound imaging (as it was intended primarily for biliary applications) but subsequently became available with an integrated x-ray system.

Bierkens and associates (1992) examined five second-generation lithotripters (Siemens Lithostar, Dornier HM4, Wolf Piezolith 2300, Direx Tripter X-1, and Breakstone) in a multicenter trial involving more than 1800 patients. The overall stone-free rate was only 45% with a re-treatment rate of 20%. There were no significant differences in the stone-free rates among the various machines (Siemens Lithostar, 49%; Dornier HM4, 53%; Wolf Piezolith 2300, 45%; Direx Tripter X-1, 50%; Breakstone, 60%). Re-treatment rates were higher with the Wolf Piezolith 2300 than with the other lithotripters. A prospective randomized trial comparing the modified Dornier HM3 with the Dornier MFL 5000 was reported by Chan and colleagues (1995). Although more patients with larger stones were treated with the HM3, overall stone-free results were equivalent for the two machines. Of further interest, they noted that the stone-free rate achieved in the lower pole for the modified HM3 was significantly better than that achieved by the MFL 5000 (80% versus 56%; $P = .05$). Chan's group also noted that treatment times were significantly shorter with the unmodified HM3 device and concluded that the MFL 5000 lithotripter offered no significant clinical advantage over the modified HM3 in terms of lithotripsy efficacy, although the multifunctional table did provide more versatility for stone treatment (i.e., ureteral stones). Since these two lithotripters use the same ellipsoid and shockwave generator, this study supports the observation of others that a water bath is the ideal mechanism for transmitting shockwave energy into the body (Rassweiler et al, 1992).

It is now recognized that SWL inflicts a trauma similar to a renal contusion, which occasionally can result in adverse clinical sequelae. Potential concerns about the long-term

effects of lithotripsy with the unmodified Dornier HM3 device may have been one motivating factor in the trend within the lithotripsy industry toward, at first, lower power but eventually higher power lithotripters with smaller focal points, with the goal that the efficacy of lithotripsy could be maintained while producing fewer deleterious effects on renal tissue (Fig. 44–13). Unfortunately, **the newer lithotripters are less efficacious than the original Dornier device, and no published information is available to suggest that newer lithotripters produce fewer adverse effects for equivalent degrees of efficacy.** Fortunately, although further study is necessary to fully characterize the bioeffects of SWL, early concerns about a markedly adverse long-term effect of lithotripsy to all patients receiving this form of treatment have not materialized, thereby eliminating any reason to move away from the concept of a powerful lithotripter with a large F2 such as the unmodified Dornier HM3 (Williams et al, 1988; Lingeman et al, 1990). The amount of lithotripsy that can be safely tolerated by a kidney during a single session of SWL remains to be determined for any of the currently available lithotripters. This is an unfortunate circumstance and one that should be addressed by the development of appropriate animal models allowing the proper dose of lithotripsy to be established for each device (Evan et al, 1991, 1998). **On the positive side, research in lithotripsy has provided a much better understanding of the mechanisms of shockwave action in SWL and has made progress in defining the characteristics of renal injury and the consequences of shockwave trauma. This research has also been an important stimulus to the effort to improve lithotripters and has suggested new strategies that may improve outcomes of patients.**

Mechanisms of Stone Comminution

Present knowledge in the field of SWL suggests that comminution of a renal stone in a lithotripter field is the consequence of failure of the stone material due to the mechanical stresses produced either directly by the incident shockwave or indirectly by the collapse of cavitation bubbles. These events could be occurring simultaneously or separately at the surface of the stone or within the interior of the stone (Fig. 44–14). Several potential mechanisms for SWL stone breakage have been described: spall fracture, squeezing, shear stress, superfocusing, acoustic cavitation, and dynamic fatigue.

Before each of these mechanisms is discussed, consideration of the typical shockwave profile is required. A typical pressure pulse generated by an electrohydraulic shockwave lithotripter is shown in Figure 44–15. It involves **an initial short and steep compressive front with pressures of about 40 MPa that is followed by a longer, lower amplitude negative (tensile) pressure of 10 MPa, with the entire pulse lasting for a duration of 4 μs.** Note that the ratio of the positive to negative peak pressures is approximately 5. Pressure measurements near the focal region of a Dornier unmodified HM3 indicate a 6-dB beam, of a width of approximately 15 mm. Since kidney stones are also generally of this dimension, the wave front incident on the stone can be considered a plane wave (Muller, 1990; Cleveland et al, 2000).

The first mechanism by which a stone might break is through spall fracture. Once the shockwave enters the stone, it will be reflected at sites of impedance mismatch. One such location is at the distal surface of the stone at the stone-fluid

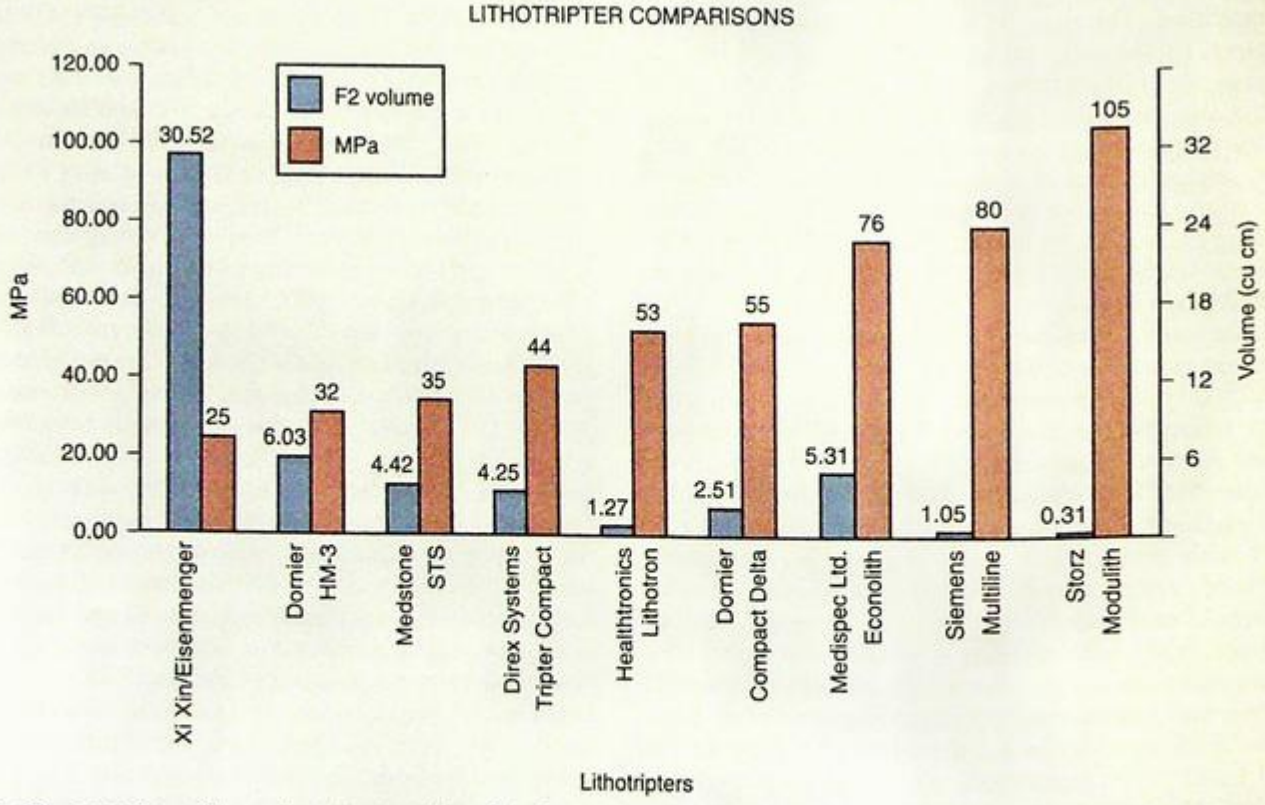

Figure 44–13. Comparison of the peak amplitude and size of the focal volume of nine different lithotripters. The general trend (from left to right) is a decrease in the device focal volume and an increase in the peak positive pressure. At the far left is the Xi Xin/Eisenmenger lithotripter, a new design that goes against the trend with a diminished peak amplitude and enlarged focal area.

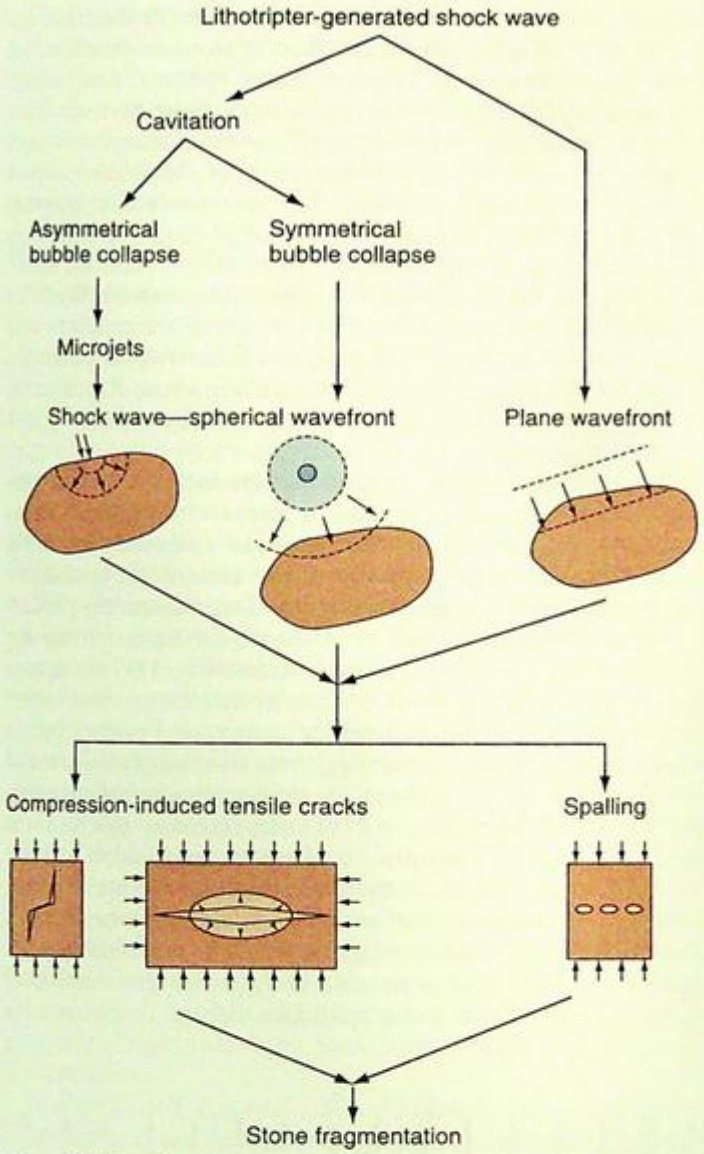

Figure 44–14. Summary of how the various mechanical forces generated by a lithotripsy shockwave might cause a kidney stone to fracture. (Reproduced with permission of Dr. Bradley Sturtevant.)

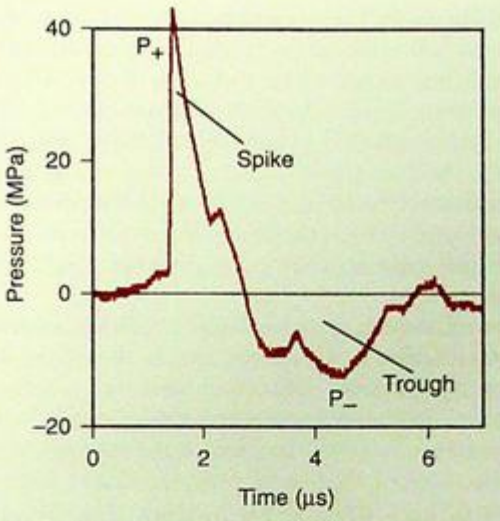

Figure 44–15. A typical pressure pulse at the lithotripter focus (F2) as measured by a PVDF membrane hydrophone. First, there is a steep positive pressure front of about 40 MPa, which is followed by a negative pressure of 10 MPa, with the entire pulse lasting for a duration of 4 μs. (From Coleman AJ, Saunders JE, Preston RC, et al: Pressure waveforms generated by a Dornier extracorporeal shockwave lithotriptor. Ultrasound Med Biol 1987;13:651-657.)

(urine) interface (although there could be other internal sites, such as cavities in the stone and interfaces of crystalline and matrix materials). As the shockwave is reflected, it is inverted in phase to a tensile (negative) wave. If the tensile wave exceeds the tensile strength of the stone, there is an induction of nucleation and growth of microcracks that eventually coalesce, resulting in stone fragmentation, which is termed spallation. The failure plane is located perpendicular to the applied tensile stress. This mechanism is thought to be of considerable importance in that kidney stones, like most brittle materials, will be much more likely to fail under tension rather than compression (Johrde and Cocks, 1985). Lokhandwalla and Sturtevant (2000) have suggested that the trailing negative pressure of the lithotripter pulse also exerts tensile stresses of an order of magnitude similar to that of the spall mechanism. Contributing factors to the effectiveness of spallation in generating stone breakage appear to be the size and the shape of the stone as well as its physical properties (i.e., fracture toughness, acoustic speed, density, and void dimensions). More spherically shaped stones may focus the tensile wave after reflection and thus further increase the tensile stress. Stones with larger diameters may allow sufficient tensile stress to be generated so that the tensile strength of the stone can more easily be exceeded. If these factors are important, then smaller, irregularly shaped stones may not fracture by spallation.

Eisenmenger (1998) has suggested that **the second mechanism for stone breakage, termed squeezing-splitting or circumferential compression, occurs because of the difference in sound speed between the stone and the surrounding fluid.** The shockwave inside the stone advances faster through the stone than the shockwave propagating in the fluid outside of the stone. The shockwave that propagates in the fluid outside of the stone thus produces a circumferential force on the stone, resulting in a tensile stress in the stone that is at its maximum at the proximal and distal ends of the stone. The resulting squeezing force could split the stone either in a plane parallel to the shockwave propagation direction or, depending on the elastic properties of the stone, possibly in a plane parallel to the shockwave front. It has been theorized that squeezing should be enhanced when the entire stone falls within the diameter of the focal zone. Thus, current third-generation lithotripters that have very small focal zones will not make use of this mechanism, as the stone size is typically greater than the focal zone, whereas the original Dornier HM3 machine would.

The third mechanism is shear stress. Shear stress will be generated by shear waves (also termed transverse waves) that develop as the shockwave passes into the stone. The shear waves propagate through the stone and will result in regions of high shear stress inside the stone. In contrast to compression waves, which move the molecules in the direction of propagation, a shear wave results in translation of molecules transverse to the direction of propagation, and therefore the molecules are not compressed but are shifted sideways by the wave. Many materials are weak in shear, particularly if they consist of layers, as the bonding strength of

the matrix between layers often has a low ultimate shear stress. Calcium oxalate stones commonly possess alternating layers of mineral and matrix, and the shear stress induced by the transverse wave could cause such stones to fail. Theoretical work by Sapozhnikov and colleagues (2003) suggests that the shear wave mechanism will lead to a tensile strain in cylindrical stones that is 5 to 10 times larger than that induced by spall. They also suggest that cracks will be initiated in the center of the stone and grow in a direction perpendicular to the axis of the stone.

The fourth mechanism for stone breakage, superfocusing, is the amplification of stresses inside the stone due to the geometry of that stone. The shockwave that is reflected at the distal surface of the stone can be focused either by refraction or by diffraction from the corners of the stone. Several groups have demonstrated that these reflected waves can be focused to regions of high stress in the interior of the stone and that this can lead to failure (Gracewski et al, 1993; Xi and Zhong, 2001). The regions of high stress (both tensile and shear) are dependent on the geometry of the stone as well as its elastic properties.

The fifth potential mechanism for SWL stone breakage is cavitation (Coleman et al, 1987; Crum, 1988; Vakil and Everbach, 1993; Zhong and Chuong, 1993; Zhong et al, 1993). Cavitation is defined as the formation and subsequent dynamic behavior of bubbles. The lithotripter-generated pressure field has been found to induce cavitation in both in vitro and in vivo studies. The negative pressure in the trailing part of the pulse causes bubbles to grow at nucleation sites. A nucleation site is an inhomogeneity in the fluid, which leads to preferential formation of free gas under stress. During the negative pressure wave, the pressure inside the bubble falls below the vapor pressure of the fluid, and the bubble fills with vapor and grows rapidly in size (almost three orders of magnitude). As these bubbles grow, they oscillate in size for about 200 μs and then collapse violently, giving rise to high pressures and temperatures. In the absence of any boundaries, a cavitation bubble remains spherical during collapse, releasing energy primarily by sound radiation, the majority of which is in the form of a shockwave (see Fig. 44–14). This shockwave generates a positive and negative wave and therefore can induce all of the fragmentation mechanisms described in the preceding. However, in the presence of a boundary, a liquid jet, also termed a cavitation microjet, forms inside the bubble during the collapse (see Fig. 44–5) (Crum, 1979, 1988). This jet can accelerate to extremely large speeds because it converts most of its kinetic energy from the collapse of the cavity interface to the jet itself. The typical bubble radii found in SWL vary from 1 μm to 1 mm, and bubble jet velocities range from 22 m/s to 800 m/s. In actual jet-impact cases, the duration of the pressure pulse is only a few microseconds, and in most instances, the peak pressure lasts for only about 1 μs. If the liquid jet is near the surface of a stone, it creates a locally compressive stress field in the stone, which propagates spherically into the stone interior.

Numerous investigators have exposed either aluminum foil or brass plates to the focused shockwave generated by a Dornier HM3 and observed significant microjet damage (pitting) on the surfaces of these metals. If this event occurs at the surface of a kidney stone, erosion of this surface would be expected; Averkiou and Crum (1996) reported this event for SWL-treated plaster of Paris target stones. To determine if cavitation is the primary mechanism of stone fragmentation, investigators have developed in vitro systems that would eliminate or dampen cavitational events. Such systems have included a viscous medium that possesses a much lower number of nucleation sites and a chamber that allows one to increase the ambient pressure that surrounds the growing cavitation bubbles (Delius, 1997; Stonehill et al, 1998; Vakil et al, 1991). These in vitro systems have shown reduced stone damage along with a reduction in cavitation activity. Work by Bailey and associates (1998, 1999), in which the positive and negative waves were inverted with a pressure release reflector, also showed a reduction in stone comminution. All of these studies suggest that cavitation plays a significant role in damaging brittle objects.

The final mechanism of stone fragmentation to be considered defines stone breakage in terms of a dynamic fracture process, in which the damage induced by SWL accumulates during the course of the treatment, leading to the eventual destruction of the stone. Essential to this process is nucleation, growth, and coalescence of flaws within the stone caused by a tensile or shear stress (Fig. 44–16; see also Fig. 44–14). As renal calculi are not homogeneous but rather have either a lamellar crystalline structure bonded by an organic matrix material or an agglomeration of crystalline and noncrystalline material, there are numerous sites of preexisting flaws (microcracks). All of the fracture mechanisms described have the potential to generate progressive damage to the interior of the stone. By use of the cohesive-zone model, a mathematical approach of predicting the qualitative features of transient microcrack damage accumulation, Lokhandwalla and Sturtevant (2000) were able to calculate the number of shockwaves required for a spall-like failure to occur in a

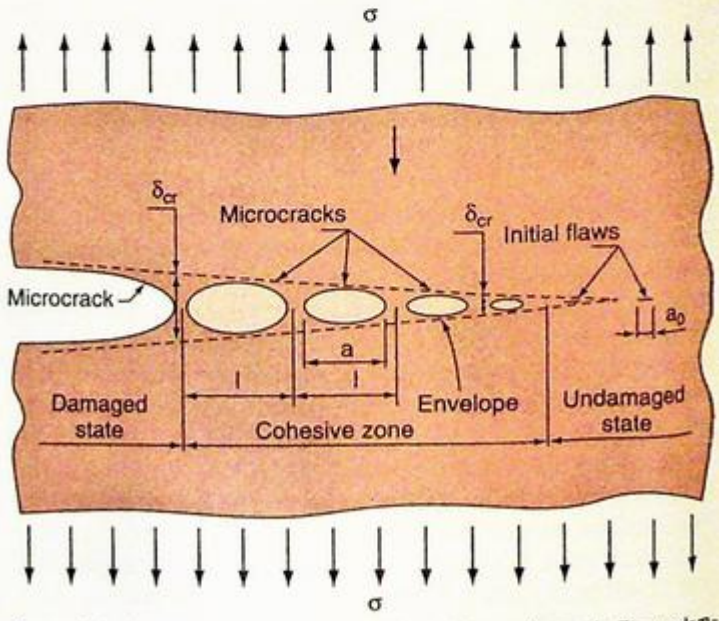

Figure 44–16. Coalescence of microcracks with a main crack. The undamaged stone has some initial flaws or microcracks of known length. These flaws occur in renal calculi either at a lamellar crystalline structure bonded by an organic matrix material or at an agglomerate of crystalline and noncrystalline material. When stressed, these microcracks grow until they coalesce with the main crack, and because this event is repeated throughout the stone, it eventually fragments. (Reproduced with permission of Dr. Bradley Sturtevant.)

typical calcium oxalate monohydrate calculus. The values they determined had a range of two orders of magnitude (30 to 3000 shocks), which is well within the clinical dose presently used to treat patients. These investigators further suggested that mechanisms other than spall are also likely to inflict damage to stones, and spall may be a factor only in a small portion of the stone.

Bioeffects: Clinical Studies

Acute Extrarenal Damage. SWL induces acute injury in a variety of extrarenal tissues (Evan et al, 1991, 1998). Patients receiving more than 200 shocks show gross hematuria, which generally resolves within 12 hours (Chaussy and Schmiedt, 1984; Kaude et al, 1985). Hematuria occurs regardless of the type of lithotripter employed. Evan and associates (1989) have noted that the SWL-induced lesion extends from the kidney capsule to the tip of the medulla, which suggests that **hematuria is the result of direct injury to the renal parenchyma.** Patients treated with an unmodified HM3 device at 18- to 24-kV settings commonly complain of pain localized to the posterior body wall (flank) near the site of shockwave entry (Lingeman et al, 1986a). The unmodified HM3 has been associated with significant trauma to such organs as the liver and skeletal muscle as detected by elevated levels of bilirubin, lactate dehydrogenase, serum aspartate transaminase, and creatine phosphokinase within 24 hours of treatment (Lingeman et al, 1986a; Ruiz Marcellan and Ibarz Servio, 1986; Parr et al, 1988). These parameters begin to fall within 3 to 7 days of SWL treatment and are normal at 3 months. Most of these deleterious effects were associated with the use of an unmodified HM3 lithotripter. However, this does not mean that the unmodified HM3 device is more likely to induce injury; rather, current clinical studies of second- and third-generation machines may have inadequately reported such complications.

Changes such as gastric and duodenal erosion have been identified and are thought to represent a common extrarenal complication of SWL therapy (Al Karawi et al, 1987). The lung parenchyma can suffer injury if it is exposed directly to shockwaves (Chaussy and Fuchs, 1986). Several cases of clinically typical acute pancreatitis, associated with a marked rise in serum amylase and lipase levels, have been observed, and even in the absence of the symptoms of overt pancreatitis, increased amylase levels have been detected (Drach et al, 1986; Lingeman et al, 1986a). Hematochezia immediately after SWL secondary to mucosal damage of the colon has also been documented (Cass, 1988). Myocardial infarctions, cerebral vascular accidents, and brachial plexus palsy have been noted after SWL. In addition, early clinical studies noted that shockwaves could induce cardiac arrhythmia, an observation that led to electrocardiographic synchronization with R-wave triggering on the Dornier HM3 device (Chaussy and Schmiedt, 1984). However, later clinical studies with non-water bath lithotripters have concluded that ungating is safe. As a consequence, many clinicians began to treat at faster rates, up to 2 Hertz, which was not possible with the gated devices. Paterson and associates first questioned the effect an accelerated treatment rate may have on stone breakage in a series of porcine studies that demonstrated inferior stone fragmentation at higher treatment rates (Paterson et al, 2002). These data were confirmed in prospective randomized studies performed by Madbouly and associates and Pace and associates (Madbouly et al, 2005; Pace et al, 2005). However, **recent evidence has demonstrated that increasing the rate of SWL delivery reduces the efficiency of stone breakage** (Paterson et al, 2002; Madbouly et al, 2005; Pace et al, 2005).

Acute Renal Injury: Structural and Functional Changes. SWL is now known to induce acute structural changes in the treated kidney in the majority if not all of SWL patients. Morphologic studies using both MRI and quantitative radionuclide renography have suggested that 63% to 85% of all SWL patients treated with an unmodified HM3 lithotripter exhibit one or more forms of renal injury within 24 hours of treatment (Kaude et al, 1985; Knapp et al, 1987; Wilson et al, 1989). These values are much larger than those reported by Chaussy and Schmiedt (1984), who described the sonographic detection of clinical hematomas in 0.6% of cases. These changes are not specific to any particular lithotripter, and numerous reports have documented identical renal bioeffects induced by second- and third-generation lithotripters (Thuroff et al, 1988; Ueda et al, 1993; Kohrmann et al, 1995; Piper et al, 2001).

The two most common renal side effects seen immediately after SWL are hemorrhage and edema within or around the kidney. Frequently, the kidney is enlarged and there is a loss of corticomedullary demarcation, suggesting acute intrarenal edema; although clinically significant fluid collections were initially determined to occur in less than 1% of SWL treatments, this incidence rises when CT or MRI is used for screening (Chaussy and Schmiedt 1984; Kaude et al, 1985; Rubin et al, 1987; Knapp et al, 1988; Mobley et al, 1993; Krishnamurthi and Streem, 1995). In addition, the newer generation lithotripters that have small focal areas and extremely high peak positive pressures are reported to produce higher clinically significant hematoma rates (3% to 12%), a trend that is worrisome (Thuroff et al, 1988; Ueda et al, 1993; Kohrmann et al, 1995; Piper et al, 2001). Dhar and associates (2004) reported clinical results with a Storz Modulith that demonstrated the probability for development of a subcapsular hematoma increased 2.2 times for every 10-year increase in the patient's age. The appearance of these changes can range in severity from a mild contusion localized within the renal parenchyma to a large hematoma (Fig. 44–17) associated with severe bleeding, possibly necessitating blood transfusion or rarely even arteriographic embolization. Such hemorrhage may produce a state of acute renal failure, and death may result if the condition is not identified in a timely fashion (Stoller et al, 1989). Rubin and associates (1987), with CT imaging, found an increase in the number of septal strands and a thickening of Gerota's fascia after SWL, suggesting focal regions of edema. In general, perirenal fluid disappears within a few days, whereas subcapsular fluid or blood may take 6 weeks to 6 months (or more) to resolve (Knapp et al, 1988).

Rigatti and associates (1989) performed a histopathologic study documenting acute changes in the kidney and surrounding tissues of SWL-treated patients. Renal biopsy specimens obtained within 1 week of SWL treatment revealed marked tubular, vascular, and interstitial changes that were localized to the plane of the pressure wave. Most renal corpuscles in this zone were disrupted, and the rest of the nephron showed mild degenerative changes with an

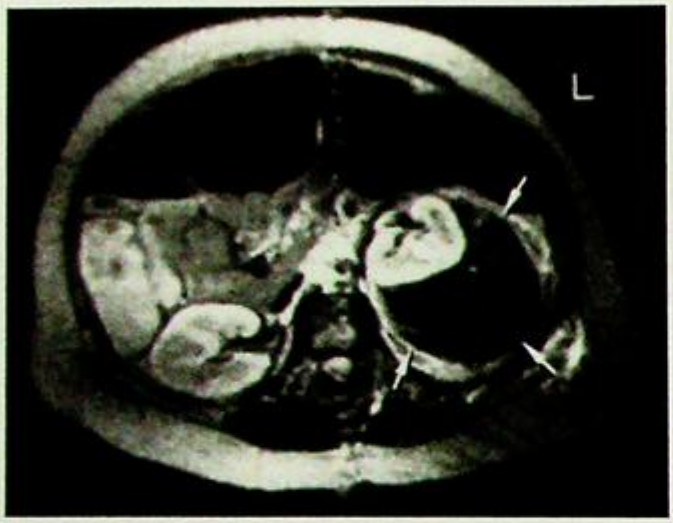

Figure 44–17. MRI scan taken 24 hours after SWL with 1200 shocks at 22 kV (by an unmodified Dornier HM3 lithotripter) shows a large subcapsular hematoma *(arrows)* in the treated (left) kidney.

accumulation of hemosiderin granules and cast material. Alterations in the microvasculature included dilation of veins, with evidence of endothelial damage and thrombus formation. Seitz and colleagues (1991) studied the kidneys from four patients treated with a piezoelectric lithotripter and detected sites of intraparenchymal hemorrhage at the corticomedullary junction that increased in severity with increasing numbers of shocks (4000 to 20,000). They commented that the gross and histologic appearances of these four SWL-treated kidneys mirrored exactly the results of animal studies published by others. Another approach used to determine the type and degree of injury induced by SWL in the human kidney has been to treat a human cadaver kidney with SWL (Brewer et al, 1988; Roessler et al, 1993). These studies clearly show that a **clinical dose always induced injury to the nephrons and small to medium-sized blood vessels within F2.** As the number of shockwaves was increased, so too was the amount of damage detected. In addition, Roessler and colleagues (1996) determined the size of a lesion induced by an electromagnetic versus an electrohydraulic lithotripter. They found a much larger lesion with the electrohydraulic machines; however, the electromagnetic machine produced complete cellular destruction at F2, an observation that may explain the higher rate of subcapsular hemorrhage for electromagnetic lithotripters. The ex vivo nature of this model has numerous disadvantages that limit the applicability of these studies to an in vivo setting.

There have been numerous observations documenting injury to the nephron, as defined by the elevation of several tubular enzymes in the urine immediately after SWL (Assimos et al, 1989a; Ruiz Marcellan and Ibarz Servio, 1986). Krongrad and colleagues (1991) noted in five men with unilateral urolithiasis that urine levels of *N*-acetyl-β-D-glucosaminidase, γ-glutamyltransferase, and β_2-microglobulin in diseased kidneys were elevated compared with the contralateral normal kidneys; however, there was not a statistically significant increase during the initial 24 hours after SWL. They suggested that the elevation was a result of a tubular defect in association with stone disease and not in response to SWL treatment. Nonetheless, the majority of observations suggest that all portions of the kidney and surrounding tissues are vulnerable to shockwaves, and the microvasculature may be the most susceptible.

Acute alterations in renal function have not been well described in SWL patients as few studies have attempted to follow parameters of renal function after SWL. Kaude and associates (1985) found an immediate decrease in effective plasma flow, measured by renal scans, in 30% of kidneys treated with SWL. Others have also noted a delay in excretion of contrast material in unobstructed kidneys undergoing SWL (Grantham et al, 1986). The decrease in renal function has been linked to the number of shocks administered. These studies are supported by observations that there is an apparent transient reduction of intrarenal blood flow at F2 as well as in the untreated kidney (Bomanji et al, 1987; Eterovic et al, 1999; Kataoka et al, 1993; Mostafavi et al, 1998a). These changes can be blocked with pretreatment pharmacologic manipulations (Strohmaier et al, 1994; Chan et al, 2000). Thomas and associates (1988) have reported that a treatment regimen of approximately 1500 shocks is safe, and others have demonstrated that the administration of greater numbers of shocks will induce a fall in renal plasma flow (Graff et al, 1988). Orestano and associates (1989) noted that fewer than 2500 shocks produced changes in renal function that totally regressed by 30 days after SWL. Their observations showed that more than 2500 shocks induced more extensive changes in renal function (reduction in creatinine clearance, prolonged ^{131}I-Hippuran transit time) in the treated kidney as well as in the contralateral kidney. In a study of solitary kidneys, Karlsen and Berg (1991) reported a significant reduction in glomerular filtration rate 3 months after SWL.

A group of investigators from the University of Innsbruck has conducted a prospective study in which they measured resistive index in a group of patients receiving a clinical dose of shockwaves sufficient to comminute a stone (mean, 2725 shockwaves; 16 to 28 kV, Dornier MFL 5000 lithotripter) (Janetschek et al, 1997). The results were stratified by age of the patients, and the only patients who were excluded from the study were those who had documented vascular disease. Resistive indices were elevated immediately after SWL in the treated kidney (but not in the contralateral kidney) of patients older than 60 years. Seventy-five percent of the patients in this age group exhibited a pathologically high resistive index, and at 26 months, 15 of the 20 patients in this group still demonstrated a statistically elevated value. Aoki and colleagues (1999) also found a larger increase in resistive index in elderly patients. In 45% (9 of 20) of these patients, resistive indices continued to increase, and these patients also developed new-onset hypertension. No changes were found in the plasma renin activity at any time point. The authors concluded that there is a strong positive correlation between elevated resistive index and blood pressure, that this is indicative of underlying renovascular disease, and that age is a risk factor for long-term complications in SWL.

All of the studies cited in this section indicate that **renal function is adversely affected, acutely, in some patients and that the primary change appears to be a vasoconstrictive response resulting in a fall in renal blood flow and glomerular filtration rate.** There are reports that SWL can result in a significant improvement in renal function in some patients (Chaussy and Schmiedt, 1984). However, many such patients

Age
Obesity
Coagulopathies
Thrombocytopenia
Diabetes mellitus
Coronary heart disease
Preexisting hypertension

show evidence of ureteral obstruction before treatment, thereby biasing such findings.

Risk factors may predispose SWL patients to increased acute renal injury. Knapp and associates (1988) found **patients with existing hypertension to be at increased risk for the development of perinephric hematomas as a consequence of SWL** (Table 44–11). In particular, those patients having unsatisfactory control of their hypertension at the time of SWL had the highest incidence of hematoma formation. Dhar and colleagues (2004) reported that the probability for development of a subcapsular hematoma after SWL with a Storz Modulith increased 2.2 times for every 10-year increase in the patient's age. Additional risk factors included increased thromboplastin time and the use of aspirin (even when it was discontinued up to 2 weeks before treatment). When the voltage applied and the number of shockwaves administered were evaluated as potential risk factors, no correlation with hematoma formation was found. Newman and Saltzman (1989) have also confirmed these observations, noting that patients with coagulopathies and thrombocytopenia were at greater risk for development of a subcapsular hematoma. Additional risk factors for hemorrhage were diabetes mellitus, coronary artery disease, and obesity, all of which suggest a link to a vascular disorder (see Table 44–11). In relation to risk factors, an interesting observation is that some patients with preexisting hypertension require increased doses of their blood pressure medication after SWL therapy (Kaude et al, 1985). Age is a factor on both ends of the spectrum in that children and the elderly both appear to be at increased risk for structural and functional changes (Janetschek et al, 1997; Lifshitz et al, 1998).

In addition to the risk factors described, another set of risk factors are linked to the parameters of treatment. These factors include discharge voltage, number of total shockwaves administered, rate of shockwave delivery, and type of lithotripsy. Most of these data have been collected in animals and are reviewed later.

Chronic Renal Injury: Structural and Functional Changes. Although there still remains a paucity of information on the subject, **four potential chronic renal changes that follow SWL are emerging. They are an accelerated rise in systemic blood pressure, a decrease in renal function, an increase in the rate of stone recurrence, and the induction of brushite stone disease. All four effects appear to be linked to the observation that the acute injury does progress to scar formation at F2.** Lechevallier and associates (1993) performed pre- and post-SWL (30 days) single-photon emission computed tomography studies in 12 patients treated with a piezoelectric lithotripter. All SWL-treated kidneys showed some loss of renal function; 4 of the 12 kidneys showed a loss of local tracer uptake of more than 4%. In addition, seven scars were detected in the region of F2. Umekawa and associates (1994) examined the kidney of a patient in acute renal failure that occurred 90 days after SWL treatment and found evidence of anti–glomerular basement membrane antibody production in glomeruli at F2.

The possibility that SWL might be associated with significant changes in systemic blood pressure was first suggested by Peterson and Finlayson (1986) and has been investigated by others (Table 44–12). Lingeman and coworkers (1987a) reported that 8.2% of 243 patients who were normotensive at the time of SWL developed blood pressure changes requiring antihypertensive medication. Mean follow-up in this group of patients was 1.5 years, giving an annualized incidence of hypertension of 5.5%. Similar data have been reported by Williams and Thomas (1989). Following these reports suggesting that hypertension could be a long-term complication of SWL, a large study involving almost 1000 patients was undertaken at the Methodist Hospital of Indiana (Lingeman et al, 1990). This study found a small but statistically significant change in diastolic blood pressure associated with SWL therapy. The observed effect of SWL on diastolic pressure change persisted even after controlling statistically for other

*Shockwave lithotripsy–treated patients compared with control group not undergoing therapy.

variables that might be associated with variation in blood pressure, such as age, sex, pretreatment baseline blood pressure, and number of treatment sessions. Strohmaier and colleagues (2000) studied 252 patients with stone disease during a 24-month period to determine if treatment modality influenced their blood pressure after stone removal. The different treatment protocols for stone removal included SWL, ureteroscopy, PNL, and spontaneous passage of renal and ureteral stones. All patients regardless of stone location or treatment type showed a rise in blood pressure. Eterovic and colleagues (2005) obtained blood pressure measurements and renal vascular resistance before and 3 months after stone removal in 30 patients treated by SWL and in another 30 patients treated by Gil-Vernet intrasinus pyelolithotomy. They noted a drop in blood pressure and renal vascular resistance from baseline in the pyelolithotomy-treated patients but no change in the SWL-treated patients, suggesting that SWL results reflect a balance between the relief of obstruction and an SWL-induced lesion. Janetschek and colleagues (1997) showed that by stratifying their results by age of the patient, there was a long-term change in both blood pressure and resistive index. What is not known at this time is the future health risk for these patients or who is at risk. Because the long-term effects of hypertension, if it is occurring, include an increased risk of stroke, myocardial infarction, and renal failure, any therapy that might increase the incidence of hypertension should be rigorously examined.

The possibility that SWL treatment might be associated with a long-term reduction in renal function has been suggested by several investigators. Williams and associates (1988) found a **significant decrease in the percentage of effective renal plasma flow 17 to 21 months after SWL for patients with two kidneys**. Orestano and colleagues (1989) noted that patients receiving more than 2500 shocks had a reduction in creatinine clearance and a prolongation of ^{131}I-Hippuran transit time 30 days after SWL in the treated kidney; in some cases, similar findings were noted in the contralateral kidney. Lingeman and associates have reported that patients with a solitary kidney demonstrated elevated serum creatinine levels 5 years after SWL (Brito et al, 1990). These observations stand in contrast to the early reports by Chaussy and Fuchs (1986), which suggested a significant increase in renal function 3 months to 1 year after SWL. In addition, a longer follow-up study of patients treated in Munich has failed to confirm this increase in renal function (Liedle et al, 1988).

An additional concern is that **stone recurrence rates may be higher after SWL because of residual stone debris** (Pearle et al, 1999). A study by Carr and associates (1996) documented new stone formation in 298 consecutive patients who initially were determined to be stone free after SWL and compared those findings with those of 62 patients treated by PNL. Their data showed a significant increase in the rate of new stone formation within 1 year of SWL treatment compared with PNL. The authors suggested that fine sand debris generated from SWL treatment remained in the kidney and gravity acted to position it as a nidus in the calyceal system.

There has been reported to be a significant increase in the number of calcium phosphate stone formers during the last three decades (Mandel et al, 2003; Parks et al, 2004). An intriguing finding in Parks' work was that when all kidney stone formers were analyzed for the number of SWL procedures, the **calcium phosphate stone formers had received significantly higher number of procedures than did the idiopathic calcium oxalate stone formers when rates were adjusted for number of stones and duration of stone disease**. Furthermore, the brushite stone formers had received a significantly greater number of SWL treatments than had the apatite stone formers. The histopathologic examination of the brushite stone formers revealed advanced levels of tissue changes in the renal cortex and papilla that included interstitial fibrosis, tubular atrophy, glomerular obsolescence, and deposition of large amounts of biologic hydroxyapatite in the lumens of inner medullary collection ducts (Evan et al, 2005). Although these data do not establish a cause and effect relationship, clearly there is an association between brushite stone disease and high levels of SWL treatment sessions. As apatite stone disease is likely to be related to higher urine pH levels in these patients, animal studies that showed the initial site of SWL injury to be localized to the microvessels and collecting duct of the renal papilla may explain the loss of control over normal urinary fluid pH.

Bioeffects: Experimental Animal Studies

Acute Renal Injury: Structural and Functional Changes. After the introduction of SWL, there was an early misperception that shockwaves did not produce injury and passed harmlessly through the body (Chaussy and Fuchs, 1986). Subsequent studies have demonstrated that SWL does, indeed, affect organ structure and function (Table 44–13).

On macroscopic examination, the acute changes noted in dog and pig kidneys treated with a clinical dose of shockwaves are strikingly similar to those described for SWL patients. This lesion is predictable in size, focal in location, and unique in the types of injuries (primarily vascular insult) induced. These changes include hematuria, contusion-like lesions, subcapsular hematomas, hemorrhage, and kidney enlargement. Although hemorrhage has been found in three general locations, perirenal, subcapsular, and intraparenchymal (Figs. 44–18 and 44-19), it is always at or near F2. The perirenal fat is a common site of extensive hemorrhage. Subcapsular hemorrhage is found to spread diffusely along the length of the capsule or to form discrete hematomas. Sites of intra-

Hyalinized and acellular scars from cortex to medulla

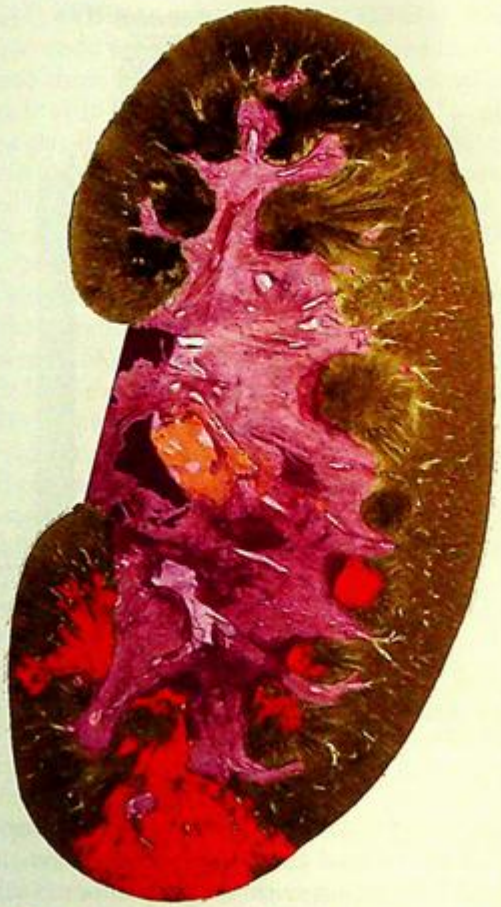

Figure 44–18. Macroscopic photomicrograph of a coronal section through the kidney of a juvenile pig (about 6 weeks old) treated with 2000 shocks at 24 kV by an unmodified Dornier HM3 lithotripter and examined 4 hours after treatment. The region of intraparenchymal hemorrhage has been colored red by an automated computer color recognition program. Note that the lesion involves multiple papillae and in some regions extends through the cortex to the renal capsule, where a subcapsular hematoma may develop.

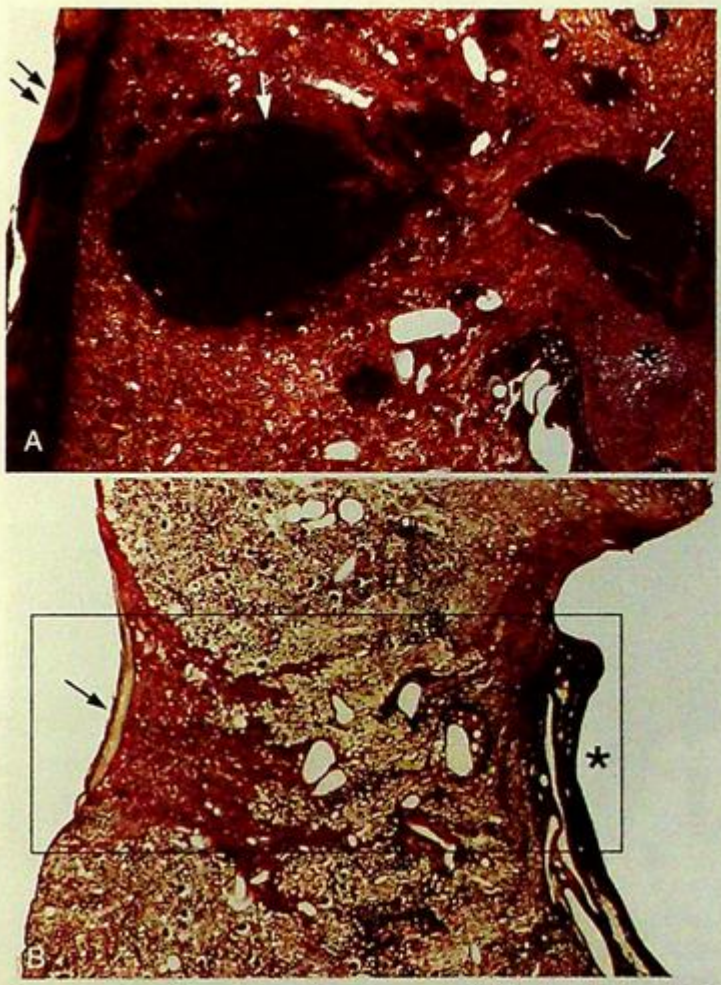

Figure 44–19. Light micrographs of an acute SWL-induced lesion at F2 (**A**) and subsequent chronic changes at a similar site 3 months after SWL treatment (**B**). Each pig kidney was treated with 2000 shockwaves at 24 kV by an unmodified Dornier HM3 lithotripter. The acute lesion is characterized by numerous sites of hemorrhage *(arrows)* that extend from individual renal papilla *(asterisk)* to the outer cortex of the kidney. Note a subcapsular hematoma *(double arrow)*. The tissue section in **B** is similar in location to that seen in **A** but is shown at 3 months after SWL. A rectangle outlines the site of F2. Within that region, there is complete loss of the renal papilla (the asterisk indicates where it should be), and only scar tissue is found in the adjacent cortical tissue *(arrow)*.

parenchymal hemorrhage are generally wedge shaped, being most severe at the corticomedullary junction and extending from the papillary tip to the capsule (see Fig. 44–19). Hematomas localized within the renal parenchyma or subcapsular zone may be up to 0.5 cm in diameter and may number up to 10 per kidney (Delius et al, 1988a, 1988b; Jaeger et al, 1988; Newman et al, 1987). The hemorrhagic lesion can occupy approximately 2% of the functional mass in an adult pig kidney that has been treated by an unmodified HM3 device with 2000 shocks at 24 kV (Willis et al, 1999). The larger hematomas appear to compress the adjacent tissue, interstitial edema is common, and the diffuse nature of this change would appear to account for enlargement of the kidney.

Regions of hemorrhage are always near the site of F2, and these regions are typically characterized by the rupture of small vessels such as thin-walled veins, small arteries, and glomerular and peritubular capillaries (Fig. 44–20; see also Figs. 44–18 and 44–19) (Evan et al, 1991; Willis et al, 1999). Furthermore, these findings correlate with the vasoconstriction measured in both the treated and untreated kidneys. Venous thrombi are frequently associated with interlobular and arcuate veins at the sites of hemorrhage. Evidence of extensive endothelial damage in these veins is noted by a loss of endothelial cells, the immediate attachment of numerous polymorphonuclear cells and activated platelets to the luminal surface of these vessels, and the appearance of vasculitis; damage to both the nephron and the vasculature is always seen first in the renal papilla and then in the cortex (Connors et al, 2000; Shao et al, 2003) (Fig. 44–21). Nephrons near areas of marked hemorrhage show evidence of direct damage from the shockwave and secondary changes that appear to be related to ischemia. These alterations consist of vacuolar changes in individual cells, tubular dilation, cast formation (hyaline-like, red blood cells), and mild tubular necrosis. These observations demonstrate that both the microvasculature and nephron are susceptible to shockwave damage; however, the primary injury appears to be a vascular insult.

Of great interest are those experimental animal studies that have determined factors of SWL administration that appear to influence the degree of renal trauma induced by shockwaves (Table 44–14). Several groups have noted that as shock

Table 44–14. Factors That Influence Degree of Renal Trauma in Animals

Aggravating factors
Increasing the number of shocks delivered
Administering a large number of shocks over a short period of time
Selecting a high voltage or high power setting
Treating a juvenile kidney or a kidney with impaired function
Mitigating factors
Pretreating with 100 to 500 shocks at low energy level

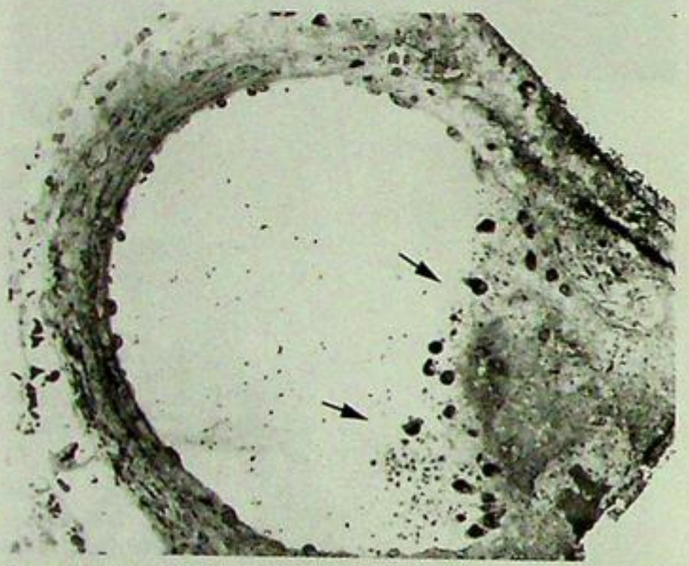

Figure 44–20. Low-magnification transmission electron micrograph demonstrating injury to a medium-sized artery located within F2 of a pig treated with 2000 shockwaves at 24 kV. The shockwave-induced injury to the right side of this vessel resulted in a rupture site that permitted extravasation of blood into the nearby interstitium. The site of injury in the vessel wall is plugged with a clot *(arrows)*.

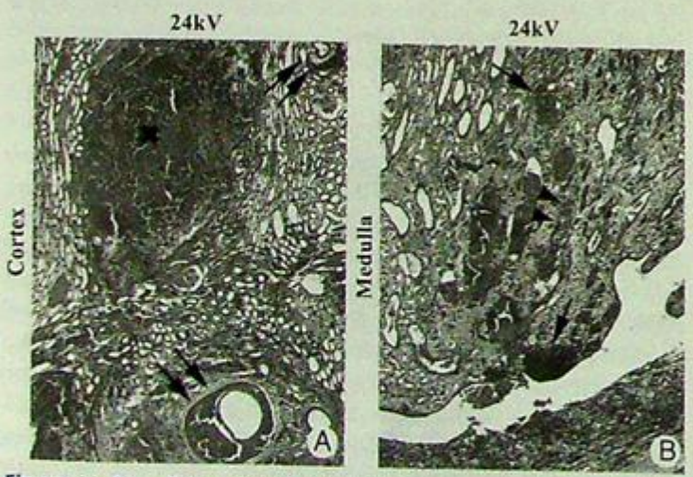

Figure 44–21. This series of light microscope panels depicts the injury seen in the cortex and medulla from an animal treated with 2000 shockwaves at 24 kV by an unmodified Dornier HM3 lithotripter. **A** and **B** illustrate extensive injury in both cortex and medulla. Within the cortex, disruption of arterial walls with hemorrhage *(double arrows)* is noted near sites of intraparenchymal bleeding *(x)*. The first site of injury appears to occur in the renal medulla, where damage is noted to small vessels, which causes intraparenchymal hemorrhage *(arrows)* adjacent to damaged collecting ducts *(arrowheads)*.

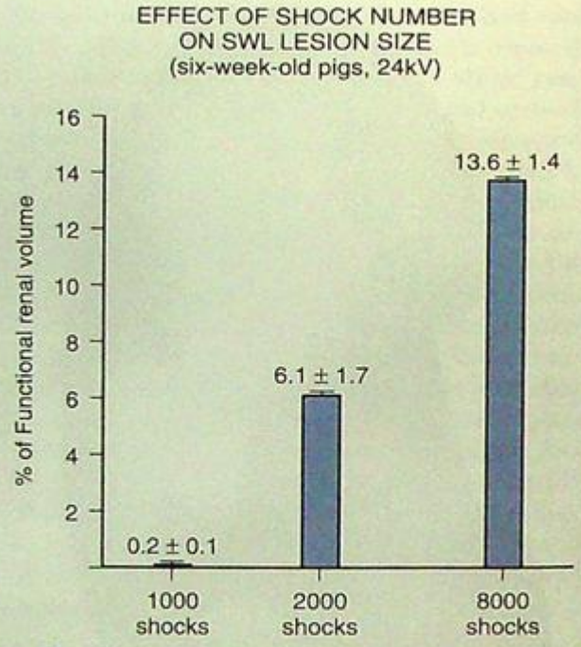

Figure 44–22. Effect of shock number (1000, 2000, and 8000 at 24 kV) on lesion size (percentage of functional renal volume) of 6-week-old pigs. Data are expressed as mean ± SEM, and all groups are statistically different from each other ($P < .05$).

number is increased (1000 to 8000 shocks), a greater number of hematomas are formed and lesion size increases, although not as a direct correlation with shock number (Delius et al, 1988b; Willis et al, 1999). An increased number of shockwaves also was associated with larger hematomas, probably related to the fact that larger arteries are injured at high shock numbers. It appears that 1000 shockwaves represents the threshold for tissue injury with the unmodified HM3 in that lesions begin to appear at this shock number and then grow rapidly in size as the shock number is increased (Fig. 44–22) (Willis et al, 2005). Delius and associates (1988b, 1990) have also reported that more massive hemorrhage and tubular damage are induced by increasing the rate (1 shock/second to 100 shocks/second) at which the shocks are administered and by administering the shockwaves in pairs. Kidney size has been shown to be a risk factor for increased intraparenchymal hemorrhage; lesion size has been reported to be 7% in a juvenile pig and 2% in an adult pig (Willis et al, 1996; Evan et al, 1998). In addition, Evan and associates (1999) noted that the degree of injury induced by a clinical dose of SWL is potentiated by a preexisting condition such as acute pyelonephritis. Under such conditions, a 2000-shock dose acts like an 8000-shock dose. Although the degree of renal injury has been linked to the type of shockwave generator used, these data are difficult to compare as the parameters for shockwave delivery are so variable among instruments (Morris et al, 1989).

An obvious void in the experimental SWL literature has been studies that examine changes in renal function after shockwave administration. Jaeger and Constantinides (1989) reported a significant decrease in creatinine clearance and an elevation of glucose excretion 1 hour after SWL in dogs treated with 3000 shocks (1500 shocks per pole of kidney). Both values returned to normal by 24 hours after SWL. They also noted an increase in serum aspartate transaminase and alanine transaminase levels at 1 hour after SWL. Karlsen and

associates (1990) detected an increase in urine osmolality and urine flow while renal plasma flow was reduced by approximately one third at 2 hours after SWL in dogs treated with 1500 shocks at 18 kV. However, these authors found no change in glomerular filtration rate or urinary electrolyte excretion. A series of experiments by Willis and associates (1996) have expanded these observations to include bilateral kidney function in the pig. These studies show that the application of 2000 shocks at 24 kV with an unmodified Dornier HM3 lithotripter to one kidney consistently reduces renal blood flow and glomerular filtration rate in that kidney. At 1 hour after SWL, the fall in renal blood flow was 27% in the young adult animals and 50% in the juvenile pigs. By 4 hours after SWL, renal blood flow returned to baseline in the young adult pigs but was still significantly reduced in the juvenile pigs. Glomerular filtration rate followed a similar course but was reduced to a lesser extent than renal blood flow measurements. In addition, these studies found a significant reduction in renal blood flow in the untreated kidney at the 1-hour post-SWL time point. These investigators also measured tubular function by use of *p*-aminohippurate extraction and found a significant reduction in the treated kidney but no fall in the untreated kidney. Again, the greatest reduction occurred in the juvenile pig compared with the young adults. These results show that the major change in renal function is vasoconstriction, and small kidney size does appear to be a risk factor for increased side effects. If the shock number is reduced to 1000 shockwaves, no detectable changes can be found acutely in renal hemodynamics. To demonstrate that the reduction in renal blood flow was focal, images of the blood flow in treated kidneys were obtained with positron emission tomographic scanning. Figure 44–23 compares blood flow in a treated and an untreated kidney by use of radiolabeled copper 62 microspheres, demonstrating **a loss of blood flow at the site of F2.** Willis and associates (2005) have found that high shock numbers (8000 shocks) do not generate a greater decrease in renal blood flow at 1 hour after SWL, but they do induce a sustained reduction at the 24 hour post-treatment mark. Connors and colleagues (2000) evaluated the effect of energy level on both renal blood flow and lesion size and found that lesion size increased as the energy level was increased from 12 to 24 kV. However, the maximal vasoconstrictive response was already induced at the 12 kV level and remained there regardless of the energy level used. These studies demonstrate the sensitivity of the renal vasculature to SWL. What is not known is whether electromagnetic lithotripters also induce renal vasoconstriction at a clinical dose.

It was known early in the era of lithotripsy that shockwaves induce a vasoconstrictive event in blood vessels. In a series of studies by Brendel and associates in 1987, video microscopy demonstrated that when shockwaves were directed at a simple microvascular bed, acute spasms of arterioles and hemorrhage of venules occurred. Vasoconstriction reached its maximum after 20 to 30 seconds and lasted between 4 and 10 minutes. Dilation followed the constriction event. In addition to the sites of microhemorrhage in the small veins were areas of macromolecule leakage and platelet aggregation. These authors also suggested that vasoconstriction is most pronounced in the region of peak pressure generated by the shockwave.

Willis (2006) reported **a practical way to protect the treated kidney from the predicted lesion induced by a clinical dose of shockwaves. Before the administration of a clinical dose of 2000 shocks at 24 kV with an unmodified HM3 lithotripter, a pretreatment dose of 100 to 500 shockwaves at 12 kV is administered, followed by the full clinical dose to the same site. Under these conditions, the normal lesion of approximately 6% is reduced to approximately 0.3%, a highly significant change** (Fig. 44–24). One hypothesis of a possible mechanism of this outcome is that the pre-dose of shockwaves induces a significant vasoconstrictive event that prevents an incoming stress from shearing the vessel wall or perhaps prevents or reduces the number of cavitation events. A reduction in cavitation potentially protects the parenchyma from cavitation-induced injury. A clinical trial is needed to test this result in patients.

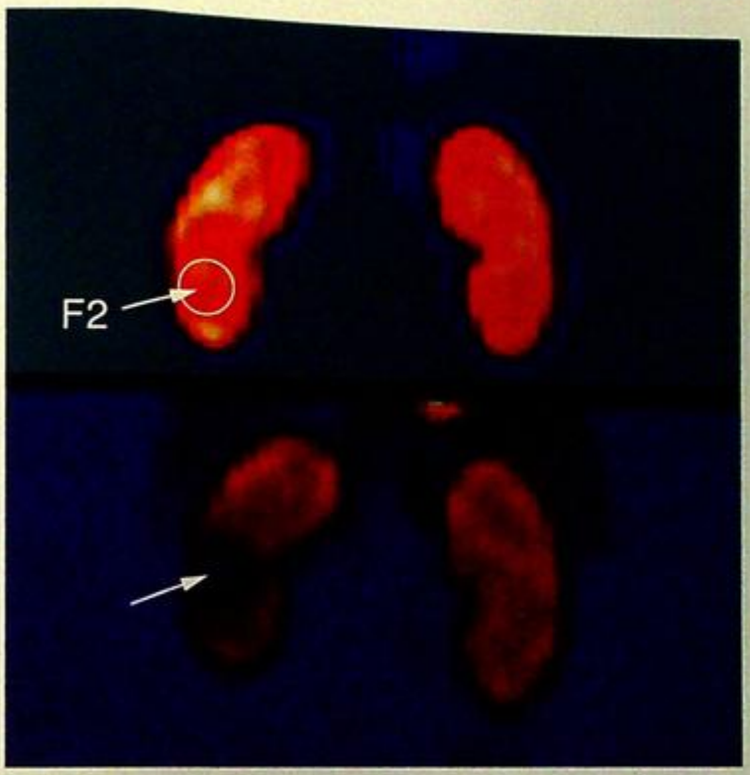

Figure 44–23. SWL-treated and control kidneys, imaged by positron emission tomographic scanning before and immediately after treatment with 3500 shockwaves to the lower pole, at level six, with a DoLi 50 device. The site of F2 (lower pole) on the shocked kidney shows a 50% reduction of renal blood flow *(arrow)*.

Vascular injury may potentiate ischemic damage to the renal parenchyma (Delvecchio et al, 2003). Both Cohen and associates (1998) and Brown and associates (2000) performed studies to confirm that the clinical dose of shockwaves induces lipid peroxidation and free radical formation in the treated kidney. The concern for ischemic changes is for both the treated and the untreated kidney, as SWL induces a vasoconstrictive response in both kidneys (Willis et al, 1999). Further evidence of the bilateral effects of SWL was provided by Delvecchio and associates (2003), who reported a dose-related increase in conjugated diene levels from the pole of the treated kidney and to a lesser degree from the untreated kidney.

Chronic changes in renal structure after shockwave treatment have received minimal investigation. At 2 weeks after SWL, Jaeger and Constantinides (1989) noted calcium deposits, streaky fibrosis, and encapsulation of sites of acute hemorrhage. Newman and coworkers (1987) identified permanent morphologic changes in the dog kidney 30 days after

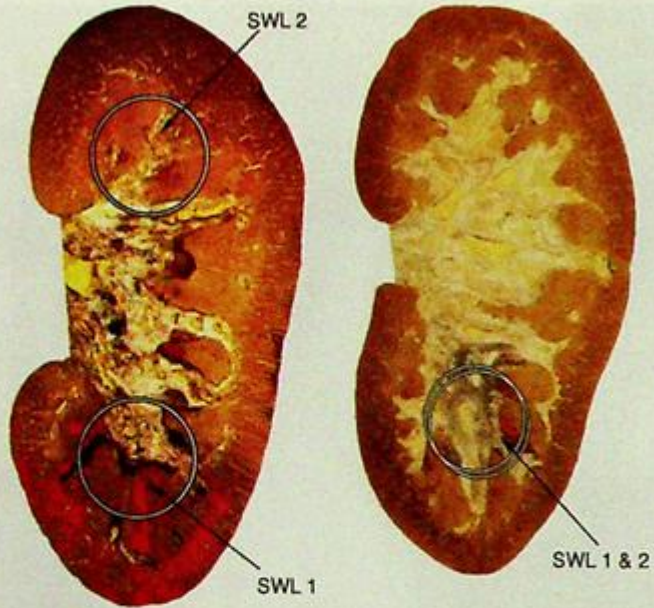

Figure 44–24. On the left is a coronal section of a kidney from an animal treated with 2000 shocks at 24 kV first to the lower pole (SWL 1) and then an additional 2000 shocks at 24 kV to the upper pole (SWL 2) of the same kidney. The typical lesion (colored in red) is seen at the lower pole; however, a greatly reduced lesion is seen on the upper pole. These data suggested that a pretreatment protocol might reduce the lesion induced by a clinical dose of shockwaves. The panel on the right shows lesion size in an animal first treated at the lower pole with 500 shocks at 12 kV (SWL 1) and then treated again at the lower pole with 2000 shocks at 24 kV (SWL 2). A greatly reduced lesion is also noted for this protocol.

SWL treatment. These alterations consisted of diffuse interstitial fibrosis, focal areas of calcification, nephron loss, dilated veins, and hyalinized and acellular scars from the cortex to the medulla. Morris and colleagues (1991) found a direct correlation between the number of shockwaves and the size of the resulting scar; as the number of shocks was increased from 1000 to 2000, the size of the scar increased from 1.4% to 12.8%. In addition, Banner and associates (1991) have noted mesangioproliferative glomerulopathy in pigs treated with either the HM3 or the EDAP lithotripter. With time, deposits of complement C3 and traces of immunoglobulin G were found to increase in amount in the mesangium. Interestingly, these changes were noted to occur in both the treated and the untreated kidney to about the same degree, suggesting the induction of a systemic factor or bilateral injury induced by SWL. Delius and associates (1990) have reported that most of these renal alterations were reversible in several weeks except for some of the large hematomas. These observations suggest that the **acute changes induced in the kidney can be classified as either reversible or irreversible** (Table 44–15); **however, a clinical dose of SWL always induces irreversible injury that ultimately forms a region of scar.**

Chronic Renal Injury: Structural and Functional Changes. Only a few studies have attempted to determine the chronic changes in renal function induced by SWL. Neal and associates (1991) treated infant and adult rhesus monkeys with 1500 shocks at 15 kV or 2000 shocks at 18 kV to each kidney. A highly significant decrease in effective renal plasma flow was noted in the infant group 6 months after treatment when those values were indexed to body surface area. In another study, immature rabbits receiving 1000 to 2000 shocks

Table 44–15. Reversible and Irreversible Injury

Reversible changes
Mild tubular necrosis
Casts and red blood cells in tubular lumen
Vacuolar changes of tubular lumen
Mild interstitial edema and hemorrhage
Irreversible changes resulting in loss of renal tissue
Disruption of nephrons
Extensive interstitial edema
Large hematomas of cortex and medulla
Rupture and occlusion of veins and arteries
Fracture of glomerular and peritubular capillaries

developed a significant rise in mean arterial blood pressure at 4 and 8 weeks after SWL compared with controls (Feagins et al, 1991). Pretreatment of these animals with either allopurinol or mannitol prevented the development of hypertension. Both of these studies strongly suggest that **there can be long-term functional consequences to a clinical dose of SWL, and the young or immature kidney is at great risk for such complications.**

Mechanism for Tissue Injury

The mechanism for the traumatic effects of SWL is not known, although Delius and colleagues (1988b) have speculated that the violent collapse of cavitation bubbles generated by the shockwaves is primarily responsible for the cellular changes. This concept is based on data showing that cavitation bubbles are present during shockwave application and that lithotripter shockwaves can cavitate water and blood in vitro (Coleman et al, 1987). Crum (1988) documented that SWL does produce acoustic cavitation, possibly as the result of the high intensity of the shockwave amplitude, and noted that the cavitation microjets are sufficiently forceful to pit or deform metal test foils. Zhong and coworkers (2001) suggested that it is expansion of the bubbles in a vessel that will lead to rupture of the wall of that blood vessel, testing this in an in vitro setting.

No group had been able to positively detect and validate acoustic cavitation within the kidney during SWL treatment until Bailey and associates (2005) created a passive cavitation detection system using two confocal spherical bowl PZT transducers. This device was used for coincidence detection of cavitation bubble emissions within a 2 × 2 × 2-mm sampling volume centered on F2 of a Dornier HM3 lithotripter. An ultrasound scan head targeted at this spot was used to image echogenicity in and around the sample volume. Signal (passive cavitation detection, hyperechoic spots) was intense in the urinary space during SWL treatment, and a signal was also seen in the renal cortex after only 1000 shocks. At that time, a small fluid space was noted at the site of the parenchymal signal. These data suggest that **once blood vessels have been ruptured and blood has collected in pools, there is a greater potential for cavitation to occur. The pooling of blood provides a large fluid-filled space for cavitation bubbles to grow and collapse.** In this model, the accuracy of tissue targeting was confirmed by inducing a lesion with high-intensity focused ultrasound. Further evidence that cavitation plays a role in tissue injury comes from a study by Evan and associates (2002) in which the degree of tissue injury was compared between a standard rigid reflector and a pressure release

reflector. The pressure release reflector generates a shockwave where the negative tail precedes the positive peak, resulting in a suppression of cavitation activity. No injury was detected in the kidneys treated with the pressure release reflector; the standard rigid reflector induced the expected lesion.

KEY POINTS: SHOCK WAVE LITHOTRIPSY

- Most patients with uncomplicated kidney stones can be successfully treated with SWL.
- Shock waves break stones via multiple different mechanisms, including both compressive and tensile forces.
- SWL is associated with both anatomic and functional injuries to the kidney.
- The harmful effects of SWL can be minimized by pre-treating with low energy shock waves and treating at the lowest power setting that fractures the stone.
- Stone breakage can be promoted by treating at slower rates, such as 1 Hz (60 shocks per minute).

Percutaneous Nephrolithotomy

Fernstrom and Johansson first reported the technique of establishing a percutaneous track specifically to remove a stone in 1976. Subsequent reports have established PNL as a routinely used technique to treat patients with large or otherwise complex calculi (Alken et al, 1981; Wickham and Kellett, 1981; Segura et al, 1982; Clayman et al, 1984). Advances in surgical technique and technology have allowed the urologist to remove calculi percutaneously with increasing efficiency. As the percutaneous approach to stone removal is superior to the open approach in terms of morbidity, convalescence, and cost, PNL has replaced open surgical removal of large or complex calculi at most institutions (Brannen et al, 1985). Herein the specific aspects of percutaneous techniques as they relate to stone removal are delineated.

Preparation of the Patient

The initial evaluation of the patient who is being considered for PNL should be a complete history and physical examination. A complete medical history will **identify those patients with an absolute contraindication to PNL, such as uncorrected coagulopathy, as well as those with an active, untreated urinary tract infection.** The placement of a percutaneous nephrostomy drain, without manipulation of the calculus, may be an appropriate therapy if the stone is associated with obstruction of the renal unit and sepsis. If it is medically feasible, **aspirin and other antiplatelet medications should be discontinued 7 days before the date of surgery** (Mak and Amoroso, 2003).

Preoperative laboratory evaluation of patients scheduled for PNL should include a complete blood count as well as serum electrolyte determinations and renal function tests. Martin and colleagues (2000) have reported that it is unnecessary to obtain screening coagulation studies before PNL for an otherwise healthy patient. **Urine culture is mandatory for all patients who undergo PNL;** perioperative antibiotics can be appropriately tailored to culture-specific organisms. Typing and screening of the patient's blood should be performed, although preoperative crossmatching is usually not necessary.

Historically, it has been viewed as mandatory to evaluate the patient's collecting system by either intravenous urography or retrograde pyelography. Recently, as more patients are initially evaluated with helical CT imaging, it is no longer mandatory to have these studies at the preoperative evaluation. **In most cases, the decision to perform PNL may be based on the stone burden displayed on the CT images.** A KUB radiographic image should be obtained immediately before the procedure to verify stone location. Retrograde pyelography can be performed at the time of the surgical procedure, acquiring information about calyceal anatomy that may aid in selecting the targeted puncture site. However, for certain patients, such as **those with calyceal diverticula, for whom the surgical approach is affected by the diverticulum's relationship to the collecting system, intravenous or retrograde pyelography may be required at the time of initial evaluation.** Retrorenal colon has been reported to be present in less than 1% of all patients, but its incidence may be higher in those who have undergone jejunoileal bypass, those in a nursing home, or those with spinal cord injury (Sherman et al, 1985). These patients may benefit from initial CT imaging. Patients with ectopic kidneys, both congenital and iatrogenic (e.g., due to renal allograft, autotransplantation), as well as patients with dysmorphic body habitus due to congenital malformations such as spinal dysraphism may also benefit from cross-sectional imaging before PNL; intra-abdominal structures, such as the bowel, may be located in the targeted track. Radionuclide scanning may be necessary in select patients, particularly those harboring staghorn calculi, to evaluate differential renal function (Schnapp and Smith, 1995).

Antibiotics. Urinary calculi may harbor bacteria even though bacteriuria is only intermittently present. This is particularly true in the patient who has been taking antibiotics in the past. For those patients who do have preoperative bacteriuria, stone cultures produced bacteria in 77% of cases in a series reported by Larsen and associates (1986). The most frequently identified organisms were *Proteus mirabilis, Escherichia coli, Klebsiella* species, *Pseudomonas* species, *Enterococcus* species, and *Enterobacter* species. Sterile urine does not preclude postoperative bacteriuria, however, as Charton and colleagues (1986) reported a 35% incidence of bacteriuria after PNL among patients with sterile preoperative urine culture specimens in whom prophylactic antibiotic therapy was not used. Mariappan and associates (2005) have also reported that the best correlate with post-PNL sepsis is stone culture or renal pelvic urine culture, not bladder urine culture. **The fragmentation of stones, despite sterile urine, may release preformed bacterial endotoxins and viable bacteria that place the patient at risk for septic complications** (Scherz and Parsons, 1987; McAleer et al, 2002, 2003; Paterson et al, 2003). Therefore, patients who have radiographic or clinical features suggestive of struvite or in whom infection is suspected should receive 2 weeks of broad-spectrum antibiotics before surgery to reduce the risk of sepsis. Antibiotic treatment may also reduce bleeding secondary to inflammation and friability of renal parenchyma. Approximately one third

of patients with an indwelling ureteral stent will, despite sterile urine on a preoperative analysis, be colonized with bacteria; *Enterococcus* and *Staphylococcus epidermidis* are the most frequent offending organisms (Reid et al, 1992; Lifshitz et al, 1999b). For patients with indwelling stents, then, antibiotic prophylaxis, particularly for gram-positive organisms, may be beneficial before instrumentation.

Patients without a history of urinary infection should receive prophylactic antibiotics before endourologic interventions; all urologic endoscopic procedures are regarded as clean-contaminated, even if infection is not evident. Inglis and Tolley (1988), in a randomized prospective study, demonstrated that antibiotic prophylaxis before PNL reduced the incidence of postoperative urinary tract infection in those patients found with sterile urine on preoperative culture. **Cephalosporins are the most appropriate antibiotic for prophylaxis before surgical procedures in noninfected patients as the most common secondarily infecting organism is *S. epidermidis*.** High-risk patients can be treated with intravenous ampicillin and gentamicin. The use of gentamicin has become simplified since the introduction of a single daily dosing schedule (Santucci and Krieger, 2000).

Anesthesia. PNL can be performed after the administration of general, epidural, or local anesthesia. Local anesthesia, usually in combination with intravenous sedatives and analgesics, has been reported in a number of centers (Clayman et al, 1983; Hulbert et al, 1986; Preminger et al, 1986; Ohlsen and Kinn, 1993). Local anesthesia may be an option when general anesthesia is contraindicated. A local anesthetic, such as lidocaine, can be delivered into the access track by use of an 8.3 French anesthetic injection catheter with multiple side holes or with a dual-lumen ureteral access catheter (Dalela et al, 2004). Regional anesthesia (e.g., epidural, spinal) can be used for percutaneous procedures, but several problems may be associated with these regional anesthetic techniques. First, a relatively high block is necessary to eliminate all renal pain. Second, distention of the renal pelvis during PNL may cause a vasovagal reaction that is not always prevented by regional anesthesia (Grasso and Taylor, 1997). General anesthesia is usually preferred when a more lengthy procedure is planned because it is the best means of protecting the airway when patients are in a prone position. **In cases in which upper pole puncture is contemplated, general anesthesia should be used as it permits control of respiratory movements** which is essential to minimize the risk of pulmonary complications.

Opacification of the Collecting System. The collecting system can be visualized in several ways in preparation for PNL. When it is performed as a single-stage procedure, PNL is initiated by the cystoscopic placement of a ureteral catheter. If the stone burden is large or when the proximal ureter is dilated, the use of a 7 French occlusion balloon catheter should be considered to prevent the migration of fragments into the ureter (Fig. 44–25). **A ureteral catheter serves several purposes: to opacify and to distend the collecting system, to provide an optimal target for percutaneous puncture, to minimize passage of stone fragments into the ureter during lithotripsy, to allow retrograde irrigation, and to instill contrast material during the procedure** (Beckmann and Roth, 1985; Littleton et al, 1986). Iodinated contrast material is the most widely used means of opacifying the collecting system in a retrograde fashion. However, as contrast material is more dense than urine, the contrast agent may layer in the more dependent, anterior calyces, making the delineation of the posterior calyces difficult. If this occurs, carbon dioxide or room air (<20 mL) can be used to outline the posterior calyces, although the resolution will not be as great as with iodinated contrast material (Lee et al, 1986; Young, 1986). However, **air embolism after air pyelography has been reported, so care must be exercised in performing this technique** (Miller et al, 1984; Cadeddu et al, 1997).

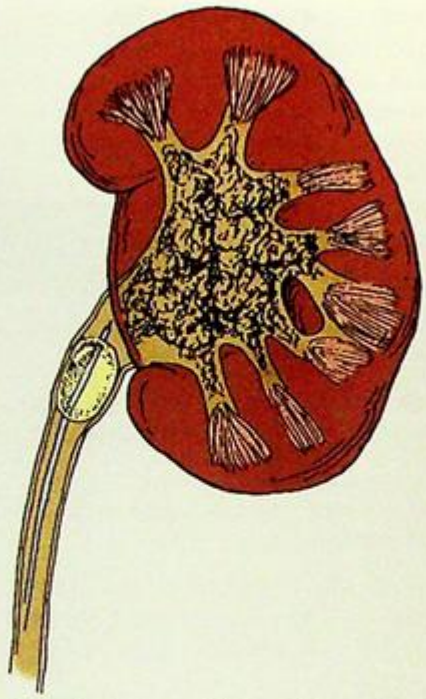

Figure 44–25. Occlusion balloon catheter at the ureteropelvic junction in preparation for PNL.

Percutaneous access is best achieved as a single-stage procedure, performed in the operating room by the urologist or, if necessary, a radiologist, by use of biplanar C-arm fluoroscopic imaging, followed immediately by track dilation and stone removal. However, in many institutions, antegrade access is created as a separate procedure by an interventional radiologist in the radiology suite (two-stage PNL). When it is done in this manner, opacification of the collecting system can be achieved with retrograde pyelography as described. Alternatively, intravenous injection of contrast material or percutaneous antegrade pyelography can be performed with a 22-gauge Chiba needle. The risk of clinically significant hemorrhage or renal damage with such a thin needle is negligible (Dunnick et al, 1985; Zagoria and Dyer, 1999). The renal collecting system is located fluoroscopically after intravenous injection of contrast material or by sonographic imaging. Alternatively, a "blind" puncture can be performed just lateral (1 to 1.5 cm) to the vertebral transverse process at the L1-2 level. In the average-sized adult patient, the renal collecting system is usually within 7 to 10 cm of the skin, and the minimal distance to the renal capsule is about 4 cm. Continuous aspiration is applied to the needle as it is slowly withdrawn, until urine appears. Entrance into the collecting system with this method can usually be achieved with three or fewer passes (Castaneda-Zuniga et al, 1986; Robert et al,

1999). Once the renal collecting system has been entered, dilute contrast material is injected to opacify the collecting system. The Chiba needle can also be used in a one-step procedure when retrograde opacification is difficult or impossible.

For solitary calculi in difficult-to-access locations or in a calyceal diverticulum, it is often best to avoid contrast material injection into the collecting system and to direct the puncture at the stone itself (Ohlsen and Kinn, 1993; Kim et al, 2005a).

Positioning of the Patient. PNL is performed with the patient in a prone position, and the stone-containing side is elevated on a foam pad to approximately 30 degrees (Fig. 44–26). **This position aids in ventilation of the patient and tends to bring the posterior calyces into a vertical position that is helpful during PNL puncture. The posterior calyces are usually oriented toward the avascular area between the anterior and posterior arterial divisions of the kidney (Brödel's bloodless line of incision), the ideal point of entry.** A puncture through a posterior calyx usually traverses this line, avoiding the major branches of the renal artery (Dyer et al, 1997). Pressure points are identified and padded, and careful attention is focused on the positioning of the patient's arms. The arm on the side of the stone is flexed at the elbow and placed on an arm board, and the contralateral arm is placed at the patient's side. Intravenous extension tubing is connected to the ureteral catheter or the occlusion balloon port to allow inflation or deflation of the balloon or the instillation of contrast material or irrigation.

Choosing Renal Access for Percutaneous Nephrolithotomy

PNL is usually performed through antegrade percutaneous access. Alternatively, percutaneous access can be achieved in a

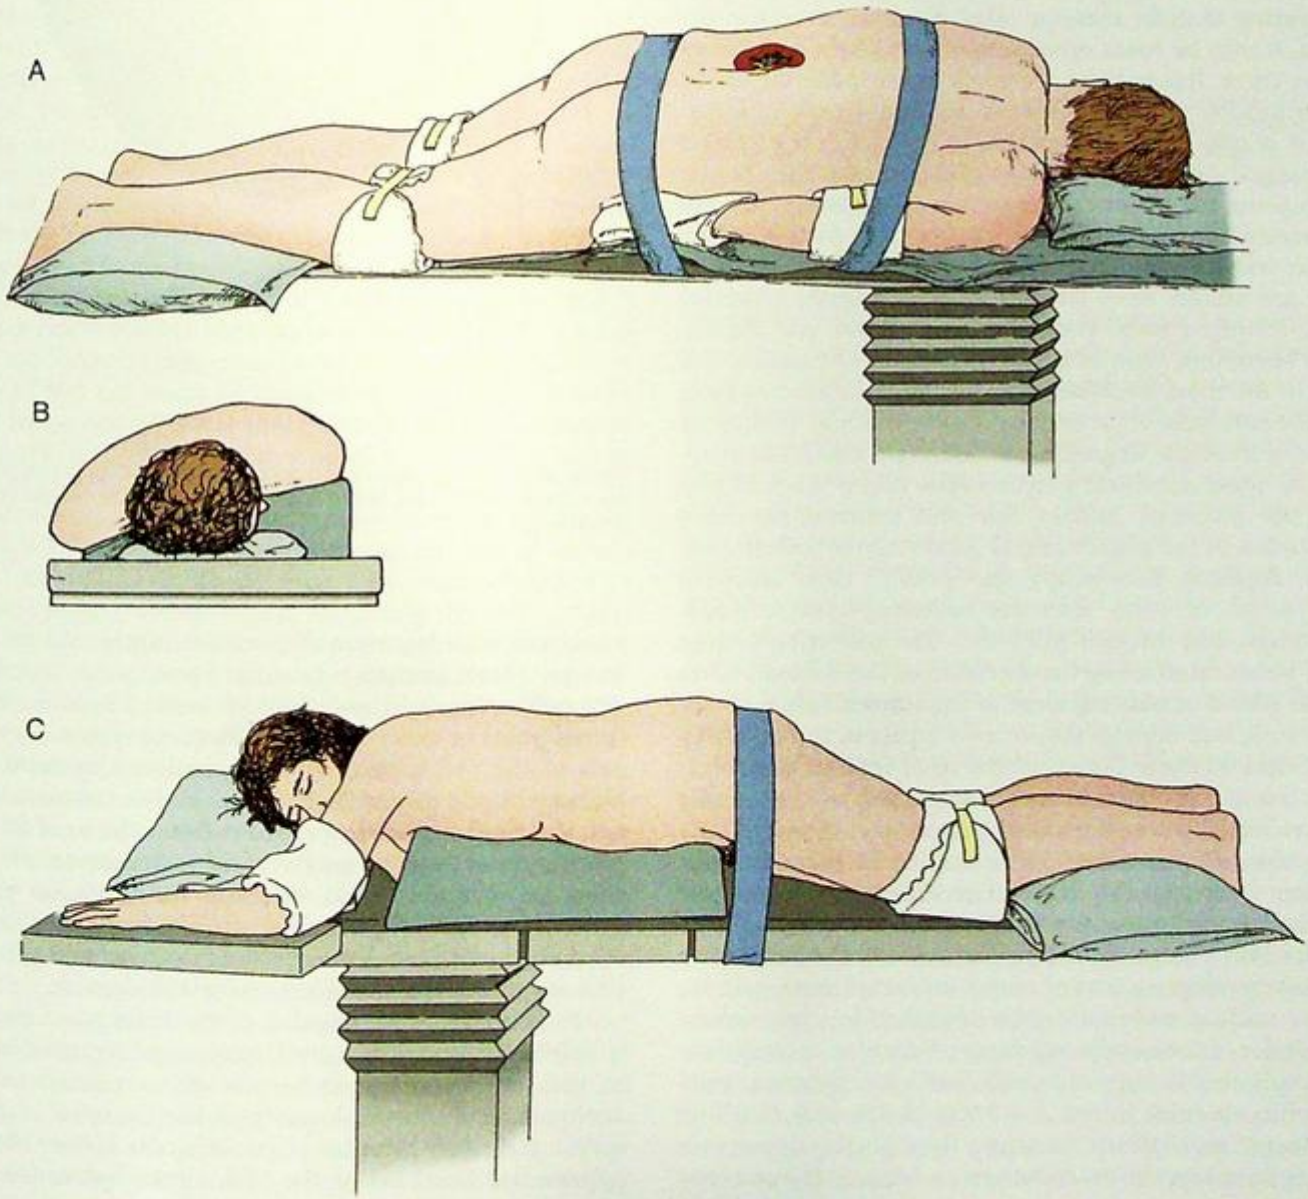

Figure 44–26. Position of the patient for PNL. **A,** Side to be treated is elevated approximately 30 degrees. The "down" arm should be placed at the patient's side. **B,** All pressure points are carefully padded. **C,** The "up" arm should be placed in an abducted position. The patient is placed far enough down the table so that the center post of the table does not impede movement of the C-arm.

retrograde fashion. The retrograde technique was first described as an attempt to simplify access for urologists, particularly in treating nondilated collecting systems (Hunter et al, 1983; Lawson et al, 1983; Kidd and Conlin, 2003). Regardless of the access technique, the selection of the calyx to enter as well as the point of puncture is critical for a successful outcome. The surgeon must select the optimal approach for stone removal, recognizing the restraints conferred by renal anatomy.

Anatomic Considerations. Familiarity with basic renal anatomy is essential for access to be obtained safely. The main renal artery typically divides into an anterior and a posterior division. The avascular field between the anterior and posterior divisions, known as Brödel's bloodless line, is the ideal point of renal entry. Because of the orientation of the kidney in the body, entry through a posterior calyx usually traverses this line (Dyer et al, 1997). **A posterior calyx is a preferred site of entry; it is usually easier to negotiate a wire out of the calyx and into the ureter when the site of puncture is a posterior rather than an anterior calyx.** However, in certain situations, it may be more optimal to obtain access through an anterior calyx; this may be accomplished by adhering to the same principles as for a posterior calyceal access. Unfortunately, it is only at the midportion of the kidney that calyces are arranged into two rows, anterior and posterior. In the polar regions, the major calyces are typically compound, with great variability in calyceal orientation (Fig. 44–27). When they are viewed on intravenous pyelography, the anterior calyces are usually more laterally situated than the posterior calyces; however, some variability exists (Kaye and Reinke, 1984). Therefore, determination of calyceal orientation and choice of the most favorable calyx for puncture are best done when the patient is in the prone position with use of biplanar C-arm fluoroscopy. Regardless of the exact calyceal orientation, the ideal subcostal percutaneous access track begins inside the posterior axillary line and traverses the renal parenchyma at the posterolateral aspect of the kidney (Fig. 44–28). Biplanar fluoroscopy also permits close attention to the point of entry into the collecting system, avoiding through-and-through puncture. **The collecting system should be accessed along the direction of the infundibulum to avoid blood vessels adjacent to the infundibulum.** Inadvertent puncture beyond the anterior aspect of the collecting system risks vascular injury of the large anterior segmental vessels; this is a problem because these vessels are not readily tamponaded with a nephrostomy tube or occlusion balloon.

Sampaio and associates (1992) studied 62 polyester resin corrosion endocasts of the kidney collecting system and intrarenal vessels to identify the preferred anatomic point of puncture into a calyx. Before performance of the endocast, a retrograde pyelogram was obtained on each kidney, and the superior, middle, and lower poles of each kidney were punctured under fluoroscopic guidance. Puncture through the infundibulum of the upper, middle, and lower poles was associated with vascular injury in 67.6%, 38.4%, and 68.2% of the kidneys, respectively. Puncture through the upper pole infundibulum was the most dangerous because the posterior segmental artery crosses the posterior surface of the infundibulum in 57% of cases (Sampaio and Aragao, 1990). Puncture through the fornix proved to be much safer and was associated with less than 8% venous injury and no arterial lesions. Direct puncture into the renal pelvis injured large retropelvic vessels in one third of cases. Therefore, **the preferred point of entry into the collecting system is along the axis of the calyx, through the papilla. Alignment of the access with the infundibulum also allows the most efficient use of a rigid nephroscope and reduces the need for one to place excessive torque on the rigid instruments,** which may cause renal trauma and bleeding. Infundibular puncture should be avoided, if possible, as should direct puncture of the renal pelvis with its elevated risk of vascular injury, potential prolonged urine leak, and easy tube dislodgment.

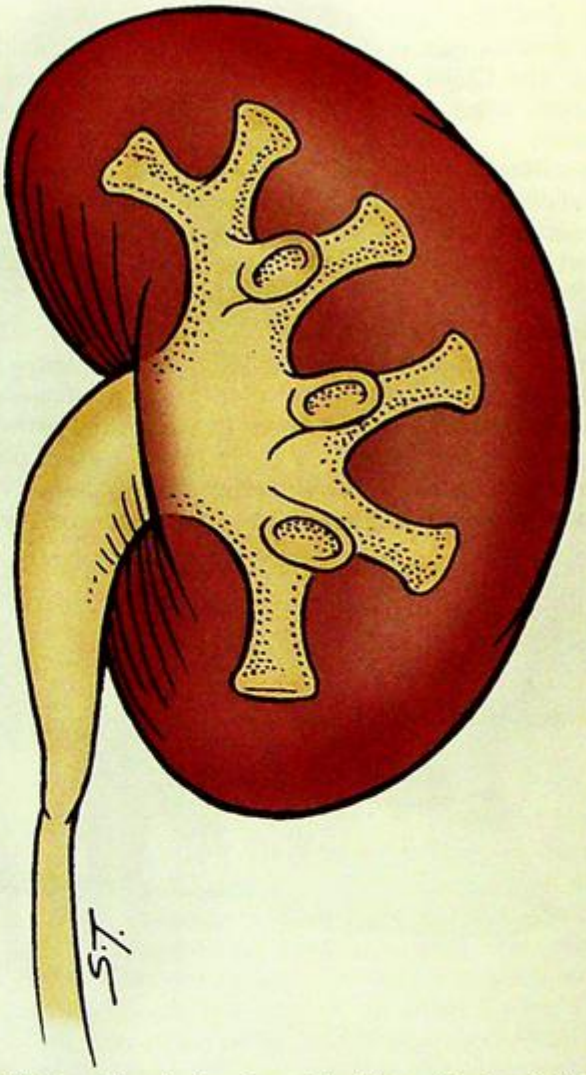

Figure 44–27. Calyceal orientation of the kidney. Only the middle calyces are arranged in two rows (anterior and posterior). Polar calyceal orientation is variable.

The retroperitoneal location of the kidney and its relation to diaphragm and pleura, liver, spleen, and right and left colon as well as the skin entrance site are important extrarenal anatomic details the urologist must keep in mind in planning a PNL puncture. When it is possible, **the kidney should be approached from below the 12th rib to reduce the risk of pleural complications.** The site of entry on the skin is usually just inferior and several centimeters medial to the tip of the 12th rib (Clayman et al, 1984). A puncture too close to the rib

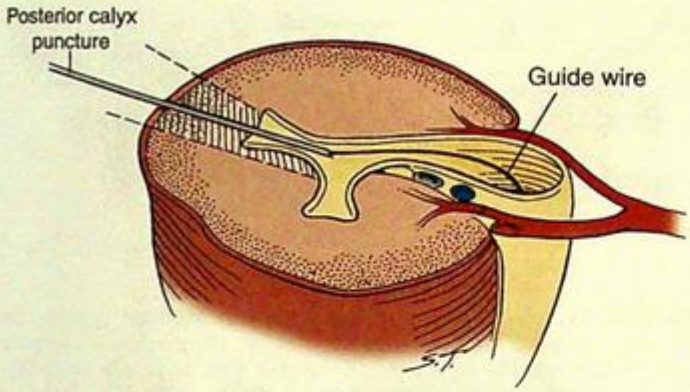

Figure 44–28. The ideal subcostal percutaneous access traverses the renal parenchyma at the posterolateral aspect of the kidney through the relatively avascular Brödel's zone, entering a posterior calyx. This approach minimizes the chance of vascular injury and allows a relatively direct path into the renal pelvis.

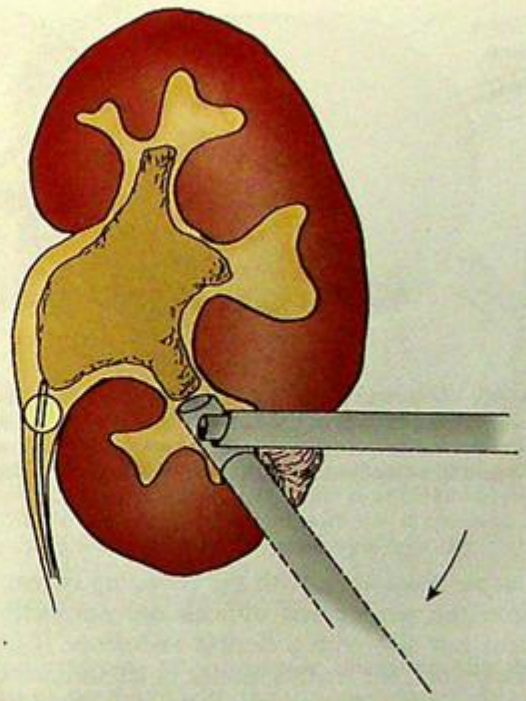

Figure 44–29. Access that is not aligned with the infundibulum requires torque to be placed on the nephroscope to achieve optimal visibility, which may traumatize renal parenchyma and cause bleeding. Aligning the access with the infundibulum allows the most efficient and least traumatic use of the rigid nephroscope.

may injure the intercostal vessels and nerve, exacerbating postoperative pain. A more medially sited track (i.e., paraspinal) is uncomfortable to the patient and may traverse the renal parenchyma too medially, increasing the risk of bleeding (Lang, 1987). A puncture placed too laterally (lateral to the posterior axillary line) may injure the colon, as the position of the retroperitoneal colon is usually anterior or anterolateral to the lateral renal border (Lang, 1987; Lee et al, 1987a). Patients with displacement of the colon posterior to the kidney are at increased risk of colon perforation, and a retrorenal colon is most likely to be situated near the inferior pole of the kidney. Hopper and coworkers (1987a, 1987b), in a study of 500 CT scans of the abdomen, reported that **the overall frequency of retrorenal colon in the supine patient is 1.9%.** When 90 patients were studied in the prone position, a retrorenal colon was found in 10% (Hopper et al, 1987a). Posterior colonic displacement is more likely in thin female patients with very little retroperitoneal fat and in elderly patients as well as in those who have been subjected to jejunoileal bypass. Other factors increasing the risk of colon injury include anterior calyceal puncture, previous extensive renal surgery, horseshoe kidney, and kyphoscoliosis; retrorenal colon is more commonly found on the left (LeRoy et al, 1985; Dyer et al, 1997; Wolf, 1998).

The liver and spleen may also be at risk for injury during percutaneous access. However, in the absence of splenomegaly or hepatomegaly, injury to these organs is extremely rare for those patients treated with a puncture below the 12th rib. The risk may be somewhat greater with upper pole punctures, especially if the puncture is incorrectly performed, such as during the inspiratory phase of respiration rather than the expiratory phase, or if the puncture is placed above the 11th rib (Hopper and Yakes, 1990; Robert et al, 1999). In an upper pole access, the skin puncture site should be as far medial as possible, adjacent to the lateral border of the paraspinal muscles, to reduce the risk of damage to the liver or spleen. **The main risk of a supracostal puncture, though, is injury to the lung and pleura;** the upper poles of both kidneys rest immediately anterior to the posterior portion of the 11th and 12th ribs or, occasionally, as high as the 10th rib (Fuchs and Forsyth, 1990). **The risk of pleural injury is much greater during the inspiratory phase of respiration, so a supracostal puncture should be performed only during full expiration.** A supracostal puncture is associated with pulmonary morbidity in approximately 16% of cases (Young et al, 1985; Picus et al, 1986; Fuchs and Forsyth, 1990; Narasimham et al, 1991; Golijanin et al, 1998; Stening and Bourne, 1998; Munver et al, 2001). Most complications are minor pleural effusions that can be managed conservatively, although there are certain patients who will require an intervention to drain an accumulation of fluid or air. Supracostal puncture has also been associated with increased postoperative pain (Fuchs and Forsyth, 1990). To reduce the morbidity of a supracostal access, the puncture site should be placed in the middle of the intercostal space, just lateral to the paraspinal muscles. If it is at all possible, puncture above the 11th rib should be avoided.

Puncture Site Selection. Stone location and stone burden should be the primary considerations in selection of the optimal access for stone removal. The lower pole approach has been associated with fewer complications, making lower pole renal access preferable, unless an upper pole access is specifically indicated. The guiding principle should be that **the goal of all approaches is the removal of the greatest stone burden with a rigid nephroscope.** A rigid nephroscope that is aligned with the infundibular access allows optimal visualization of the stone and easier access into the renal pelvis (Fig. 44–29). The risk of renal trauma is reduced, as there should be little need to place significant torque on the rigid instruments. For patients with a solitary calyceal stone, the preferred approach is usually directly into the calyx containing the stone (Hulbert et al, 1986). However, stones in anterior calyces may be difficult to access in this manner; a direct puncture into the calyx

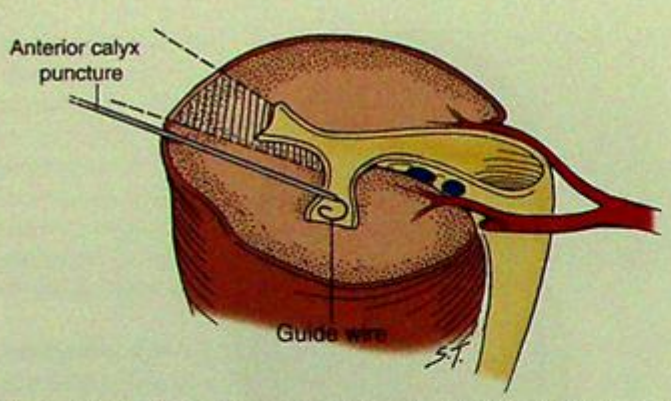

Figure 44–30. In puncture of an anterior calyx, it may be difficult to pass a wire or an instrument through the infundibulum owing to the acute angle created between the line of puncture and the infundibulum. Anterior calyx puncture may also be associated with an increased risk of vascular injury.

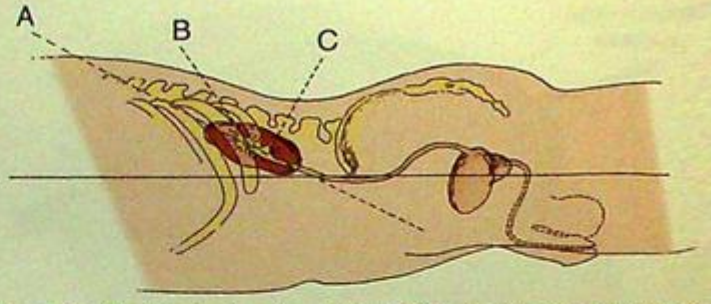

Figure 44–31. Angle of entry. Lateral view of abdomen demonstrates the renal axis (**A**). PNL through the upper pole (**B**) provides a less acute angle of entry into the collecting system than does lower pole access (**C**).

is often at an acute angle with the collecting system, making access into the renal pelvis difficult not only with a rigid instrument but also with a flexible endoscope (Glanz et al, 1986). Therefore, for smaller stones in an anterior calyx, an indirect approach through a posterior calyx followed by flexible nephroscopy may be preferred (Fig. 44–30). However, for those patients with large stones, a direct approach may be required to maximize the efficiency of the procedure (Coleman, 1986). Nonstaghorn stones usually can be accessed from a posterior lower or mid-kidney calyx (Coleman, 1986; Lee et al, 1986).

A supracostal puncture is usually necessary when the predominant distribution of stone material is in the upper calyces, when there is an associated ureteropelvic junction stricture requiring endopyelotomy, in cases of multiple lower pole infundibula and calyces containing stone material or an associated ureteral stone, in staghorn calculi with substantial upper pole stone burden, and in horseshoe kidneys (Lam et al, 1992c). A supracostal puncture may also be used when stone removal is incomplete through a lower pole access (Munver et al, 2001). The major advantage of a supracostal puncture is that the line of puncture aligns the access track most closely with the renal axis (Fig. 44–31 and Table 44–16).

Upper pole renal access can be performed through an infracostal, intercostal, or supracostal puncture (Fig. 44–32). For a solitary stone in an upper pole calyx or an upper pole calyceal diverticulum, a subcostal puncture directed toward the upper pole may be used. However, directing a rigid nephroscope from the upper pole into the renal pelvis after such a puncture may be impossible or unduly traumatic. On occasion, the upper pole can be reached through a laterally situated track between the tips of the 11th and 12th ribs. Although by strict definition this is an intercostal access track, the risk for pleural injury is significantly lower than when a vertical supracostal puncture is selected (LeRoy et al, 1985). Karlin and Smith (1989) described a technique of renal displacement that may be used to avoid a supracostal puncture. An Amplatz sheath passed through a central or lower pole calyx is used to displace the kidney caudally, and a second puncture is performed toward the upper pole. The authors reported that failures have occurred in patients with kidneys that are immobile due to previous operations.

Multiple accesses should be considered when any calyx contains a stone larger than 2 cm and is unreachable through the primary access with a rigid instrument or when stones are smaller than 2 cm but cannot be reached with a flexible instrument through the primary access. In general, additional accesses may be undertaken during the primary PNL, unless the procedure has been unduly prolonged or bleeding is deemed excessive. In such instances, further intervention may be best delayed until the time of secondary PNL. The frequency of multiple accesses varies widely. Newmark and colleagues reported that in a group of 229 patients (246 renal units) with staghorn stones, 13.4% of the kidneys required access with track dilation in addition to the primary track (Lingeman et al, 1995). Furthermore, 7.3% of kidneys required an additional puncture without track dilation to

Table 44–16. Percutaneous Nephrolithotomy Through Supracostal Access

Author	Overall PNL Patients (n)	No. of Supracostal Punctures (%)	Overall Pleural Complications (%)	Pleural Complications Treated (%)	Stone-Free Rate (%)

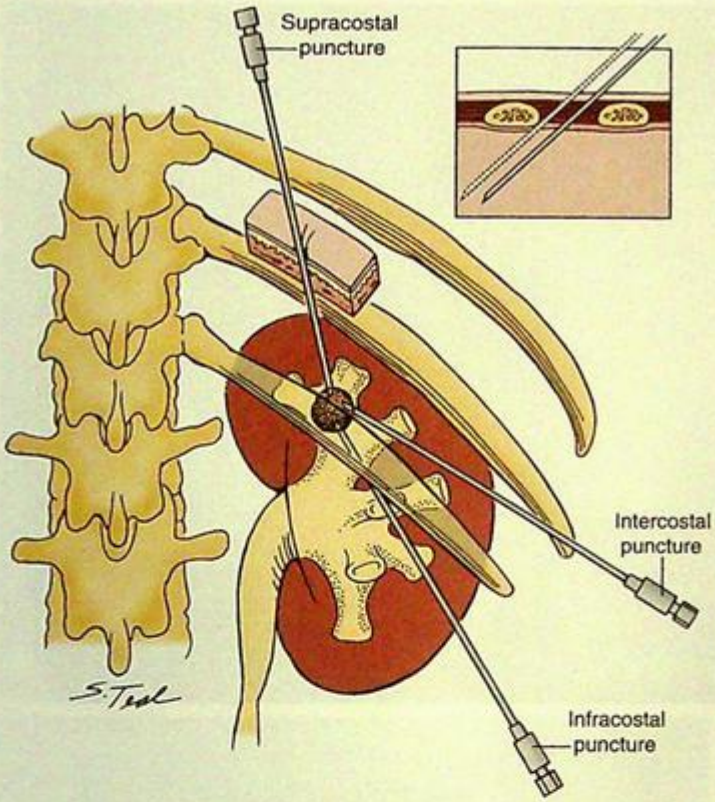

Figure 44–32. Upper pole access can be achieved with a supracostal, intercostal, or infracostal approach. A supracostal approach most closely aligns the puncture with the renal axis, whereas an infracostal puncture allows access to the upper pole only. Supracostal puncture should be initiated closer to the upper rib to allow proper passage of the needle through the intercostal space *(inset)*. A midline puncture *(inset, dotted line)* risks hitting the lower rib.

assist in identification of a stone-containing calyx during flexible nephroscopy. Matlaga and associates (2004) reported on a series of 133 patients with large-volume calculi, of whom 16.5% required multiple access tracks. In comparison, multiple accesses were used by Lee and associates (1987b) in 73% and by Merhej and coworkers (1998) in 78% of patients treated for staghorn stones. These differences may reflect different preferences in the use of flexible nephroscopy during PNL for staghorn stones. Multiple accesses are usually best created as separate punctures. However, when calculi are located in parallel or adjacent calyces, a Y puncture, in which the secondary puncture angles off the existing nephrostomy track, can be considered (Lange et al, 1984; Hulbert et al, 1986). Once the first calyx has been completely cleared, the Amplatz sheath is retracted outside of the renal capsule and angled toward the second calyx. The second puncture is made through the Amplatz sheath (Fig. 44–33).

Access and Track Dilation. Once the point of puncture and the preferred calyx have been selected, the C-arm unit is angled in the direction opposite the line of puncture (i.e., to the head for a lower pole puncture or to the feet for an upper pole puncture) to minimize x-ray exposure of the surgeon's hands. **After the targeted calyx is identified with fluoroscopy, an 18-gauge needle is directed into it by the triangulation method. Mediolateral adjustments of the needle (showing the point of entrance to the calyx) are made with the C-arm directed parallel to the needle** (Fig. 44–34). **Cephalad or caudad adjustments of the needle (showing the depth of penetration) are made with the C-arm rotated obliquely as much as is feasible relative to the needle axis** (Fig. 44–35). It is critical to maintain the needle orientation in one plane while adjustments in the other plane are made. If the surgeon rests his or her forearm on the patient's torso, the line of puncture is stabilized and drift is minimized, facilitating precise puncture. After the direction of puncture is correctly aligned in both planes, the needle is advanced, with the C-arm rotated obliquely to the sagittal plane of the needle so that the depth of puncture can be monitored. Before the renal capsule is entered, final adjustments are made. Manipulation of the needle after renal parenchyma is entered is a problem because movements of the needle invariably displace the kidney and thus affect the position of the target calyx as well.

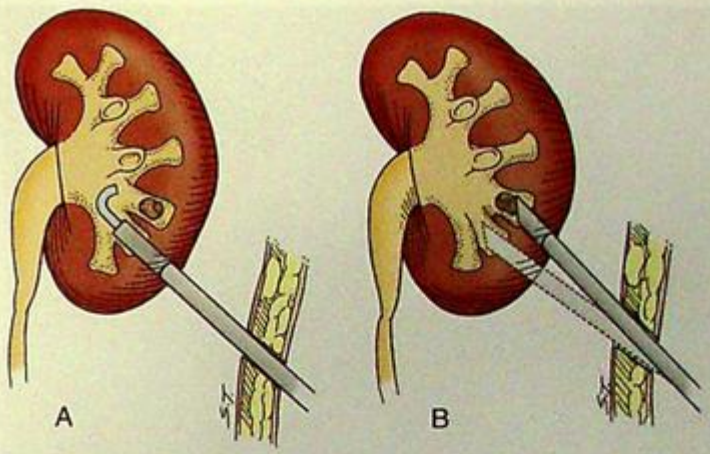

Figure 44–33. When a stone in an adjoining calyx cannot be reached with a flexible nephroscope (**A**), the Amplatz sheath is withdrawn to just beyond the renal capsule, and a second puncture with use of the same skin incision (Y puncture) is directed into the neighboring calyx (**B**).

Proper location of the needle is verified by aspiration of urine. On occasion, the needle must be withdrawn gradually while constant suction is applied until urine appears in the suction tubing. **After the needle is satisfactorily positioned in the collecting system, a hydrophilic guide wire is passed. A hydrophilic wire is preferred for entering the collecting system as it is the most flexible and maneuverable wire currently available.** Ideally, the guide wire is advanced into the ureter, a most secure position. **When a lower pole puncture is performed, an angiographic catheter (i.e., Cobra) is often helpful in directing the guide wire through the ureteropelvic junction.** When an upper pole puncture is used, manipulation of the guide wire into the ureter is usually straightforward. If the guide wire cannot be manipulated down the ureter, the wire should be coiled as much as possible in a calyx or the renal pelvis. Care should be taken to avoid excessive force in this situation because perforations of the calyx and renal pelvis are distressingly easy to create. **Once the guide wire is positioned in the ureter, it is exchanged for a stiffer, Teflon-coated working wire such as an Amplatz super-stiff wire. An 8-10 French coaxial dilating system is then used to place a second safety wire. Renal track dilation should not proceed without a safety wire in place.** Several methods of track dilation are available, including metal telescoping dilators, semirigid Amplatz dilators, and balloon dilators (Alken

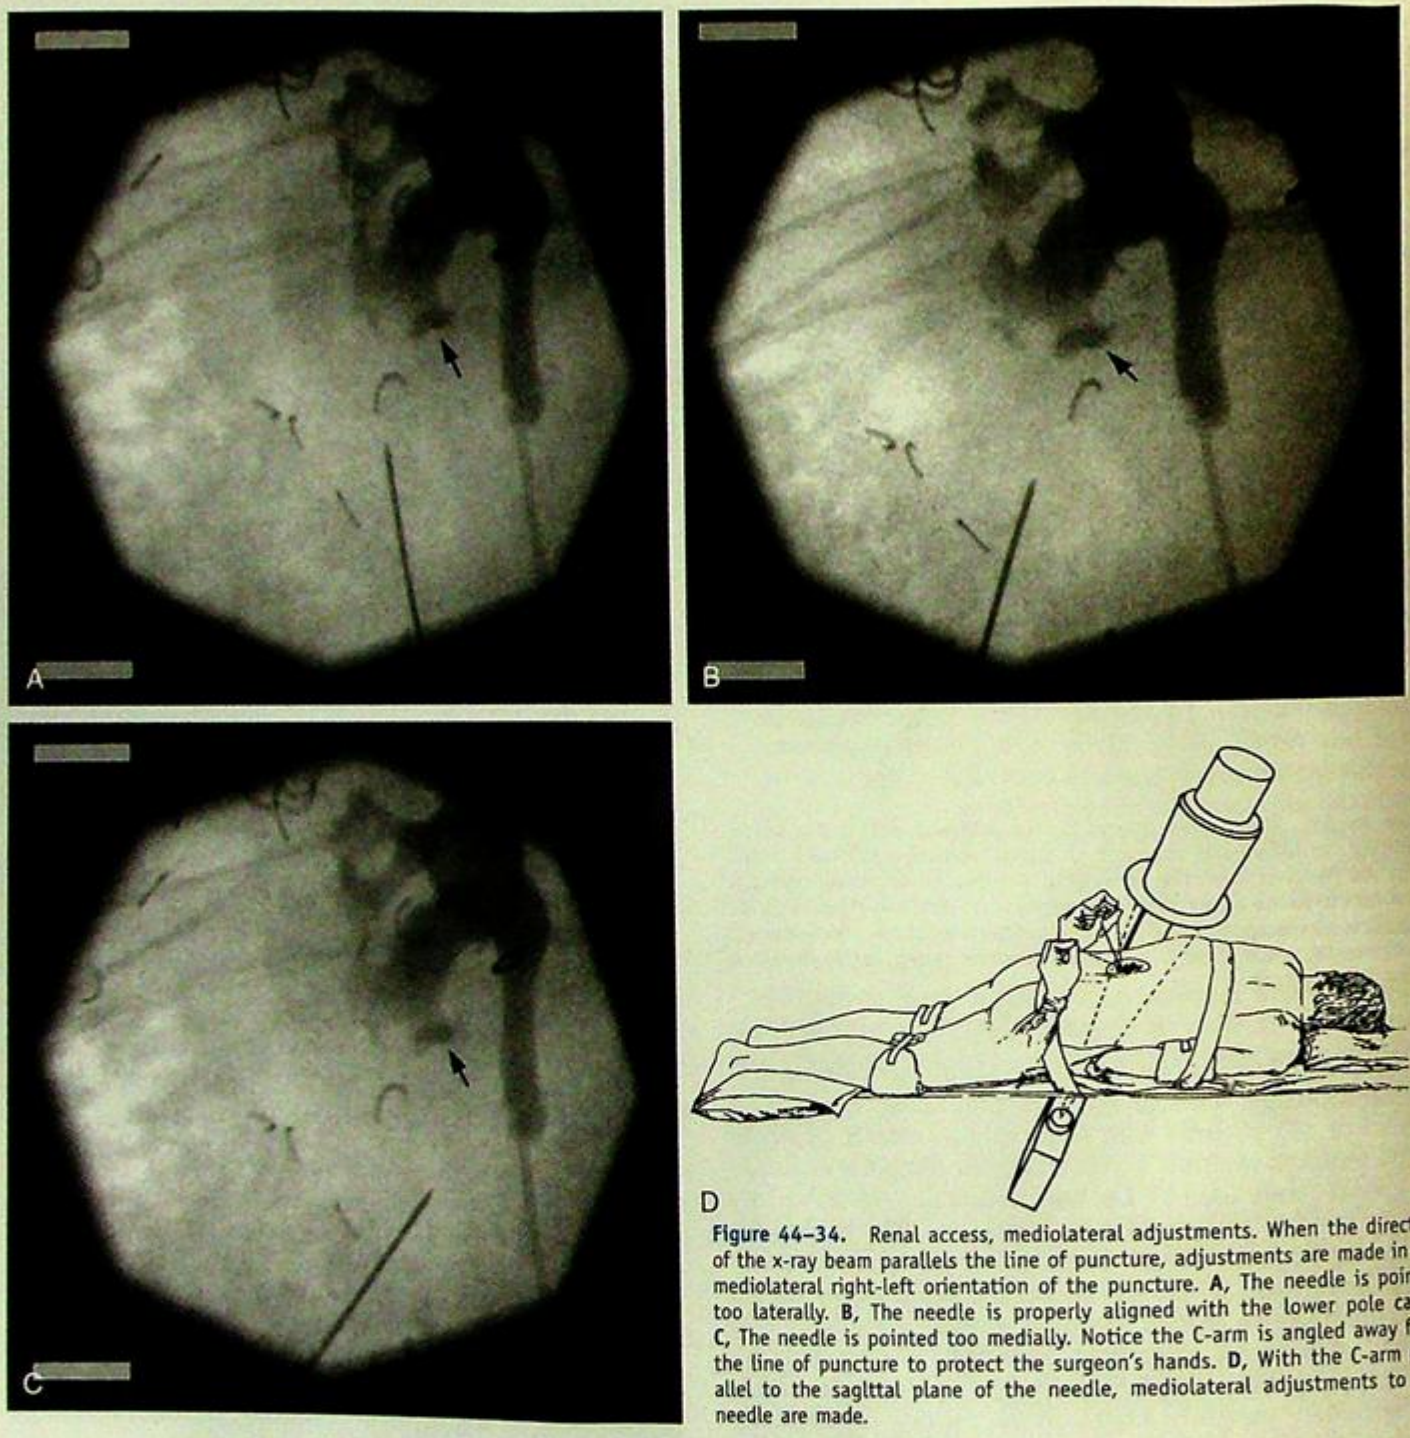

Figure 44–34. Renal access, mediolateral adjustments. When the direction of the x-ray beam parallels the line of puncture, adjustments are made in the mediolateral right-left orientation of the puncture. **A,** The needle is pointed too laterally. **B,** The needle is properly aligned with the lower pole calyx. **C,** The needle is pointed too medially. Notice the C-arm is angled away from the line of puncture to protect the surgeon's hands. **D,** With the C-arm parallel to the sagittal plane of the needle, mediolateral adjustments to the needle are made.

et al, 1981; Clayman et al, 1983; Kerlan et al, 1984). **Balloon dilators, although more costly, are often quicker and safer than the other dilators.** Davidoff and Bellman (1997) reported that use of balloon dilators was associated with significantly less bleeding as well as a reduced rate of transfusion compared with Amplatz dilation. In select cases, such as those patients with extensive perirenal fibrosis after open renal surgery, balloon dilation may not be possible, and Amplatz or metal dilators may be necessary. Excessive force, especially with use of Amplatz or metal dilators, can lead to perforation of the renal pelvis, causing significant hemorrhage and urine extravasation. In the presence of flank scarring, a 4.5-mm fascial incising needle that can be placed over the working wire will often facilitate subsequent balloon dilation.

After track dilation, the operating nephroscope is inserted through an **open, low-pressure system** with an Amplatz working sheath or through a **closed, high-pressure system** with the nephroscope serving as its own sheath. The advantages of the closed system are that the nephrostomy track is smaller (depending on the nephroscope used), hydrodistention of the collecting system occurs (which facilitates intrarenal inspection), and bleeding may be reduced (Segura, 1998). However, a closed system is a low-flow, high-pressure (16 to 33 cm H_2O) system that can lead to significant fluid

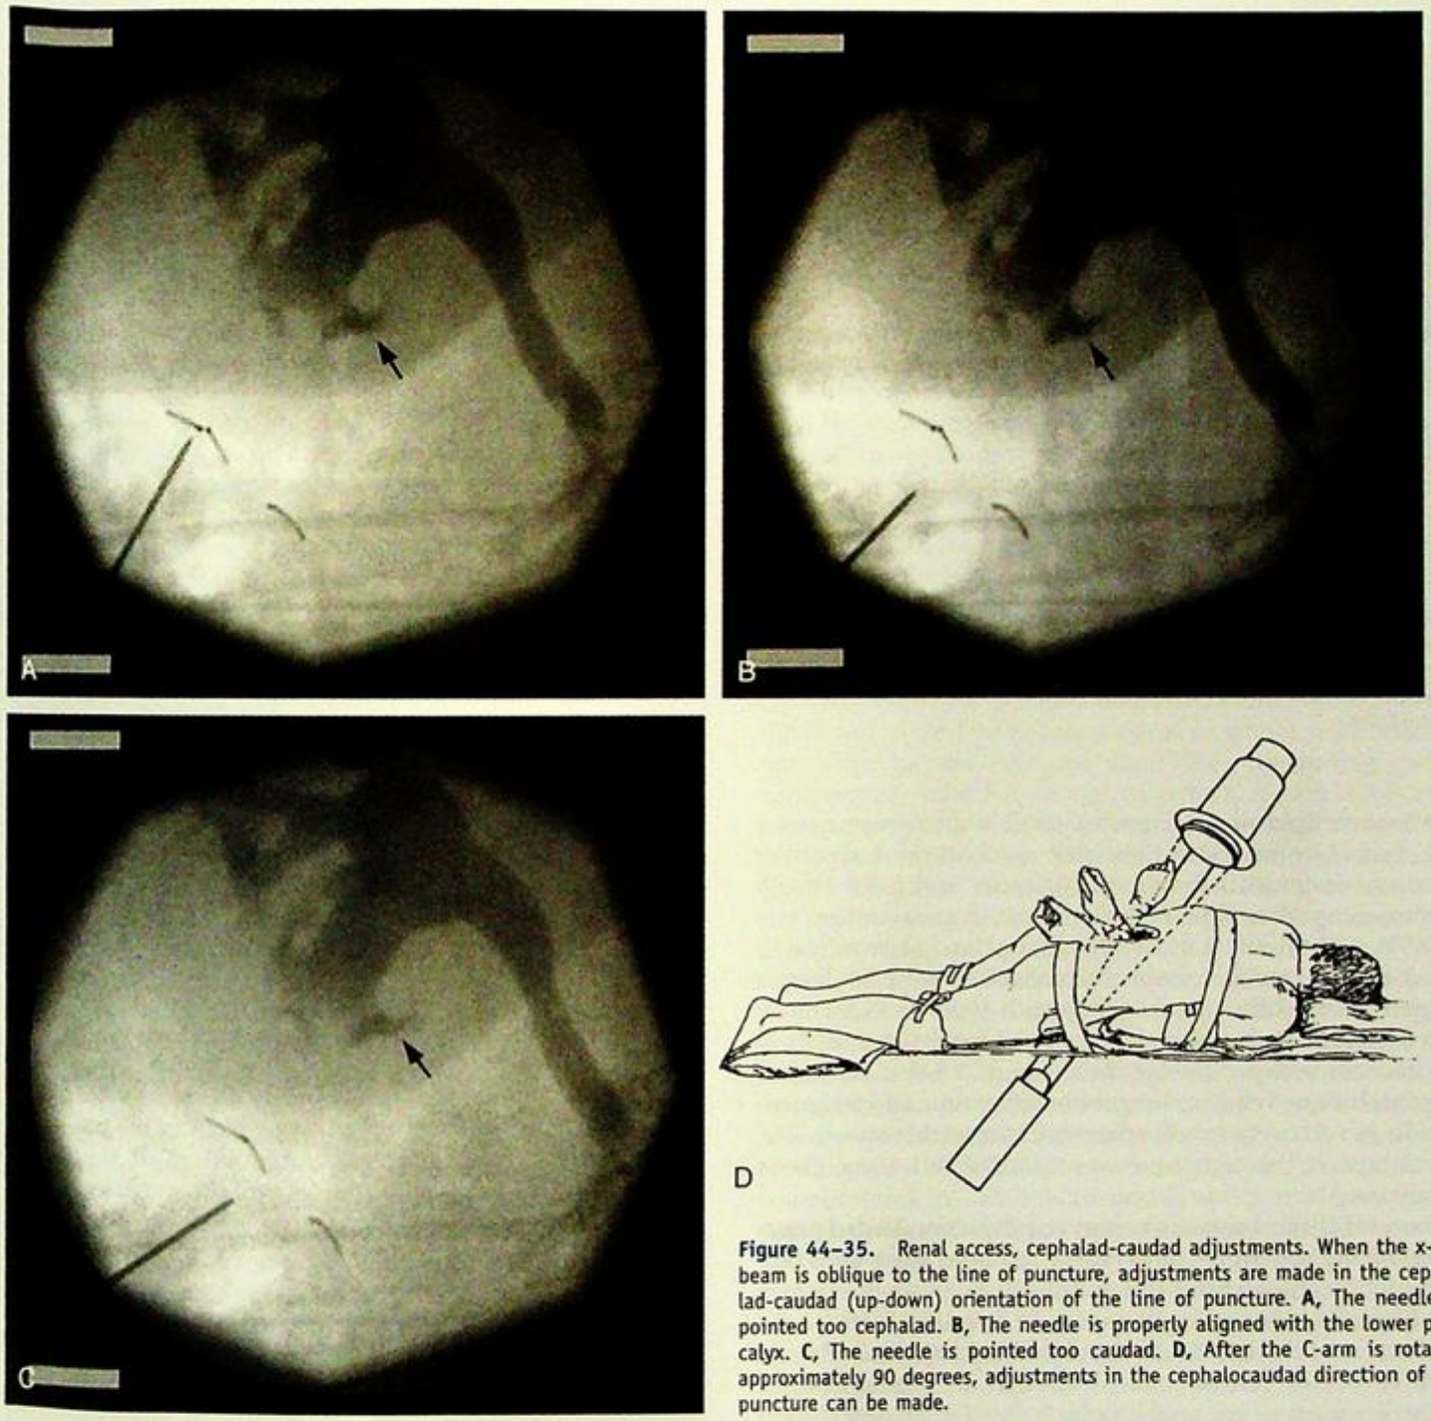

Figure 44–35. Renal access, cephalad-caudad adjustments. When the x-ray beam is oblique to the line of puncture, adjustments are made in the cephalad-caudad (up-down) orientation of the line of puncture. **A,** The needle is pointed too cephalad. **B,** The needle is properly aligned with the lower pole calyx. **C,** The needle is pointed too caudad. **D,** After the C-arm is rotated approximately 90 degrees, adjustments in the cephalocaudad direction of the puncture can be made.

absorption. When an Amplatz working sheath is used, pressures remain below 16 cm H_2O at all times and usually below 7 cm H_2O (Saltzman et al, 1987). Absorption of irrigant into the circulation and the risk of a large-volume extravasation event are higher when a closed system is used. For these reasons, use of an Amplatz sheath during PNL is always preferred. Furthermore, the use of a working sheath allows easy insertion and removal of the nephroscope and permits a simple exchange from rigid to flexible nephroscopy. In addition, the internal diameter of the Amplatz sheath is larger than that of the operating nephroscope, allowing the grasping and basketing of larger stone fragments. When the Amplatz working sheath is advanced over the dilating system into the calyx of puncture, care must be taken not to overadvance the dilator and sheath. This is a common and potentially serious error in obtaining access for PNL and may result in significant trauma to the renal collecting system or extensive hemorrhage (Fig. 44–36).

"Mini-Perc" and Nondilated Punctures. The "mini-perc" technique was first developed for use in children. An 11 to 15 French peel-away vascular access sheath was used, instead of the more commonly used 24 to 30 French Amplatz sheaths. PNL was performed with pediatric instruments (Helal et al, 1997; Jackman et al, 1998). The mini-perc technique was adapted to adult patients with stones smaller than 2 cm by use of a 13 French ureteroscopy sheath for percutaneous access,

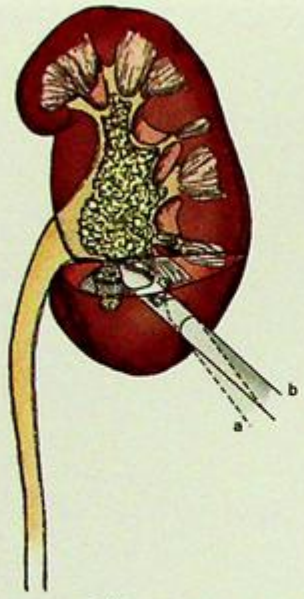

Figure 44–36. Placement of dilator–working sheath for staghorn calculus. Care should be taken to avoid overadvancement of dilators. The correct position, *a*, is just short of the renal collecting system. Overadvancement, *b*, slides past the stone-containing calyx and traumatizes adjacent renal parenchyma.

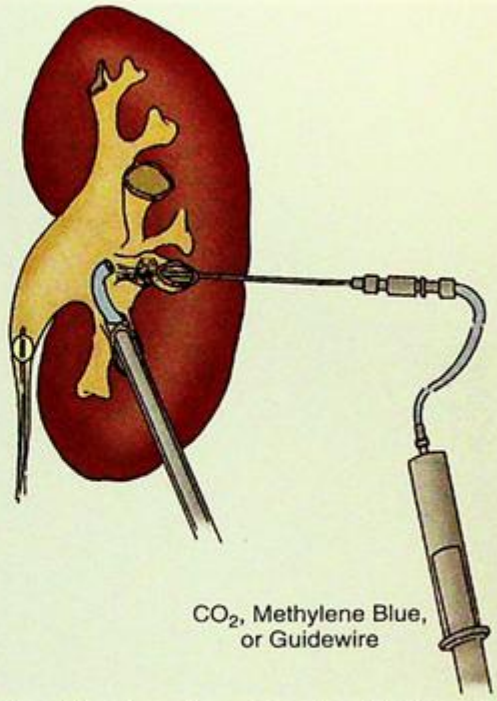

Figure 44–37. Adjuvant needle puncture (nondilated puncture) to aid in identification of difficult-to-locate calyx. Methylene blue, carbon dioxide, or a guide wire is instilled to mark entry into the desired calyx.

6.9 French rigid or 7.2 French flexible ureteroscopes, and a 7.7 French rigid offset pediatric cystoscope. Lithotripsy was achieved with a holmium:YAG laser and a 4.5 French ultrasonic probe. The authors reported a stone-free rate of 89% with minimal morbidity. Monga and Oglevie (2000) used an 18 French balloon dilation catheter, a 20 French nephrostomy sheath, and a 9.8 French rigid or 15.5 French flexible endoscope and reported similar results in a series of 16 patients with an average stone size of 2.8 cm. **The mini-perc technique requires longer operative time and fragmentation of relatively small, otherwise extractable stones.** The advantages of this technique over standard PNL remain to be established.

Several clinical situations may require a nondilated puncture during the course of PNL. For example, when an eccentric calyx is encountered that is difficult to locate through an established access, a needle puncture into the desired calyx without track dilation can be helpful. Methylene blue or carbon dioxide can be injected through the needle, and the colored stream or gas bubbles may be used to guide a flexible nephroscope into the appropriate calyx (Fig. 44–37). If the stone-containing calyx still cannot be identified after this maneuver, a glide wire may be passed through the calyx into the renal pelvis and grasped with the nephroscope. If a narrow infundibulum precludes advancement of the nephroscope, a flexible ureteroscope may be required; alternatively, the infundibulum may be dilated with a balloon. The flexible nephroscope can also be backloaded onto the guide wire and passed into the desired calyx with a push-pull technique (Lingeman, 1995). A nondilated puncture may also be used for the insertion of a small-diameter nephrostomy tube into a lower pole calyx when the initial access was placed through an upper pole calyx. Kim and associates (2005b) reported use of this technique for patients undergoing PNL through an upper pole access, when the patients were judged to have minimal or no residual stones at the conclusion of the procedure. Puncture of the lower pole was directed onto a flexible nephroscope that was inserted through the upper pole access and placed into the desired lower pole calyx. In cases in which secondary PNL was required, the procedure could be accomplished successfully by a flexible ureteroscope inserted through the nondilated lower pole access. When indicated, the insertion of a lower pole nephrostomy tube in patients undergoing PNL through upper pole access provided the benefits of a supracostal puncture with less discomfort of the patient postoperatively. This technique allows the surgeon to take advantage of the benefits of a supracostal access while minimizing postoperative discomfort.

Stone Removal. After the track has been appropriately dilated and the Amplatz sheath positioned, the urologist can proceed with stone removal by endoscopic techniques. In the early days of PNL, several authors reported the successful extraction of renal calculi with Randall's forceps (modified to allow passage over a guide wire) or stone baskets under only fluoroscopic, not visual, guidance (Castaneda-Zuniga et al, 1982; Pollack and Banner, 1984). However, fluoroscopically guided stone removal is no longer recommended because it is not as safe or as efficient as the removal of calculi under direct vision.

Physiologic solutions should be used for irrigation during PNL to minimize the risk of dilutional hyponatremia in the event of large-volume extravasation (Carson, 1986). The height of the irrigant should be maintained at 80 cm or less above the patient to minimize intrapelvic pressure and to prevent fluid absorption through pyelovenous backflow (Miller and Whitfield, 1985). The use of an Amplatz working sheath also prevents elevated intrapelvic pressures. Rigid nephroscopy is performed initially, and stones up to 1 cm in

diameter can be grasped with rigid graspers or stone baskets and extracted intact through the 30 French Amplatz sheath. Stones larger than 1 cm require fragmentation before extraction. Several intracorporeal lithotripsy techniques are available.

Rigid nephroscopy is the preferred method for stone removal; however, only the simplest intrarenal collecting systems can be completely inspected with a rigid nephroscope through a single access. Therefore, **flexible nephroscopy should be used during every PNL to survey the entire intrarenal collecting system for residual stone fragments.** Pressurization of irrigation fluid (to 300 mm Hg) during flexible nephroscopy is necessary to adequately distend the collecting system and to improve visualization (the use of an Amplatz sheath is mandatory when pressurized irrigation is used). The entire collecting system should be examined systematically, including the proximal ureter. Injection of contrast material through the flexible nephroscope is helpful in maintaining orientation and verifying that each calyx has been inspected. Small stone fragments can be removed with a stone basket passed through the flexible instrument, and larger stones can be fragmented with laser or EHL. Alternatively, fragments may be flushed or manipulated into the renal pelvis with a combination of high-pressure irrigant and a floppy-tipped J wire, where they may be retrieved more easily with rigid instruments. The goal of PNL is complete or nearly complete clearance of stone material at the time of the primary procedure, which greatly simplifies secondary procedures, if necessary. Furosemide is administered intravenously when the nephrostomy tube is placed at the conclusion of PNL to promote and to maintain diuresis.

Postoperative Considerations: Nephrostomy Tubes. After completion of PNL, percutaneous drainage through a nephrostomy tube is usually advocated. The nephrostomy tube serves several purposes: to tamponade bleeding emanating from the nephrostomy track, to allow the renal puncture to heal, to allow proper drainage of urine, and to allow access to the collecting system if a secondary PNL is required (Winfield et al, 1986). Various nephrostomy tubes are available that may be divided into several categories: catheters without self-retention features (such as red rubber Robinson-type catheters), self-retaining catheters (pigtail, Cope loop, Malecot, and balloon catheters), nephrostomy-stent combinations (reentry catheters), and circle nephrostomy tubes (U-loop catheters) (Fig. 44–38) (Babayan, 1993; Lee, 1995).

The size and type of catheter used are largely dependent on the extent of stone manipulation and urothelial trauma during PNL, the extent of hemorrhage during and after the procedure, the patient's body habitus, and the surgeon's preferences. Self-retaining catheters have an obvious advantage over catheters without self-retention properties as they are less likely to migrate or to be dislodged. Smaller, softer, self-retaining tubes (such as 10 French Cope loop catheters) cause less discomfort to the patient than do stiffer, larger diameter tubes (Kim et al, 2005b). In addition, the smaller nephrostomy track closes more readily after tube removal. However, in the presence of significant bleeding, smaller tubes may be more likely to occlude and may be insufficient to tamponade the nephrostomy track. The reentry catheter consists of a Malecot catheter with a ureteral catheter attached to the tip of the Malecot, which extends across the ureteropelvic junction into the midureter. The benefit of the reentry catheter is that access to the collecting system is maintained even when the nephrostomy tube is partially dislodged. Therefore, its use is preferable in patients prone to tube dislodgment, such as the morbidly obese. If tube dislodgment is a concern, a ureteral catheter or an angiographic catheter may also be placed through the access track in addition to the nephrostomy tube, allowing easy access to the ureter, if necessary. Finally, a circle (or loop) nephrostomy tube is a useful option after PNL with multiple accesses. After tube placement, a nephrostogram is usually obtained 24 to 48 hours after PNL. If all the stones have been removed and there is free flow of contrast material down the ureter without extravasation, the nephrostomy tube can be removed or clamped and then removed.

Bellman and associates (1997) have suggested that to minimize PNL morbidity, no nephrostomy tube may be placed after PNL in select patients. The concept of "tubeless" PNL is not new. In 1984, Wickham and coworkers omitted percutaneous drainage in selected patients, with good outcomes reported. However, Winfield and associates (1986) reported significant morbidity in two patients in whom nephrostomy tube drainage was not used after PNL, concluding that a nephrostomy tube is essential to ensure an uncomplicated postoperative course; in these two cases, no alternative form of upper tract drainage was used. Bellman and associates (1997) described 50 patients who had early removal of the nephrostomy tube after PNL. The first 30 patients had a nephrostomy tube removed within 2 to 3 hours after surgery, and the remaining 20 patients had the nephrostomy tube removed in the operating room. All patients had a double-J stent placed during PNL, and a Foley catheter was left in place for 24 hours. Patients with significant residual stone burden, procedures longer than 2 hours, multiple accesses, perforation of the collecting system, or significant bleeding were excluded. The authors reported no significant complications in this cohort, and hospitalization, analgesia requirements, and time to return to normal activity were significantly reduced in the group with double-J stent drainage compared with a control group in whom nephrostomy tubes were placed. However, no data were presented regarding postoperative assessment of residual calculi possibly necessitating secondary PNL.

Goh and Wolf (1999) reported on 10 of 26 renal units treated with an internal stent or externalized ureteral catheter placed for 1 or 2 days after PNL. Exclusion criteria included stone burden larger than 3 cm, more than one access, obstructive renal anatomy, need for a second-look procedure, and significant bleeding or perforation during the procedure. The authors reported a reduction in hospital stay in the tubeless group with morbidity comparable to that of patients with standard nephrostomy tube drainage. However, 4-mm residual fragments were noted in two patients. Delnay and Wake (1998) described 33 patients in whom an internal stent was placed in lieu of a nephrostomy tube after PNL with use of similar exclusion criteria. Average hospital stay was 1.5 days, and no significant complications occurred, but several patients harbored residual calculi that necessitated additional procedures (SWL) after PNL. Limb and Bellman (2002)

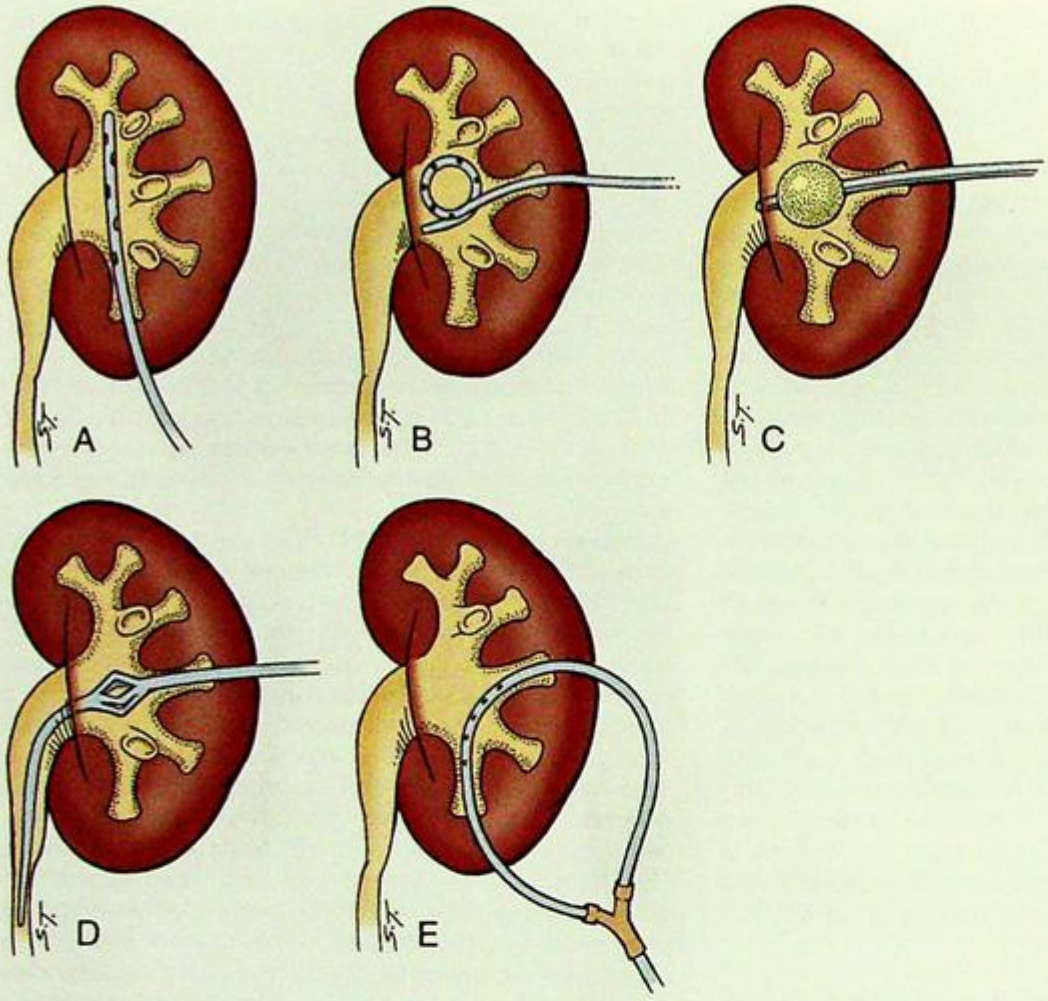

Figure 44–38. Various nephrostomy tubes. Without self-retention: a red rubber catheter (**A**). Self-retaining catheters: Cope loop (**B**), Foley catheter (**C**), nephrostomy-stent combination or reentry catheter (**D**). Multiaccess drainage: a circle (U-loop) tube (**E**).

described 112 patients undergoing tubeless PNL; strict criteria were used to select these patients, who had a mean stone burden of 3.30 cm^2. The authors reported a 93% stone-free rate and a mean length of hospitalization of 1.56 days; 7% required subsequent SWL ancillary treatments. Feng and associates (2001) performed a randomized controlled study comparing standard PNL, mini-PNL, and tubeless PNL. They found no advantage for the mini-PNL over the standard PNL and also found that the tubeless cohort experienced the least morbidity. Desai and associates (2004) also performed a prospective randomized study of patients undergoing PNL with conventional large-bore nephrostomy drainage, small-bore nephrostomy drainage, or no nephrostomy drainage. The authors reported that tubeless PNL was associated with the least pain. However, they did not comment on the need for ancillary procedures or the stone-free status of the patients.

Tubeless PNL (with internal drainage) remains controversial but may be considered for select, relatively straightforward cases for which the urologist is certain that no secondary procedures will be required. An important caveat is that all tubeless procedures have been reported to include the placement of an internalized ureteral stent, which requires a second procedure to accomplish stent removal.

Percutaneous Nephrolithotomy in Special Situations

Calyceal Diverticula

Calyceal diverticula are nonsecretory, transitional cell epithelium–lined cystic cavities within the renal parenchyma. A narrow communication with the pelvicalyceal system almost always exists. The incidence of calyceal diverticula diagnosed on routine intravenous pyelography ranges from 0.21% to 0.45% (Hulbert et al, 1986). Calculi have been reported in 9.5% to 50% of calyceal diverticula (Jones et al, 1991). Percutaneous access into stone-bearing diverticula poses several unique problems. Direct puncture is often difficult because of the small size of the cavity and the frequent occurrence of calyceal diverticula in the upper pole of the kidney. After successful puncture is achieved, negotiation of a guide wire into the renal pelvis is often not possible. A similar situation can occur when a stone fills a calyx so completely that a guide wire cannot be passed through the infundibulum into the renal pelvis or in the rare case of infundibular stenosis. To overcome these difficulties, a special access technique is required.

Contrast media can be instilled through a ureteral catheter to localize the diverticulum. However, if the stones are visible

on fluoroscopy, it is often preferred to puncture directly onto the stone (Ohlsen and Kinn, 1993). **Direct puncture into the diverticulum allows use of rigid instruments that provide superior visualization compared with flexible instruments that are used in an indirect approach.** Optimal visualization is essential in trying to identify the communication between the diverticulum and the renal collecting system. Direct access is also beneficial because fulguration of the urothelium can easily be achieved by a resectoscope equipped with a roller-ball electrode. Jones and colleagues (1991) reported that direct percutaneous access into the diverticulum could be established in all but 2 of 24 patients. Likewise, Shalhav and associates (1998) reported that in a group of 30 patients with calyceal diverticula, direct access was performed in 28 patients. When direct puncture fails, a neighboring calyx can be punctured and the diverticulum entered indirectly by perforating the wall of the diverticulum or by entering in a retrograde fashion, through the diverticular neck (Hedelin et al, 1988). However, the results with an indirect approach are inferior (Jarrett and Smith, 1986).

Kim and associates (2005a) have described a single-stage technique for the treatment of patients with calculi residing in a calyceal diverticulum (Fig. 44–39). Once the diverticulum is punctured, a 0.035-inch movable core J wire is coiled within the diverticulum. It is important to ensure that not only the floppy tip of the wire but also the solid core is coiled within the diverticulum, so that sufficient stabilization is provided for proper placement of coaxial dilators. A second 0.035-inch movable core J wire serving as a safety wire is then passed through the 10 French sheath of the coaxial dilator. With two guide wires coiled within the diverticular lumen, balloon dilation of the track can be performed safely. Care should be taken to avoid perforation of the back wall of the diverticulum. Once the balloon dilator is inflated, the working sheath is passed over the balloon as close as possible to the diverticulum without advancing the balloon. In small diverticula, this results in the placement of the sheath outside the diverticulum. An 11 French alligator forceps is passed through the rigid nephroscope and used to follow the wire and gently spread renal parenchyma to allow entry into the calyceal diverticulum under direct vision. Stone material is extracted with grasping forceps or ultrasonic lithotripsy. Careful inspection of the urothelium with the rigid nephroscope is performed in an effort to identify a flattened renal papilla, which suggests an obstructed calyx rather than a diverticulum. The neck of the diverticulum is often difficult to identify as it can be diminutive. Methylene blue injected through the ureteral catheter can facilitate visualization of the ostium. Once a guide wire is passed into the renal pelvis, the neck of the diverticulum can be balloon dilated or incised.

Because calyceal diverticula are lined by a nonsecretory endothelium, most authors advocate fulguration at the time of PNL as this will ablate 76% to 100% of diverticula (Ellis et al, 1991; Jones et al, 1991; Shalhav et al, 1998; Monga, 2000). Alternatively, Hulbert and coworkers (1986) reported treating 10 patients with calyceal diverticula and suggested that trauma to the wall of the diverticulum caused by the dilation process is sufficient to ablate the diverticular lumen. In this series, a nephrostomy tube was left in place for 2 weeks. However, Donnellan and colleagues (1999) reported that treatment of 20 patients with calyceal diverticula by dilation or incision of the diverticular neck without fulguration resulted in complete ablation of the diverticulum in only 30% of patients, leading the authors to conclude that fulguration should be performed routinely to ensure diverticular ablation. Typically, after ablation of the diverticulum, a nephrostomy tube is placed for 48 to 72 hours.

Horseshoe Kidney

Horseshoe kidney is the most common congenital renal anomaly, with an estimated incidence of 1 in 400 and a male-to-female ratio of 2:1 (Jones et al, 1991). The unique location and orientation of the horseshoe kidney are due to the incomplete cephalad migration and malrotation of the kidney, a

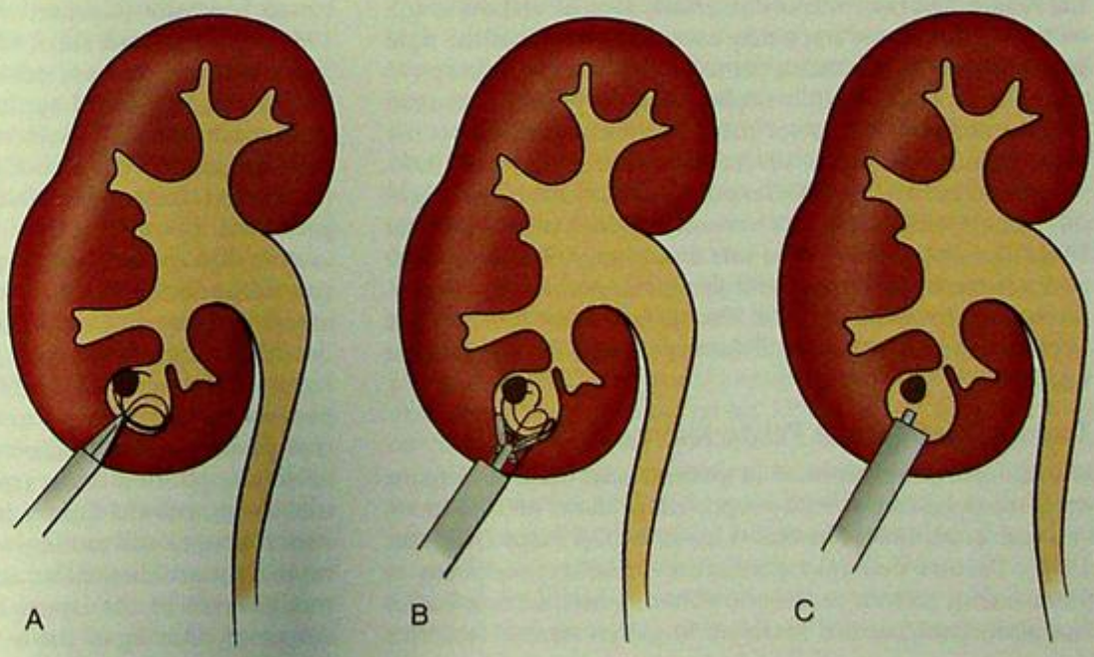

Figure 44–39. Access into small diverticula. **A,** Balloon dilator is advanced as far as possible without perforating the back wall of the diverticulum. The working sheath is placed just outside the diverticulum. **B,** Alligator forceps spread the parenchyma and allow advancement of the nephroscope under vision into the diverticulum. The working sheath is then advanced over the nephroscope and into the diverticulum (**C**).

consequence of the entrapment of the isthmus under the inferior mesenteric artery (Hohenfellner et al, 1992). The ureteropelvic junction is commonly deformed owing to the high insertion of the ureter into a typically elongated renal pelvis. The course of the proximal ureter is similarly aberrant; it drapes ventrally over the renal symphysis, where it may be compressed by vessels supplying the lower pole and isthmus. Ureteral obstruction that may result from these anomalies can give rise to hydronephrosis, urinary stasis, sepsis, and calculi formation in up to 70% of patients (Jones et al, 1991; Lampel et al, 1996).

In considering PNL in a horseshoe kidney, the characteristic lower and centrally oriented position of the kidney, the orientation of the collecting system, and the abnormal blood supply should be taken into account. Janetschek and Kunzel (1988) performed postmortem examinations of six horseshoe kidneys, in situ, and found normal renal arteries in all specimens. However, accessory arteries entering the renal hilum, aberrant polar and isthmus arteries originating from the aorta, and hypogastric and common iliac arteries were noted as well; all blood vessels, except a select few supplying the isthmus, entered the kidney from its ventromedial aspect. Therefore, **a puncture of the dorsal or dorsolateral aspect of the kidney will be well away from major renal vessels.**

Skoog and associates (1985) have reported an association between horseshoe kidney and retrorenal colon. A preoperative CT scan can be of assistance, then, in determining the presence of a retrorenal colon as well as in defining the stone-bearing calyces. **The lower pole calyces lie within a coronal plane, angled medially, and are seldom suitable for direct puncture** (Al-Otaibi and Hosking, 1999). However, the **upper pole calyces are more posterior and lateral and are often subcostal, providing a convenient and relatively safe route for PNL access.** The standard site for PNL (inside the posterior axillary line just caudad to the 12th rib) is punctured, but the angle of the puncture is caudad rather than cephalad. Because most of the calyces of horseshoe kidneys point either dorsomedially or dorsolaterally, they are more favorably positioned for puncture than are normal renal units (Janetschek and Kunzel, 1988). Because of the malrotation of the kidney, the renal pelvis may be more anteriorly located, and the length of the nephrostomy track may exceed the length of the rigid nephroscope, necessitating the use of flexible nephroscopy or multiple accesses. Flexible nephroscopy may also be required to gain access to the lower medial calyces, where stones are often found (Jones et al, 1991; Al-Otaibi and Hosking, 1999).

Raj and associates (2003) reported a multicenter analysis of 24 patients with calculi in a horseshoe kidney who underwent PNL. The overall stone-free rate was greater than 90%, most accesses were upper pole, and flexible nephroscopy was performed in almost all patients. The authors noted that the rigid nephroscope was rarely sufficient to remove the whole stone burden.

Transplantation and Pelvic Kidneys

Urolithiasis is uncommon in patients who have undergone renal transplantation, with a reported incidence of 0.5% to 3% (Harper et al, 1994; Shoskes et al, 1995; Del Pizzo and Sklar, 1999). Factors that may predispose transplant recipients to form calculi include metabolic abnormalities, foreign bodies (nonabsorbable suture material, forgotten stents), recurrent infection, and papillary necrosis. On occasion, calculi may have been present in the donor kidney (Pardalidis et al, 1994). Typical renal colic does not occur because the transplantation kidney and ureter are denervated; the presentation may instead resemble acute rejection or acute tubular necrosis (Harper et al, 1994; Rhee et al, 1999). Benoit and colleagues (1996) reported that in a series of 1500 transplantation patients, 12 (0.8%) were diagnosed with urinary calculi. Three patients presented with obstructive anuria, one patient presented with abdominal pain, and eight patients were asymptomatic and diagnosed by ultrasonography.

Renal allografts present a unique anatomic situation for PNL. The most common surgical anatomy is for the donor left kidney to be placed extraperitoneally into the recipient's right iliac fossa; alternatively, the right kidney is transplanted in the left iliac fossa. In either case, the renal pelvis is located medially, requiring that the kidney be rotated 180 degrees on its axis. Thus, the posterior calyces point anteriorly, and consequently an anterior approach to the kidney is similar to a posterior approach to native kidneys. In the usual percutaneous approach to a transplanted kidney, the patient is placed in the lithotomy position, which allows simultaneous cystoscopic access to the bladder. A ureteral catheter is inserted for instillation of contrast material. Access is most safely established (i.e., avoiding intraperitoneal contents) into the lower pole with the skin puncture as caudal as possible. Percutaneous access to transplanted kidneys is actually facilitated by their superficial location. However, scar formation around the graft may make the initial needle puncture and track dilation more difficult (Rhee et al, 1999). Once access is established, PNL can be performed by standard methods (Pardalidis et al, 1994). Del Pizzo and Sklar (1999) have reported the use of a mini-perc technique in 14 transplantation patients in whom access was established with the aid of intraoperative ultrasonography with a 16 French suprapubic peel-away introducer and sheath. No data are available to show an advantage of the mini-perc technique compared with the larger diameter working sheaths. Although delayed closure of the access track after catheter removal in immunosuppressed transplantation patients is a concern, most authors report that dilated tracks closed normally (Caldwell and Burns, 1988; Gedroyc et al, 1989; Del Pizzo and Sklar, 1999).

Patients with ectopic pelvic kidneys necessitate a different and more complicated approach for PNL as a result of their unique anatomy. The incidence of pelvic kidney has been estimated to range from 1 in 2200 to 1 in 3000 in autopsy series (Zafar and Lingeman, 1996). The pelvic kidney is retroperitoneal, posterior to the peritoneum and anterior to the sacrum. Interposing bowel loops between the kidney and the anterior abdominal wall prevent a direct puncture through the anterior abdominal wall. Eshghi and colleagues (1985) first described a laparoscopically assisted PNL technique for pelvic kidneys. Holman and Toth (1998) reported a series of 15 patients treated with laparoscopically assisted percutaneous transperitoneal nephrolithotomy. With patients in the Trendelenburg position under laparoscopic control, the bowel was mobilized until the kidney became visible, allowing percutaneous access. All stones were removed successfully with minimal morbidity. Zafar and Lingeman (1996) described a modification of the laparoscopic technique in which intracorporeal suturing of the nephrotomy site and ureteral stent

placement allowed elimination of a transperitoneal nephrostomy tube. Alternatively, Matlaga and associates (2003b) reported the utility of obtaining percutaneous access with CT guidance for select patients harboring calculi in ectopic renal units.

Morbid Obesity

Patients suffering from morbid obesity, defined as more than 100 pounds overweight, greater than 200% of ideal body weight, or a body mass index (a value obtained by weight in kilograms divided by height in meters^2) greater than 40, present technical as well as anesthetic challenges (Freedman et al, 2002). Often, one or more comorbid factors complicate management of these patients. Pearle and coworkers (1998) described a group of 57 patients undergoing PNL. Of the patients, 59.6% were classified by the anesthesiologist as American Society of Anesthesiologists class II and 40.4% as class III. General anesthesia may be a special concern for patients in the prone position because of restricted respiratory capacity that may require higher ventilation pressures intraoperatively. Some studies suggest an increased postoperative morbidity in morbidly obese patients, mostly because of the higher incidence of wound infection and thromboembolic events.

However, when Carson and colleagues (1988) compared 44 obese patients with 226 nonobese patients undergoing PNL, they found **no significant difference in postoperative morbidity.** Pearle and associates (1998), too, reported **no significant difference in complication and transfusion rates as well as in length of hospitalization** between obese and nonobese patients. Koo and colleagues (2004) similarly reported that **the outcome of PNL is independent of the patient's body mass index.**

There are a number of challenges in performing a radiographic evaluation of a morbidly obese patient suffering from renal or ureteral calculi. Attenuation of the ultrasound beam can make identification of the kidney difficult. Weight limitations of CT gantries (usually in the range of 300 pounds) as well as the wide girth of these patients may restrict the use of CT (Hofmann and Stoller, 1992). However, imaging is essential not only to evaluate the stone burden and location but also to determine the distance from skin to stone.

PNL in morbidly obese patients presents several unique challenges. Positioning the patient can be difficult, and in particular for large patients, two surgical tables may need to be secured together (Hofmann and Stoller, 1992). Kerbl and colleagues (1994) reported use of the flank position in two very obese patients to facilitate ventilation. However, the lateral decubitus position resulted in greater renal mobility and a longer nephrostomy track. Furthermore, Hoffman and Stoller (1992) described a morbidly obese patient who developed acute rhabdomyolysis secondary to crush injuries from placement in the lateral approach. The major difficulty in performing PNL in the morbidly obese patient is the long distance from the skin to the collecting system, which may exceed the length of the working sheath or the length of the rigid nephroscope. **Extralong Amplatz working sheaths (20 cm or more) and extralong rigid nephroscopes are now available that can overcome this challenge.** Alternatively, the Amplatz sheath can be secured by a suture, allowing easy retrieval even when it migrates under the skin (Nguyen and Belis, 1998). On occasion, when the long Amplatz sheath is not sufficient to reach the kidney, an incision can be made through the subcutaneous tissue to the muscles of the flank, and the PNL track is created from the level of the muscle sheath (Curtis et al, 1997). Giblin and colleagues (1995) described the successful use of extralong Amplatz sheaths (18 to 24 cm) and a 30 French gynecologic laparoscope (with a working length of 27 cm) in five patients in whom the skin-to-stone distance precluded the use of standard percutaneous access sheaths and nephroscopes. Another possibility is to dilate the track and place a nephrostomy tube for 1 week to let the track mature. Flexible nephroscopy can then be performed through the mature track. In some cases, maturation of the track allows the kidney to fall back posteriorly closer to the skin, allowing the use of standard nephroscopic instrumentation (Hofmann and Stoller, 1992). Liberal use of flexible nephroscopy in obese patients improves the stone-free rate and decreases the need for additional access (Pearle et al, 1998).

After stone removal, consideration should be given to the type of nephrostomy tube used. **Tube displacement tends to occur more often in morbidly obese patients,** so balloon-type catheters or reentry Malecot catheters may be preferable (Carson et al, 1988). Alternatively, if a Cope loop catheter is used, placement of a ureteral catheter should be considered to ensure that access to the kidney is not lost should the nephrostomy tube become displaced.

Bilateral Simultaneous Percutaneous Nephrolithotomy

Patients with large, bilateral stone burdens present a formidable challenge to the urologist; rendering these patients stone free can require separate staged procedures and multiple anesthetics. In 1987, Colon-Perez and associates (1987) first reported simultaneous bilateral PNL in a series of three patients. Since that time, the procedure has evolved, and several dictums have been established. It is recommended that either the side that is more symptomatic or the side that is more difficult be treated first. Patients may be positioned prone or with the treated side elevated.

Dushinski and Lingeman (1997) reported their experience with 48 patients with a mean stone surface area of 929 mm (approximately half of the stones were staghorn stones). Mean operative time was 269 minutes, and mean hospital stay was 5.6 days. Of these patients, 96.6% were rendered stone free. Complications were infrequent, and intrathecal morphine injections at the end of the case decreased the need for postoperative narcotics, possibly shortening the length of hospitalization. Nadler and coworkers (1998) compared a group of four patients undergoing simultaneous bilateral PNL under general anesthesia plus subarachnoid spinal anesthesia with a group of four patients undergoing staged bilateral PNL without subarachnoid spinal anesthesia. A marked advantage in hospital stay (4.8 days versus 11 days) and postoperative narcotics requirements was demonstrated for the simultaneous bilateral PNL group, leading the authors to conclude that simultaneous bilateral PNL provides the patient with a less morbid, more rapid method of stone resolution than does staged PNL or a sandwich technique (PNL followed by SWL followed by PNL). Silverstein and associates (2004) also reported that stone-free rates, blood loss per operation, and

transfusion rates for simultaneous and staged bilateral PNL were similar. Furthermore, the reduced total operative time, hospital stay, and total blood loss along with the requirement for only one anesthesia session makes simultaneous bilateral PNL an attractive option for select patients. The authors recommend, though, that the decision should be made to pursue the second side only if no significant bleeding is encountered on the first side, the first side did not take an undue amount of time, the patient is clinically stable, and the anesthesia team is agreeable. Holman and associates (2002) confirmed these findings in a larger series, reporting that simultaneous bilateral PNL was not associated with greater hazards than was unilateral PNL.

Complications

Even for the most experienced urologist, major complications can still occur in 1.1% to 7% of patients undergoing PNL, and minor complications may be encountered in 11% to 25% of patients. **Hemorrhage is the most significant complication of PNL, with transfusion rates reported to be from less than 1% to 10%.** Bleeding from an arteriovenous fistula or pseudoaneurysm that requires angiographic embolization occurs in less than 0.5% of patients. Other potential complications include sepsis in 0.3% to 2.5% (postoperative temperature below 38.5°C is found in almost one fourth of patients), adjacent organ injury (bowel, spleen) in less than 0.5%, failed access in less than 5%, and perforation of renal pelvis and ureter in less than 2%. The need for open surgery is rare and mostly reported as part of early experience in various studies. The mortality rate of PNL is between 0.046% and 0.8% (Lang, 1987; Lee et al, 1987a; Henriksson et al, 1989; Jones et al, 1991; Lam et al, 1992c; Segura et al, 1994; Dyer et al, 1997; Matlaga et al, 2004). When supracostal puncture is performed, the risk of pneumothorax or pleural effusion requiring drainage is 4% to 12% (Young et al, 1985; Picus et al, 1986; Fuchs and Forsyth, 1990; Narasimham et al, 1991; Golijanin et al, 1998; Munver et al, 2001) (see Table 44–16). Finally, failure of equipment is an often-ignored but significant potential complication.

During initial experiences with PNL, concern was expressed about the extent of renal damage caused by the creation and dilation of the transparenchymal nephrostomy track. However, several studies have shown that although some scarring occurs along the percutaneous track, there is little or no significant effect on renal function (Eshghi et al, 1989).

As the kidney is an extremely vascular organ, some degree of bleeding occurs during every PNL. Significant bleeding usually requires cessation of the procedure because of impaired visualization. In most cases, the source of hemorrhage is venous, and placement of a nephrostomy tube is usually sufficient to control the bleeding. If bleeding persists despite the placement of a nephrostomy tube, clamping the tube for a time may facilitate the tamponade of any bleeding points (Carson, 1986). If these measures do not control the hemorrhage, a Kaye nephrostomy tamponade balloon catheter should be placed. The Kaye nephrostomy tube incorporates a low-pressure 12-mm balloon that may be left inflated for prolonged periods to tamponade bleeding from the nephrostomy track (Kaye and Clayman, 1986). If bleeding persists despite placement of a Kaye catheter, immediate angiography should be performed to identify a possible arteriovenous fistula or false aneurysm. Angiography is both diagnostic and therapeutic, as arteriovenous fistulas and false aneurysms are best managed by embolization. In the rare event that bleeding cannot be controlled with angiography, partial nephrectomy may be required.

PNL can lead to some absorption of irrigation fluid; therefore, the use of physiologic irrigating solutions is mandatory. The amount of absorbed fluid depends mostly on the irrigant pressure and the length of the procedure. Larger amounts of fluid absorption may occur with extravasation of fluid due to collecting system perforation. Extravasation usually occurs into the retroperitoneal tissue and may be noted by medial displacement of the kidney during fluoroscopy. Minor perforations are common during PNL; premature termination of the procedure is usually not necessary if a low-pressure system (i.e., Amplatz sheath) is being used. However, with more significant perforations, termination of the procedure and nephrostomy drainage are advisable (Irby et al, 1999). Intraperitoneal extravasation is a less common but potentially more serious complication than retroperitoneal extravasation. As the patient is prone, abdominal distention may be difficult to recognize, although the anesthesiologist will usually note a gradual rise in the patient's diastolic blood pressure with consequent narrowing of the pulse pressure and increase in central venous pressure; in advanced cases, ventilation may become difficult because of increased abdominal pressure (Carson, 1986). Early recognition of major extravasation is crucial. Some authors have suggested that irrigant input and output should be monitored during PNL, and if a discrepancy of more than 500 mL is encountered, cessation of the procedure should be considered (Lee et al, 1986; Segura, 1993). This is often not possible and should not be considered mandatory. Intraperitoneal extravasation may be treated by vigorous diuresis; alternatively, peritoneal drainage has been reported (Carson and Nesbitt, 1985).

When a supracostal puncture is performed, extravasation of irrigant into the pleural cavity may occur. The use of a working sheath tends to minimize extravasation into this space because intrarenal pressure remains low. The chest should be examined at the end of PNL procedures in which a supracostal puncture is used. Fluoroscopy with use of the C-arm is usually sufficient to examine for pneumothorax or hydrothorax (Ogan et al, 2003). If the surgeon has a high index of suspicion for a thoracic complication, a chest radiograph may be obtained postoperatively. If a greater than 10% pneumothorax or hydrothorax occurs, aspiration is generally sufficient because lung injury is extremely rare. Should the pneumothorax recur, a chest tube should be placed. Ogan and Pearle (2002) have described placement of a chest tube under fluoroscopic guidance at the time of the PNL.

Colonic injury is an unusual complication and is often diagnosed on postoperative nephrostogram, although passage of gas or feculent material through the nephrostomy track, intraoperative diarrhea, and hematochezia or peritonitis are all signs of a possible colonic perforation. Typically, the injury is retroperitoneal; thus, signs and symptoms of peritonitis are infrequent. If the perforation is extraperitoneal, management may be expectant, with placement of a ureteral catheter or double-J stent to decompress the collecting system and withdrawal of the nephrostomy tube from an intrarenal position to an intracolonic position to serve as a colostomy tube (Gerspach et al, 1997). The colostomy tube is left in place for

a minimum of 7 days and is removed after a nephrostogram or a retrograde pyelogram shows no communication between the colon and the kidney (LeRoy et al, 1985; Wolf, 1998).

Ureteroscopic Management of Ureteral Stones

Basic ureteroscopic techniques and intracorporeal lithotripsy techniques have been reviewed elsewhere. Herein, issues of anesthesia and specific points of technique and complications of ureteral stone management are reviewed.

The increasing miniaturization of and improvements in the technology of ureteroscopy have greatly altered the anesthetic considerations associated with this procedure. Ureteroscopy was initially performed exclusively under general or regional anesthesia as a consequence of the large-caliber ureteroscopes that were available. However, as ureteroscopes have become more diminutive, intravenous sedation, or sedoanalgesia, has provided another practical anesthetic option for patients harboring ureteral stones. The short duration of modern sedoanalgesic agents allows rapid relief of pain, efficient titration of analgesia, and rapid recovery after the procedure. Ureteroscopy can be safely and efficiently performed under local or intravenous sedation, with success rates equivalent to those of patients undergoing general regional anesthesia (Rittenberg and Bagley, 1988; Abdel-Razzak and Bagley, 1992, 1993; Grasso and Bagley, 1998; Cybulski et al, 2004). As most ureteral orifices will accommodate a 6 to 7 French device, immediate access to ureteral calculi with a 7 French flexible ureteroscope is possible. Furthermore, the small-diameter fibers of the holmium:YAG laser allow the immediate treatment of ureteral calculi.

The ability to fragment and remove calculi with a ureteroscope has dramatically advanced the urologist's ability to render patients stone free with one procedure. Early stone-free results with flexible ureteroscopy did not greatly exceed those of in situ SWL, both being approximately 80% (Drach et al, 1986; Bagley, 1990; Frang et al, 1992; Mogensen and Andersen, 1994). However, as smaller ureteroscopes were introduced and the holmium:YAG laser became available, success rates increased (Grasso et al, 1998). Although it is a more invasive technique than SWL, ureteroscopy with small, rigid or flexible endoscopes is the most efficient technique for treatment and removal of ureteral stones. Patients desiring a single procedure with maximal efficacy should consider primary ureteroscopy.

When the ureteral orifice is too narrow to accommodate a ureteroscope, dilation may be accomplished with serial dilators, balloons, or even the ureteroscope itself. The anatomy of male patients may not allow a rigid ureteroscope to be easily passed above the iliac vessels, but a flexible ureteroscope can usually be advanced over a guide wire. The entire ureter can be more easily accessed with a rigid ureteroscope in female patients. Once the stone is visualized, fragmentation with the lithotrite of choice is performed. Complete fragmentation to a size less than that of the safety wire (0.035 inch) should allow passage of all fragments without sequelae. Alternatively, fragmentation to a size sufficient for extraction by a stone retrieval device achieves a stone-free state for the patient at the end of the procedure.

Ureteral access sheaths have been developed to facilitate difficult ureteroscopic access. Kourambas and associates (2001) reported a randomized controlled study comparing patients who underwent ureteroscopy with a 12 to 14 French ureteral access sheath and those who underwent ureteroscopy with no access sheath. They found that use of the access sheath decreased operating time and costs and simplified ureteral reentry. Others have reported that intrapelvic pressures remain low when an access sheath is employed, a potentially significant finding when patients with infection-related calculi are treated (Rehman et al, 2003).

If significant ureteral edema or manipulation occurs, a post-ureteroscopy stent should be placed to prevent colic and obstruction. If the clinical situation does not allow primary ureteroscopy (sepsis, inability to advance the ureteroscope, ureteral injury, equipment failure), a ureteral stent is placed and the problem corrected. Secondary or post-stent ureteroscopy has the advantage of working through a dilated ureter, often allowing the use of larger rigid ureteroscopes.

Steinstrasse

Steinstrasse, literally "street of stones," describes the accumulation of stone fragments in the ureter, obstructing the collecting system, after SWL. This complication has been reported in 2% to 10% of SWL cases and directly correlates with increasing stone burden (Coptcoat et al, 1987; Weinerth et al, 1989; Sulaiman et al, 1999; Madbouly et al, 2002). Large stone burden, staghorn calculi, bilateral SWL, and preexisting ureteral obstruction are all known to be risk factors for steinstrasse (Weinerth et al, 1989). Steinstrasse may occur in as many as 41% of patients undergoing SWL monotherapy for staghorn calculi, although with the increasing use of PNL in the treatment of patients with large stones, the incidence of steinstrasse has lessened (Coptcoat et al, 1987; Wirth et al, 1992).

The spectrum of presentation of patients suffering from steinstrasse is variable. Some patients may be entirely asymptomatic; others will present with the typical symptoms of renal colic, urinary tract infection, and renal insufficiency, with a time to presentation ranging from hours to months after SWL. More than 70% of steinstrasse occurs in the distal ureter (Coptcoat et al, 1987; Fedullo et al, 1988; Al-Awadi et al, 1999b; Sulaiman et al, 1999).

The placement of a ureteral stent before SWL therapy may decrease although not eliminate the risk of steinstrasse. However, the benefit of ureteral stent placement is probably limited to those patients with large stone burdens or solitary kidneys (Coptcoat et al, 1987; Riehle and Naslund, 1987; Libby et al, 1988; Sulaiman et al, 1999). Sulaiman and associates (1999) reviewed 1087 patients who underwent treatment for renal calculi with a piezoelectric lithotripter and found the incidence of steinstrasse to be 6.3%. The authors routinely placed a ureteral stent in all patients with a stone burden of more than 20 mm. However, regardless of ureteral stent placement, steinstrasse occurred in 4%, 14%, and 30% of patients with stones of 10 to 19 mm, 20 to 29 mm, and more than 30 mm, respectively. No patient with a stone smaller than 10 mm developed steinstrasse. Libby and associates (1988) reviewed 283 patients harboring a stone burden larger than 2.5 cm; they found a significant reduction in complications, most commonly ureteral obstruction, from 26% to 7%, and a

significant reduction in ancillary procedures, from 15% to 6%, favoring ureteral stent placement before SWL. Al-Awadi and associates (1999b) reported a prospective, randomized study comparing 400 patients harboring calculi of 1.5 to 3.5 cm mean diameter who underwent SWL treatment; 200 patients underwent ureteral stent placement before treatment, and the other 200 did not. The authors found that the placement of a ureteral stent significantly reduced the incidence of steinstrasse. However, regardless of the placement of a ureteral stent, steinstrasse occurred more commonly as stone burden increased.

It may be particularly beneficial for patients with stones larger than 20 mm to undergo ureteral stent placement before SWL treatment. Sulaiman and colleagues (1999) reported that steinstrasse developed in 15% of patients with a ureteral stent versus 38% of patients without a ureteral stent. The authors also reported a reduced rate of hospitalization after SWL for those patients who underwent ureteral stent placement than for those who did not have a ureteral stent placed (5% versus 23%).

However, other authors have reported that there is no benefit to placement of a ureteral stent before SWL. Pryor and Jenkins (1990), in a prospective randomized comparison of 25 patients who underwent pre-SWL ureteral stent placement and 25 patients who did not, found no benefit to routine ureteral stent placement in the prevention of steinstrasse; the stone burden in this study was 7 to 25 mm. Interestingly, Kirkali and associates (1993) reported that in a series of 351 patients with stones larger than 30 mm who were treated by SWL, there was no significant difference in the need for auxiliary treatment for steinstrasse between the group of 85 patients who had undergone stent placement and the 266 patients who did not. However, there was a significant increase in the rate of steinstrasse; 24% of patients in the non-stent group experienced this complication compared with 15% in the stent group.

As there are a wide variety of manifestations of the symptoms of steinstrasse, the management of these patients depends on their clinical presentation. Patients with steinstrasse who are asymptomatic can often be observed initially; spontaneous stone clearance occurs in 60% to 80% of cases (Fedullo et al, 1988; Preminger et al, 1989; Kim et al, 1991). Fedullo and associates (1988) reported that steinstrasse occurred in 20% of the first 1000 patients they treated with the HM3 lithotripter, 65% of which resolved spontaneously. Preminger and colleagues (1989) reported a 1.7% incidence of steinstrasse in 302 patients treated by an HM3 lithotripter, with all cases resolving at 6 weeks after treatment. Kirkali and associates (1993) also reported that steinstrasse spontaneously resolved in 50 of 64 cases (82%). Sayed and associates (2001) similarly reported that in a series of 52 patients who developed steinstrasse after SWL, conservative management was successful in 25 patients. However, patients with bilateral obstruction, obstruction of a solitary kidney, severe refractory pain, or infected hydronephrosis should be managed with prompt urinary tract decompression by internal ureteral stenting, nephrostomy tube drainage, or ureteroscopic management. Large leading fragments unlikely to pass spontaneously and failure of expectant management are additional indications for intervention (Coptcoat et al, 1987; Weinerth et al, 1989).

When intervention is required, a minimally invasive approach is often successful. Coptcoat and associates (1988b) reported that percutaneous nephrostomy alone permitted passage of all stone fragments in 75% of cases. Dretler (1994) also recommended placement of a percutaneous nephrostomy tube for patients with pain or sepsis, reserving endoscopic intervention for afebrile patients with large leading fragments or after at least 4 weeks of observation. However, Weinerth and colleagues (1989) found that seven of nine patients initially treated with percutaneous nephrostomy eventually required ureteroscopic basket extraction or lithotripsy. The use of prophylactic antibiotics in expectantly managed cases is recommended, as are frequent radiologic and ultrasound examinations. Failure of steinstrasse to resolve within 3 to 4 weeks may necessitate intervention (Coptcoat et al, 1987).

In those cases that do require intervention, ureteroscopy is often used; basket extraction of larger fragments or additional lithotripsy is easily accomplished and has a success rate approaching 100% (Coptcoat et al, 1988a; Weinerth et al, 1989). Coptcoat and associates (1988a) employed ureteroscopic pulsed-dye laser lithotripsy, after initial renal decompression by percutaneous nephrostomy, in five patients with large leading fragments, reporting successful outcomes in all cases. However, primary ureteroscopic intervention without initial decompression was difficult, and successful outcomes were reported in only 60% of cases. Weinerth and colleagues (1989) reported a 3% incidence (19 of 650 cases) of large steinstrasse (a third or more of the ureteral length), which was not always prevented by the placement of ureteral stents or percutaneous nephrostomy tubes. In 37% of cases, the steinstrasse spontaneously cleared, and ureteroscopic ultrasonic lithotripsy was successful in all 10 cases. Sulaiman and colleagues (1999) reported that ureteroscopic laser lithotripsy or basket extraction was used in 31% of non-stented and 45% of stented patients with steinstrasse, with success in 96% of cases.

Caution is warranted in undertaking the retrograde endoscopic treatment of a patient with steinstrasse; the complication rate of ureteroscopy may be increased over that of percutaneous nephrostomy or SWL. Al-Awadi and associates (1999b) reported that steinstrasse resolved in 50% of cases (19 of 38); but during three of seven attempted ureteroscopies, ureteral perforations occurred that necessitated open surgery.

SWL of the lead fragment of steinstrasse has a high reported success rate and has been associated with few complications. Kim and colleagues (1991), using a piezoelectric lithotripter, noted a 6% incidence of steinstrasse in a series of 958 SWL cases; 64% resolved spontaneously, and 90% of the refractory cases were treated successfully with additional SWL. The authors reported some difficulty in the retrograde placement of a ureteral catheter in those patients who suffered steinstrasse as well as a higher incidence of spontaneous passage of distal, rather than proximal, ureteral steinstrasse (82% versus 33%). Sulaiman and colleagues (1999) reported success with SWL in persistent steinstrasse for seven of nine patients who had undergone ureteral stent placement before SWL and three of three patients who did not undergo ureteral stent placement.

PNL, with or without concomitant ureteroscopy, can also be used to treat patients suffering from steinstrasse. Coptcoat and associates (1988b) reported 100% success in three cases of proximal ureteral steinstrasse. PNL is particularly appeal-

ing if significant stone burden remains in the kidney, as is commonly the case. Open ureterolithotomy has been reported by multiple authors as a salvage procedure for steinstrasse but is rarely required in the modern endoscopic era (Kim et al, 1991; Al-Awadi et al, 1999b; Sulaiman et al, 1999).

In summary, steinstrasse is a well-known complication of SWL, with most cases resolving spontaneously. When intervention is required, percutaneous nephrostomy alone has a success rate of more than 70%. Ureteroscopic intervention is definitive and predictable with an immediate success rate approaching 100%. Additional SWL may be successful, but the results are less predictable than with ureteroscopy. PNL may be used as a salvage procedure, with open ureterolithotomy reserved for failure or for complications of less invasive modalities.

Complications of Ureteral Stone Management

As modern ureteroscopes have become smaller and less traumatic, as safer intracorporeal lithotripters have become widely available, and as a better understanding of the technical principles of ureteroscopy has been developed, the number of complications arising from the management of ureteral stones has been steadily decreasing. Grasso and Bagley (1998) reviewed their experience with 492 patients undergoing 584 ureteroscopic procedures and reported an overall complication rate of less than 1%, with no ureteral perforations, avulsions, septic episodes, or deaths.

Fortunately, most of the complications caused by ureteral stones and their management respond favorably to simple drainage of urine with ureteral catheters or stents.

Perforation. Perforation of the ureter is decreasing in frequency, in part because of the widespread availability of smaller flexible endoscopes, lithotrites with more precise energy delivery, and increasing experience with ureteroscopy. However, ureteral perforation does occasionally still occur, and it is a significant risk factor for the development of a ureteral stricture. The incidence of ureteral perforation varies among the different intracorporeal lithotrites; the highest incidence of ureteral perforation occurs with EHL (see Table 44–4). The treatment of patients who suffer ureteral perforation consists of immediate termination of the procedure, placement of a ureteral stent for 2 to 4 weeks, and careful radiographic follow-up.

Stricture. Ureteral strictures occur secondary to ureteral trauma or alternatively from stone impaction, iatrogenic injury (perforation, lithotrite or stone retrieval device use), or retained stone fragments in the ureteral wall. Duration of stone impaction and ureteral perforation were found to be significant risk factors for ureteral stricture formation by Roberts and coworkers (1998), who reported a 24% stricture rate for stones that had been impacted an average of 11 months. Concomitant iatrogenic ureteral perforation occurred in four of five patients who developed ureteral stricture. If significant trauma does occur, placement of a ureteral stent for an extended period (4 to 6 weeks) may prevent the development of a ureteral stricture. If a ureteral stricture occurs, incision (with cold knife, cautery, or laser) and ureteral stent placement may be successful; balloon dilation with subsequent placement of a ureteral stent is another treatment option (Singal and Denstedt, 1997). Open repair with either excision or bypass of the strictured segment may be necessary if endoscopic measures fail (Matlaga et al, 2003a).

Submucosal Stone. Submucosal stones, defined as calculi iatrogenically displaced into the wall of the ureter, are a problematic complication. Removal of such stones is difficult, ureteral perforation with urinoma can occur, and intense fibrosis may result. If submucosal stones are encountered, laser excision followed by ureteral stent placement is recommended. If laser excision fails, open resection of the affected segment of ureter may be necessary.

Lost Stone. The lost stone, or a stone that has been manipulated to a position outside the ureter, is usually harmless and requires no further treatment. The process (i.e., perforation) that placed the stone outside the ureter may induce stricture formation or other complications. If the stone is associated with infection, a retroperitoneal abscess can result.

Avulsion. Ureteral avulsion is the most severe ureteral complication. It usually occurs when aggressive stone removal maneuvers result in entrapment of a portion of the ureter with the stone during basket extraction or when excessively large stones are withdrawn through narrow areas of the ureter. To reduce the risk of avulsion, some urologists advocate the use of grasping devices instead of baskets for stone retrieval. If ureteral avulsion does occur, open repair of the avulsed ureter is usually required, although if the continuity of the ureter can be re-established by a guide wire already in place, a trial of ureteral stent drainage for several months to allow the ureter to heal may be attempted. However, ureteral stricture is a common outcome. Conversely, if no safety wire is in place or if the ureteral injury is severe, immediate open reconstruction of the ureter is required. All surgical options for replacing ureteral loss, including ureteral reimplantation and psoas hitch of the bladder, ileal ureter, and autotransplantation, must be entertained (Matlaga et al, 2003a).

Ureteroscopic Management of Intrarenal Calculi

Huffman and associates (1983) first described the removal of large ureteral and renal pelvic calculi with a rigid rod-lens ureteroscope and an ultrasonic lithotripter. However, rigid ureteroscopy is limited to stones in certain renal locations, such as the renal pelvis and upper pole calyces. As advancements in fiberoptic technology have facilitated the development of practical flexible ureteroscopes, the therapeutic potential of flexible ureteroscopes has also been improved by several design changes, including a working channel to allow irrigation and passage of flexible instruments and active tip deflection combined with passive deflection to allow access to the entire collecting system. Concomitant improvements in flexible intracorporeal lithotripters have allowed the use of flexible ureteroscopes for the treatment of upper urinary tract calculi with a high degree of success.

Fuchs and Fuchs (1990) reported the first large series (208 patients) of renal calculi treated by ureteroscopy, using a flexible deflectable ureteroscope after a 1- to 2-week period of ureteral stent placement. Indications for ureteroscopy included patients whose SWL treatment failed (single stone smaller than 1 cm or up to five stones smaller than 5 mm),

patients with radiolucent stones (smaller than 1.5 cm), patients with concomitant ureteral and renal stones, patients with renal stones associated with intrarenal stenosis, patients with nephrocalcinosis or urinary diversion, patients with a need for complete stone removal (e.g., pilots), and patients with bleeding disorders. The overall stone-free rate was 87%, and the only complications reported were two cases of sepsis. The subsequent introduction of flexible, actively deflectable ureteroscopes (7.5 French) has permitted more procedures to be performed without routine ureteral dilation. In a series of 598 patients with ureteral and renal stones treated by holmium laser lithotripsy, ureteral dilation was necessary in only 185 (31%) (Sofer and Denstedt, 2000). Numerous baskets and graspers now allow full deflection of flexible ureteroscopes, facilitating treatment of often difficult-to-access lower pole stones (Honey, 1998; Lukasewycz et al, 2004).

As improvements in technique and technology have led to increased numbers of patients treated with ureteroscopy, a review of the literature (Table 44–17) shows that the mean overall success (defined as successful fragmentation with complete stone clearance or presence of "insignificant" residual fragments) of ureteroscopy for the treatment of patients with renal stones (mostly smaller than 3 cm) in a single session is 86%. Higher success rates can be achieved after a second-look procedure. About half the stones treated were located in the lower pole, and a mean success rate of greater than 80% was reported. Complication rates are low (between 0% and 4%); fever and urinary tract infection are the most common complications.

Fabrizio and associates (1998) evaluated the characteristics of residual calculi after ureteroscopy in a group of 100 patients treated for renal stones. As expected, increased stone burden correlated with a higher percentage of patients with residual fragments. Residual fragments were present in only 20% of patients with stones 10 mm or smaller, whereas patients with stones larger than 16 mm were left with residual fragments in more than 50% of cases. In addition, as the number of stones increased, the percentage of patients with residual fragments increased. When success rates of ureteroscopy were stratified by intrarenal location and size, the results for lower pole calculi compared with middle and upper pole calculi were 84%, 93%, and 100%, respectively. A multicenter study evaluated the results of ureteroscopy in 51 patients with 66 large (2 to 6 cm) upper urinary tract stones. Many of the patients failed prior SWL or failed or refused prior PNL. Of 51 patients, 48 were treated solely in a retrograde ureteroscopic manner; 3 were converted to PNL as a result of failure to access the lower pole or because infectious material was encountered on initial endoscopy. One third of the patients with large renal calculi underwent a second-look procedure, and the initial and subsequent success rates after a second treatment session were 76% and 91%, respectively. No intraoperative complications were noted, and the postoperative complication rate was 3% (Grasso et al, 1998).

Treatment of staghorn stones with ureteroscopy has been described, but it is not a widely used technique. In 1990, Aso and colleagues described 34 patients with complete and partial staghorn stones treated with flexible ureteroscopic lithotripsy with a success rate of 88%. In 1994, Dretler proposed ureterorenoscopic fragmentation followed by SWL as an alternative technique for select patients harboring large-volume renal stones (>500 mm^2). In this small series, seven of eight patients became stone free after an average of 2.6 procedures. Female patients with moderate-volume, fragile-looking (i.e., struvite) stones as well as patients with bleeding disorders or a solitary kidney were proposed as possible candidates for the combined ureteroscopic and SWL technique. Mugiya and associates (1998) described 27 patients with partial and complete staghorn stones treated by ureteroscopic lithotripsy followed by SWL, reporting stone-free rates of 61% and 80% for complete and partial staghorn stones, respectively; however, 3 to 26 SWL sessions (mean, 8.4) were required per patient.

EHL, electrohydraulic lithotripsy.

Gould (1998) reported a success rate of only 33% in the treatment of patients with partial staghorn calculi by retrograde flexible ureterorenoscopic holmium laser lithotripsy. Therefore, except in unusual circumstances, ureteroscopic treatment of staghorn stones is inefficient and is generally not an appropriate alternative to PNL.

Technique

Proximal ureteral and intrarenal calculi can be accessed with actively deflectable, flexible ureteroscopes. Although, historically, a ureteral stent was left indwelling before ureterorenoscopy, this maneuver is currently necessary only when difficulty is encountered introducing the flexible ureteroscope into the ureter. If necessary, the stent is left for 2 to 4 weeks before the procedure (Erhard et al, 1996). The use of small-diameter ureteroscopes minimizes the necessity of ureteral dilation for stone access and may decrease associated morbidity. In a series of 155 ureteroscopic treatments for upper tract calculi, ureteral dilation was performed in only 8.3% of patients (Tawfiek and Bagley, 1999). In cases of multiple stones or large stone burden requiring multiple passages of a basket, a ureteral access sheath may facilitate stone removal (Elashry et al, 1996). A comparative study of ureteroscopic lithotripsy with or without access sheath showed that operative time was significantly reduced by use of the access sheath, despite a greater mean stone burden in the access sheath group (Kourambas et al, 2001).

When a retrograde ureteroscopic approach is used to treat patients with intrarenal calculi, two wires are placed initially. The flexible ureteroscope is passed over one working wire in a monorail fashion. Saline is used for irrigation. When an implement is present within the working channel, simple gravity irrigation is inadequate, and pressurized irrigation is required. The holmium:YAG laser lithotripter is used in almost all cases, and the laser energy required usually does not exceed 1 J and 15 Hz (Gould, 1998; Sofer and Denstedt, 2000). Stones in lower pole calyces can be treated in situ or moved, with flexible 2.5 French graspers or a basket, into a position that allows better visualization. A head-down position with the ipsilateral flank elevated may help with stone and fragment visualization because fragments tend to migrate superiorly and are thus more easily localized during treatment (Grasso and Chalik, 1998). When access into the lower pole is difficult, prone positioning of the patient with the head down 20 degrees has been shown to provide the broadest angle of entry to the lower pole infundibulum (Bercowsky et al, 1999). The goal of holmium laser lithotripsy is to reduce the stone to fine dust and to small fragments 2 mm or less in diameter. If the stone is large, the collecting system may often become lined with fine dust and debris, which can obscure residual stones. Furthermore, poor visualization may lead to perforation. In such cases, retrograde catheters can be placed to allow irrigation of the collecting system postoperatively and planning of a staged procedure (Grasso, 1999). Alternatively, the irrigant in the intrarenal collecting system may be aspirated through the ureteroscope, which may also provide a clearer field in which to work.

Fragmentation of stones in situ in the lower pole can be challenging. One technique to aid in the application of the laser fiber to a lower pole stone is to first coil an open-ended 0.035-inch guide wire into the calyx of interest, then pass the flexible ureteroscope over the wire into the calyx. The laser fiber is then passed through the open-ended wire onto the stone for fragmentation (Perez and Pahira, 1995). Alternatively, the ureteroscope can be passively directed into the calyx with the laser fiber already extended, obviating the need to advance the fiber through the ureteroscope when it is maximally deflected. Finally, if the infundibulum is accommodating, the easiest way to treat the stone is to engage it in a nitinol basket and displace it to the renal pelvis or an upper pole calyx. Disassembly of the basket device with removal of the sheath, to create a "bare naked basket," will also enhance the deflectability of the ureteroscope (Landman et al, 2002).

Open Stone Surgery

Historically, most patients with symptomatic upper urinary tract calculi underwent open surgical lithotomy. Those patients with a small to moderate stone burden typically underwent pyelolithotomy, radial nephrolithotomy, or ureterolithotomy. For those patients harboring staghorn calculi, more extensive procedures were required, including anatrophic nephrolithotomy, extended pyelolithotomy combined with radial lithotomies, and bench surgery with autotransplantation. However, the introduction of SWL and the development of endourologic techniques for stone removal have dramatically diminished the role of open stone surgery, especially for stone removal procedures, and open surgery is now one of the least common treatments of patients harboring upper urinary tract calculi. Matlaga and Assimos (2002) reported that of 986 surgical procedures for stone removal performed at their institution between 1998 and 2001, 0.7% were open surgical procedures. Others have reported similar findings (Table 44–18), with an incidence of open stone

Table 44–18. Open Stone Surgery in the Modern Era

	Assimos et al, 1989	*Kare et al, 1995*	*Paik et al, 1998*	*Matlaga and Assimos, 2002*

surgery ranging from 0.3% to 5.4% (Assimos et al, 1989b; Segura, 1990; Kane et al, 1995; Paik et al, 1998).

Renal Calculi

Minimally invasive techniques have clear advantages over open surgical techniques for patients harboring small to moderate burdens in otherwise normal kidneys. In 1985, Brannen and associates retrospectively compared PNL and open surgery for the treatment of patients with renal and proximal ureteral stones. Although the overall stone-free rate was similar, those patients treated by PNL experienced a shorter hospital stay, a lower narcotic requirement, and a shorter recovery period. Preminger and associates (1985) compared 88 patients undergoing PNL with 41 patients undergoing open stone surgery and found that PNL was associated with lower postoperative morbidity, more rapid convalescence, greater satisfaction of the patient, and reduced hospital costs for stones smaller than 2.5 cm. Brown and associates (1986) have also demonstrated that PNL is more cost-effective than open stone surgery because of its reduced morbidity.

A more controversial issue has been the treatment of patients harboring staghorn calculi, a condition that carries a significant risk of mortality if it is untreated. Boyce and Elkins (1974) established anatrophic nephrolithotomy as a standard treatment of patients with staghorn stones in the United States. Overall, the reported stone-free rate after open surgery for struvite calculi is about 85%, with a 30% stone recurrence rate during 6 years (Griffith, 1978). In comparing results for a combination of PNL and SWL with reported results of anatrophic nephrolithotomy, Kahnoski and associates (1986) reported stone-free rates (85%) similar to those for the open surgical procedures, although convalescence and hospital stay for PNL were shorter and blood loss was less.

Snyder and Smith (1986) compared PNL with anatrophic nephrolithotomy for patients with staghorn calculi. They reported that although the retained stone fragment rate was higher for PNL than for anatrophic nephrolithotomy (13% versus 0%), shorter procedure times, reduced need for blood transfusions and narcotics, and far more rapid return to work were achieved with PNL.

A meta-analysis undertaken by the AUA documented stone-free rates of 81.6% for open stone surgery, 80.8% for combined PNL and SWL, 73.3% for PNL, and only 50% for SWL monotherapy (Segura et al, 1994; Preminger et al, 2005). The more invasive the procedure, the greater the stone-free rate; however, morbidity was higher as well. Although SWL carried the lowest morbidity, a greater number of unplanned post-treatment interventions were necessary. The AUA concluded that for most patients, neither SWL monotherapy nor open stone surgery should be the first-line treatment of staghorn stones. As a guideline, PNL, followed by SWL or repeated PNL procedures as warranted, should be used for most patients with struvite staghorn calculi.

There are no strict guidelines that define which patient should undergo an open surgical procedure for stone removal. Some indications, such as a stone burden too large for PNL, clearly rely on the surgeon's judgment and experience and the availability of equipment. Also, those patients harboring calculi that may require multiple PNL or SWL treatments may be good candidates for an open procedure. Although a single open surgical procedure may seem to be the optimal procedure in the short term, the inevitable scar tissue that develops will compromise any future stone removal procedures. A small group of patients who are refractory to PNL, SWL, and ureteroscopy may require an open surgical procedure as a salvage technique.

Nephrectomy remains an option for patients with nonfunctioning kidneys or stone disease with a normal contralateral kidney. Partial nephrectomy is also an option for a stone in a localized area of irrevocably poor function. In addition, patients with an associated anatomic abnormality requiring open operative intervention, such as ureteropelvic obstruction and infundibular stenosis, may be candidates for an open surgical approach. Some patients requiring open surgery unrelated to their urologic problem may also benefit from a simultaneously performed open procedure.

Ureteral Calculi

Although ureterolithotomy has been a time-honored technique for many decades, it is seldom performed in the modern, endourologic era. A meta-analysis undertaken by Segura and associates (1997) for the AUA demonstrated median stone-free rates of 87% and 90% for stones in the distal ureter treated by open surgical removal and ureteroscopy, respectively. In the proximal ureter, the stone-free rate for ureterolithotomy was 97% compared with 83% and 72% for SWL and ureteroscopy, respectively. Although the results of open surgery in the proximal ureter were somewhat better than those of minimally invasive techniques, the greater morbidity and longer hospitalization associated with open surgery favored a primary endourologic solution for ureteral stones. Further miniaturization of ureteroscopes, combined with the now widespread availability of the holmium:YAG laser, has increased the success rate for a ureteroscopic approach to proximal ureteral calculi. Grasso and Bagley (1998) have reported a large series of patients undergoing ureteroscopy for proximal ureteral calculi, finding a 97% stone-free rate. Open surgery for patients with ureteral stones is now indicated only as a salvage procedure, when a planned abdominal operation coincides with a symptomatic ureteral stone episode, or when another ureteral abnormality requires open surgical repair.

Laparoscopic Stone Removal

The advent of laparoscopic stone removal procedures has provided the urologist with another means to circumvent open stone surgery. Every type of "lithotomy" procedure has been reported by use of a laparoscopic approach (Raboy et al, 1992; Winfield et al, 1993; Ruckle and Segura, 1994; Van Cangh et al, 1995; Harmon et al, 1996; Deger et al, 2004). However, laparoscopic approach to stone removal should be considered only if the results with SWL or endoscopic approaches are expected to be poor.

There are certain cases in which a laparoscopic lithotomy may be considered a reasonable therapy. Situations that may benefit from a laparoscopic approach include the following: pyeloplasty with pyelolithotomy; patients harboring stones in poorly functioning polar areas or with nonfunctioning

kidneys; pelvic kidneys containing a large stone volume, in which laparoscopic techniques can be used to reflect overlying bowel, allowing pyelolithotomy or percutaneous stone removal; and ureterolithotomy for the extremely rare endoscopic failure.

KEY POINTS: STONE REMOVAL: SURGICAL TECHNIQUES AND TECHNOLOGY

- The holmium:YAG laser is one of the safest, most versatile, and most effective intracorporeal lithotripters and has become the standard lithotrite for the ureteroscopic approach.
- For patients undergoing PNL, a rigid lithotripter such as a ballistic or ultrasonic device will provide for more efficient stone removal than will a flexible lithotripter.
- For PNL, the preferred point of entry into the collecting system is along the axis of the calyx, through the papilla.
- The goal in selecting access for PNL is to remove the greatest stone burden with the rigid nephroscope thereby maximizing the efficiency of the procedure.

INDICATIONS FOR URETEROSCOPY AND RETROGRADE ACCESS

Ureteroscopy has become a standard urologic technique and is used in a wide variety of situations for diagnosis and treatment. The diagnostic and therapeutic indications for ureteroscopy are summarized in Table 45–1. The main use for the technique of supravesical endoscopy is in the treatment of urolithiasis. The advent of smaller semirigid and flexible fiberoptic endoscopes has allowed routine retrograde access to the proximal ureter and kidney, and when combined with the holmium:yttrium-aluminum-garnet (YAG) laser, provides a safe and highly effective retrograde method of intracorporeal lithotripsy. The current generation of flexible, actively deflectable fiberoptic endoscopes makes virtually every part of the kidney, including the lower pole, accessible for the treatment of calculi.

Ureteroscopy is also used in the diagnosis and treatment of upper tract transitional cell carcinoma, ureteral strictures, and ureteropelvic junction obstruction. The investigation of undiagnosed hematuria or filling defects seen on intravenous or retrograde pyelography may also include ureteroscopy.

EQUIPMENT NECESSARY FOR URETEROSCOPY AND RETROGRADE ACCESS

Endoscopes

The first ureteroscopy was performed in 1912 by Hugh Hampton Young in a patient with posterior urethral valves when a rigid cystoscope was advanced into the dilated ureter (Young and McKay, 1929). In the 1960s a rudimentary ureteroscope was placed into a ureter through a ureterolithotomy during open surgery (Marshall, 1964). Initially, all ureteroscopes were rigid in design and consisted of a rod-lens system with outer diameters ranging from 12 to 13.5 Fr. These endoscopes required routine dilation of the ureter in order to gain access as well as an indwelling stent postoperatively. By the mid-1980s, improvements in design and engineering had resulted in miniaturization of ureteroscopes and a corresponding decrease in trauma associated with the procedure. Rigid endoscopes were reduced to 8.5 Fr in diameter and contained a working channel (Huffman, 1989a; Huffman, 1989b). It was not until 1989 that the next generation of "semirigid" ureteroscopes was developed and contained fiberoptics rather than a rod-lens system (Dretler and Cho, 1989), and in 1993 the current generation of smaller endoscopes was available for use (Abdel-Razzak and Bagley, 1993; Bagley et al, 2004).

Ureteroscopes are produced as semirigid (a rigid instrument able to accommodate a small amount of bend) or flexible instruments. Semirigid ureteroscopes typically have a tapered distal tip (e.g., 6.75 to 9.0 Fr) that dilates to a larger diameter shaft closer to the eyepiece (e.g., 8.4 to 10.1 Fr). The advantages of the semirigid ureteroscope include a large

working channel, faster irrigation flow, and a larger field of view because of the larger number of fiberoptic bundles compared with the corresponding flexible instruments. Semirigid ureteroscopes are typically used for treatment of ureteral pathology below the iliac vessels but may be utilized above the iliac vessels especially in female patients. Caution must be used as the semirigid instrument can accommodate some bend but may sustain damage or even fracture when the metal fatigues. This is particularly hazardous in patients with large psoas muscles and longer urethras (i.e., males), in whom it is often difficult to use the semirigid ureteroscope above the iliac vessels.

Flexible, actively deflectable ureteroscopes range from 6.75 to 9 Fr in diameter at the tip and offer the distinct advantage of being able to reach the entire urinary system including the lower pole of the kidney. Table 45–2 lists some of the currently available flexible ureteroscopes. Typical endoscopes offer 120 to 170 degrees of deflection in one direction and 170 to 270 degrees in the other (Ferraro et al, 1999; Chiu et al, 2004; Johnson and Grasso, 2004); however, the degree of deflection may be altered with instruments (such as laser fibers) in the working channel that increase the stiffness and resistance to deflection of the endoscope (Poon et al, 1997; Landman et al, 2002a ; Parkin et al, 2002). The extra flexibility of such instruments comes with the disadvantages of inferior image quality compared with semirigid ureteroscopes and frequent repairs for a variety of problems including damaged fiberoptic bundles, perforation of the working channel by accessory instruments, or malfunctioning deflection mechanisms (Afane et al, 2000; Pietrow et al, 2002; Landman et al, 2003a). Active dual-deflection ureteroscopes are now available and offer two deflection points in the shaft of the instrument to facilitate access to all calyces, particularly the lower pole (Fig. 45–1) (Grasso and Bagley, 1998; Ankem et al, 2004; Shvarts et al, 2004). In addition to increased repair costs, the capital costs of flexible ureteroscopes are greater than those of semirigid instruments (Elashry et al, 1997; Ferraro et al, 1999; Afane et al, 2000; Chiu et al, 2004). **The flexible ureteroscope is used almost exclusively in cases with ureteral stones and pathology above the iliac vessels at the authors' institution.** Attempting to work in the most distal portion of the ureter with a flexible ureteroscope can be difficult because of a lack of "purchase" by the instrument.

Table 45–1. Indications for Ureteroscopy

Therapeutic Indications
Urolithiasis
Endoureterotomy for ureteral stricture
Retrograde endopyelotomy for ureteropelvic junction obstruction
Biopsy/ablation of upper tract transitional cell carcinoma (TCC)
Retrieval of migrated ureteral stent
Diagnostic Indications
Evaluation of positive cytology with normal cystoscopy
Monitoring of previous upper tract TCC
Evaluation of filling defects on intravenous pyelography/retrograde pyelography
Undiagnosed gross hematuria

Ancillary Equipment

A variety of ancillary equipment is required for the effective and safe performance of ureteroscopy as outlined in Table 45–3 and Figure 45–2. Fluoroscopy by way of a C-arm or fixed urology-specific endoscopy table is necessary for retrograde pyelography, ureteral stenting, and localizing equipment and instruments within the urinary tract intraoperatively. Operating room personnel must take the proper protective precautions including wearing lead aprons, thyroid protectors, and lead glasses. Radioprotective shields are also available to protect anesthesia staff. A video tower consisting of a monitor, fiberoptic light source, camera source, and optional documentation components should be placed near the head of the table facing the surgeon.

A variety of instruments and hardware should be at the urologist's disposal, but not all equipment is opened before surgery because it is unknown exactly which accessories may be needed or which difficulties may be encountered during endoscopic cases. Waste of disposable devices and single-use accessories should be minimized during ureteroscopy; therefore, it is recommended that these items be opened on an as-needed basis.

Guide Wires

Guide wires can vary in their tips, shaft rigidity, material, and shaft diameter. Polytetrafluorethylene (PTFE)-coated guide wires with a stainless steel core and a floppy tip are commonly used utilitarian guide wires. Various guide wires and their different characteristics are outlined in Table 45–3 and Figure 45–3. Hydrophilic-tipped guide wires require sterile water or

Table 45-3. Equipment Necessary for Ureteroscopy and Retrograde Access

Equipment	*Factors to Consider*
Fluoroscopy	
Operating room table	Documentation devices including digital capture devices for still photographs and motion pictures
Video tower with monitor	
Endoscopes	
Cystoscopes (rigid/flexible)	Flexible cystoscopes offer various angles and are more comfortable for the patient
Ureteroscope (semirigid)	Typically for stones below the iliac vessels **Advantages:** more durable, larger working channel for larger instruments (e.g., laser fibers, baskets), better visibility related to increased irrigating ability **Disadvantages:** may be more traumatic to the urethra/ureter, limited access within the ureter
Ureteroscope (flexible)	Typically used for stones above the iliac vessels and in the kidney Can reach every part of the urinary tract (including lower pole of the kidney) Some models have "double deflection" allowing easier access to all calyces **Disadvantages:** flexible fiberoptics require frequent repairs, which are costly; smaller working channels have lower flow rates; the image is not as sharp as with semirigid endoscopes because of the smaller fiberoptic bundles
Ureteral catheters	
5 Fr open ended, straight or angled	These catheters can be used to provide backing to help maneuver guide wires Angled vascular catheters are useful in manipulating guide wires past obstructions and tight areas
Guide wires	
Polytetrafluoroethylene (PTFE) coated	PTFE is the commonest wire and is a good utilitarian wire. The floppy tip prevents urothelial damage
Hydrophilic	Hydrophilic wires absorb water and have a very decreased coefficient of friction, making them very slippery to help maneuver past obstructions
Extra stiff	The extra stiff wire is more resistant to kinking than regular PTFE guide wires and is a good backing for coaxial or balloon dilation and insertion of ureteral access sheaths
Combination wires	Combination wires combine a hydrophilic tip with a more robust and easier to manipulate PTFE body
Double floppy tip	Double floppy tips may be used to backload flexible ureteroscopes in an attempt to prevent damage to the working channel of the ureteroscope
Exchange wire	An exchange wire is longer than a typical guide wire to facilitate certain procedures
Dilators	
8/10 coaxial dilators	These are used in serial fashion using progressively larger dilators A good dilator to dilate the ureter and orifice to accommodate semirigid and flexible ureteroscopes Is also helpful for inserting ureteral stents under fluoroscopic guidance Is also used to introduce the second guide wire for flexible ureteroscopy
Balloon dilator	Potentially less traumatic than coaxial dilation and very efficient for dilating tight ureteral orifices, ureters, and ureteral strictures in one step
Irrigation devices	
Hand pressure irrigation (large syringes or self-refilling pistol grip syringes)	
Pressure bag	
Foot pump	
Laser fiber (holmium:YAG)	These come in a variety of sizes ranging from 200 to 1000 µm.
Laser fiber sealing device for the endoscope	Typically, fibers ranging from 200 to µm or 400 µm are utilized in ureteroscopic lithotripsy
Working channel graspers/baskets	These are typically made of a nickel-titanium (nitinol) combination that provides a strong metal that is thin and flexible but also retains its original shape (memory) when deployed
Stone baskets	
Stone graspers	
Specialty baskets that have a working channel in the middle to allow a laser fiber to break up a stone being held in the basket or special coils that prevent ureteral stones from migrating proximally during lithotripsy	
Ureteral access sheath	These come in a variety of sizes ranging from 9 to 18 Fr and a variety of lengths. The shorter lengths are generally used in women and the longer sheaths in men
Biopsy forceps	These are small enough to fit in the channel of the ureteroscope to biopsy any ureteral or renal pelvic masses
Intracorporeal lithotriptors	
Holmium:YAG laser	Ho:YAG lasers can fragment all stone compositions and have a high margin of safety.
Electrohydraulic lithotriptor	
Pneumatic ballistic lithotriptor	
Ultrasonic lithotriptor	
Self-retaining ureteral stents (double pigtails)	These come in a variety of sizes and a diameter of 5 to 7 Fr is standard.

YAG, yttrium-aluminum-garnet.

saline flushes through the holding jacket before use. The hydrophilic material absorbs water and becomes slippery to facilitate manipulation past tight obstructions. The main disadvantage of the hydrophilic wire is also its slipperiness, which allows it to slide easily out of the ureter. Stenting over a hydrophilic wire is difficult, and a ureteral catheter (Fig. 45–4) may be used to exchange to a PTFE-coated guide wire before ureteral stenting. A hybrid wire combines a hydrophilic tip to facilitate maneuverability with a PTFE-coated nitinol shaft for stiffness and grip. Ureteral stents can be easily placed over hybrid guide wires.

Guide wires are also used to facilitate the insertion of endoscopes. Advancing a flexible ureteroscope over a rigid guide wire can damage the working channel, necessitating costly repairs (Vanlangendonck and Landman, 2004). Double floppy tipped guide wires may be less traumatic to the working channel and reduce the possibility of endoscope damage (Monga et al, 2001). Semirigid ureteroscopes are typically advanced adjacent to guide wires.

Ureteral Dilation

Ureteral catheters (see Fig. 45–4) **and dilators** (Fig. 45–5) **are important for retrograde access** and include 5 Fr open-ended catheters both for the instillation of contrast material and to provide a buttress for guide wire manipulation past tight junctions or obstructing stones.

Ureteral dilation, if required, is typically performed at the narrowest point, the ureteral orifice, in order to facilitate passage of the ureteroscope. Occasionally, the ureter more proximal to the orifice requires dilation. Sets of progressively larger **polyethylene coaxial dilators** are available for dilation of the ureter but may produce a shearing force and ureteral trauma (Ford et al, 1984; Gaylis et al, 2000). **Balloon dilators** (see Fig. 45–5) provide radial dilation with less trauma and come in 5 to 7 Fr catheter shaft diameters with balloons ranging from 4 to 10 mm in diameter that can exert up to 220 psi (15 atm) (Huffman and Bagley, 1988; Garvin and Clayman, 1991). After the balloon is positioned fluoroscopically with the area requiring dilation between the two radiopaque markers, an assistant uses a locking screw syringe or other inflating device to instill contrast material into the balloon while the surgeon steadies the dilating catheter to prevent inadvertent movement during dilation. Care must be taken to avoid overinflation of the balloon, which may burst, resulting in ureteral damage (Huffman and Bagley, 1988).

Ureteral dilation is not necessary in every ureteroscopic case and should be performed only if passage of the ureteroscope is met with difficulty (Rodrigues et al, 1990; Stoller et al, 1992). **The earlier generation of ureteroscopes required routine dilation, but with newer, smaller endoscopes and miniaturized intracorporeal lithotripsy devices, ureteral dilation is seldom necessary (<14% of cases), particularly when the endoscopes used are 9 Fr or smaller in diameter** (Rodrigues et al, 1990; Stoller et al, 1992; Elashry et al, 1997; Harmon et al, 1997).

Irrigation

Adequate irrigation flow is necessary to maintain visibility. Ureteroscopes have either two separate channels (one working channel for an instrument such as a laser fiber and the second for irrigation) or one common channel for both irrigation and working instruments. Irrigation can be provided by gravity, a pressure bag, or a variety of hand or foot pumps. Manual hand irrigation has been shown to produce pressures greater than 100 mm Hg in the kidney (Auge et al, 2004). Theoretically, this may lead to bacteremia and sepsis in an infected system because of pyelovenous and pyelolymphatic backflow. Distention of the renal pelvis during ureterorenoscopy may also interfere with maneuverability of the ureteroscope inside the kidney if the pelvis is so capacious that it cannot provide a "backboard" for secondary deflection of the ureteroscope. Furthermore, higher pressures may result in increased fluid absorption by the patient. One study measured fluid absorp-

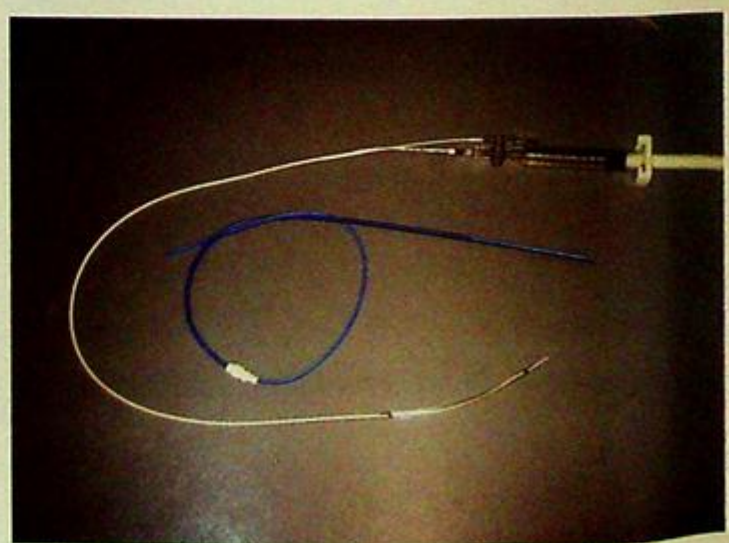

Figure 45–5. A one-step ureteral balloon dilator (white) attached to a locking screw syringe (white). A 8/10 Fr coaxial dilator used for ureteral dilation and insertion of a secondary guide wire (blue). Serial ureteral coaxial dilators are not shown in this picture.

tion of approximately 135 mL per hour by the patient during ureteroscopy (Cybulski et al, 2004a). Care should be taken to apply the correct level of pressure irrigation necessary for visualization and to avoid fluid overload and fluid extravasation. Ureteral access sheaths may be used to decrease renal pressure from irrigation during ureteroscopy (Landman et al, 2002b; Auge et al, 2004).

Ureteral Access Sheath

This accessory was originally developed in the 1970s to facilitate insertion of the flexible ureteroscope (Takayasu and Aso, 1974) and has been shown to decrease renal pressures during ureteroscopy (Landman et al, 2002b; Auge et al, 2004). A variety of companies produce **ureteral access sheaths** (UASs), which come in sizes ranging from 9 to 18 Fr and are inserted with a tapered dilating obturator over a guide wire. UASs can provide ureteral dilation because of the tapered tip, and there has been one report of less postoperative pain following ureteroscopy utilizing a UAS for dilation compared with balloon dilation (Kourambas et al, 2001). As an open conduit into the kidney, the UAS allows irrigation to flow in through the endoscope and back out of the kidney, thus preventing high renal pressures (Kourambas et al, 2001; Landman et al, 2002b; Rehman et al, 2003; Auge et al, 2004). **Shorter operating room times and greater cost savings have been demonstrated when UASs are utilized in conjunction with ureteroscopy** (Kourambas et al, 2001; Monga et al, 2001). The shortened surgical times are thought to be due to the ease of repeated insertion of the flexible ureteroscope and thus facilitation of basketing to remove stone fragments from the kidney, which would otherwise require intracorporeal lithotripsy into small enough fragments to pass spontaneously. **Part of the overall decrease in costs was due to a decreased incidence of ureteroscope damage.** As the ureteroscope is not in direct contact with a potentially tight ureter undergoing axial forces during insertion, the endoscope appears to sustain less damage over time and can be used in more cases before servicing is required (Pietrow et al, 2002). Previous concerns that UASs may cause ureteral ischemia and necrosis resulting in a ureteral stricture have been unfounded, as the stricture incidence has been demonstrated to be the same as that with ureteroscopy alone (~1.4%) (Delvecchio et al, 2003; Vanlangendonck and Landman, 2004).

Although use of UASs has been reported to decrease operating times and cost, there has been only a single study to date regarding stone-free rates (L'Esperance et al, 2004). In 181 patients, the overall stone-free rate was higher in patients who underwent ureteroscopy utilizing a UAS compared with control subjects who underwent ureteroscopy without a UAS (L'Esperance et al, 2004).

Flexible ureteroscopy is better facilitated by UASs than semirigid ureteroscopy. De Sio and colleagues (2004) managed distal ureteral stones with semirigid ureteroscopy and used UASs but found that in 5 of 12 (42%) of the patients, the procedure could not be completed until the sheath was removed. There were no differences in operating time or stone-free rates. Thus, UASs do not appear to be useful in semirigid ureteroscopic management of distal ureteral stones.

The use of UASs has been extended to simultaneous ureteroscopic access during percutaneous nephrolithotomy (Landman et al, 2003b) and extracorporeal shockwave lithotripsy (SWL) for large stone burdens in patients surgically unfit for percutaneous nephrolithotomy (Okeke et al, 2004).

In summary, use of UASs during flexible ureteroscopy shortens operating times, reduces renal pelvic pressures, and can limit endoscope damage.

Intracorporeal Lithotriptors

A variety of devices for intracorporeal lithotripsy are reviewed in detail in Chapter 46. The holmium:YAG laser is the current "gold standard" because of its effectiveness in fragmenting any stone composition and its excellent safety profile. Before the advent of the holmium:YAG laser, other methods of intracorporeal lithotripsy included ultrasonic lithotripsy, which was first described in 1973 using a hollow rigid probe (Goodfriend, 1973). Ultrasound was not used with flexible ureteroscopy until a flexible solid wire probe later became available. Briefly, electrical energy is delivered to piezoceramic elements in the handpiece, which generates sound waves at frequencies of 23,000 to 25,000 Hz. Vibrations of the hollow probe are then transmitted to the stone, resulting in fragmentation. The hollow center allows simultaneous suction to evacuate stone fragments. A disadvantage, however, is that ultrasonic lithotripsy probes are rather large and require a semirigid ureteroscope. More flexible ureteral probes available for use in flexible ureteroscopy are solid and do not contain a suctioning device, making them less efficient than their rigid counterparts. Because of the lack of simultaneous suction, the solid-wire probes failed to gain widespread popularity. Ultrasonic lithotripsy in combination with ureteroscopy is now rarely used because of the drawbacks of the larger rigid probes (Gur et al, 2004).

Ballistic lithotripsy involves energy generated from an electrokinetic source (Keeley et al, 1999) **or more commonly a pneumatic energy source** (Leidi et al, 1997; Yinghao et al, 2000; Aghamir et al, 2003). Ballistic lithotripsy utilizes compressed air or electrokinetic energy to propel a missile or ballistic body against the probe that strikes the stone, producing a "jackhammer" effect. Advantages of ballistic lithotripsy include relatively inexpensive equipment with reusable components and a high margin of safety because very little heat is generated at the probe tip. Disadvantages include the inability to remove fragments simultaneously, stone retropulsion, and the lack of efficacy of flexible probes for use in flexible ureteroscopy. In an effort to improve simultaneous fragment removal, ballistic lithotripsy was combined with a suction device (Delvecchio et al, 2000). The overall stone-free rate was 95% at 3 months, and the authors found the addition of suction to aid in fragment removal and prevent fragment migration. However, the combined ballistic lithotripsy–suction device can be used only with rigid probes and, therefore, can be utilized only with rigid ureteroscopy.

Electrohydraulic lithotripsy (EHL) utilizes electrical energy that overcomes the insulative gap of an electrode to produce a spark and an ensuing cavitation bubble (Yang and Hong, 1996). Symmetrical collapse of the cavitation bubble results in a secondary shockwave or high-speed microjets if the bubble collapses asymmetrically. Both the secondary shockwave and microjets are responsible for stone fragmentation (Willscher et al, 1988; Denstedt and Clayman, 1990). An

advantage of EHL is its low capital cost compared with laser units. EHL probes are a disposable component and, depending on stone hardness, more than one probe may be required to achieve complete stone fragmentation. The probes are more flexible than laser fibers and do not affect the deflection of flexible ureteroscopes to the same extent as quartz laser fibers. The two most important disadvantages of EHL are that some stones are resistant to fragmentation and that high peak pressures are generated at a distance from the probe tip, producing a narrow margin of safety (Vorreuther, 1993). High peak pressures can result in ureteral perforation. Two studies reported extravasation rates of 18% to 40% using EHL as an intracorporeal lithotriptor for ureteral stones (Raney, 1978; Hofbauer et al, 1995).

The first laser employed to fragment a stone was the **long-pulsed ruby laser,** which in 1968 was utilized in vitro. The ruby laser was never used clinically because of the large amount of energy delivered to surrounding tissues, resulting in damage (Mulvaney and Beck, 1968). **The carbon dioxide (CO_2)** and **neodymium:yttrium-aluminum-garnet (Nd:YAG)** lasers subsequently became available for general clinical use; however, the CO_2 laser lacked fibers for endoscopic use and the Nd:YAG converted much of the energy to heat, causing thermal tissue damage. It was not until 1988 that the Nd:YAG was altered to enable the first clinically applicable laser lithotriptor (Hofmann and Hartung, 1988). The Nd:YAG laser was combined with Q-switching and a specially designed coupling tip to produce short-pulse laser beams that generated high peak pressures with reduced heat. This modification improved the safety of the laser even when directly discharged on urothelium in an animal model (Hofmann and Hartung, 1988). The drawbacks of the Nd:YAG laser are the inability to fragment calcium oxalate monohydrate and brushite stones, the relatively large-diameter fiber, and the fragile delivery system (Zheng and Denstedt, 2000). Three additional laser lithotripsy platforms for clinical use have since been developed: the pulsed-dye, alexandrite, and holmium:YAG lasers.

One of the most important developments in the endoscopic approach to urolithiasis has been the **holmium:YAG laser** for intracorporeal lithotripsy. The holmium:YAG laser is now recognized to be the gold standard for ureteroscopic intracorporeal lithotripsy. The active medium is the rare earth element holmium combined with a YAG crystal. This pulsed solid-state laser system operates at 2100 nm, which is in the near infrared portion of the electromagnetic spectrum and, therefore, invisible to the human eye. The holmium:YAG laser was successfully used in ophthalmology, otolaryngology, and orthopedics before it was introduced to urology in 1993 (Webb et al, 1993). As the 2100 nm wavelength can be transmitted through flexible silica quartz fibers, the holmium laser is especially suited for endoscopic procedures using both flexible and rigid endoscopes.

The method of stone fragmentation using the holmium:YAG laser differs from the photoacoustic method utilized by other lasers. **Energy from the holmium:YAG laser produces a photothermal effect resulting in vaporization of the stone** (Dushinski and Lingeman, 1998; Wollin and Denstedt, 1998). **The 2100 nm holmium:YAG laser energy is strongly absorbed by water and travels no farther than 0.5 to 1.0 mm in a liquid medium, providing a substantial margin of safety in preventing ureteral damage** (Grasso and Chalik, 1998; Wollin and Denstedt, 1998). Furthermore, when the laser fiber is oriented in the same direction as the ureter during ureteroscopy, there is a high laser incident angle with the mucosa, causing low mucosal damage after accidental exposure (Vassar et al, 1999). In addition, because of the paucity of holmium:YAG shockwaves, there is little risk of shockwave-induced collateral injury (Vassar et al, 1999). In vitro studies have demonstrated that the holmium:YAG laser cuts and incises soft tissue with precision and fragments all types of calculi, which is a distinct advantage over the other lasers used in urology (Wollin and Denstedt, 1998). **Stone-free rates using this method of intracorporeal lithotripsy are in excess of 90% in several series** (Grasso, 1996; Hosking and Bard, 1996; Devarajan et al, 1998; Yip et al, 1998; Sofer et al, 2002). Fibers are available in sizes 200, 365, 400, 550, and 1000 μm. Typically, 200 to 400 μm fibers are utilized during ureteroscopy.

STEP-BY-STEP URETEROSCOPY IN THE TREATMENT OF URETERONEPHROLITHIASIS

Preparation of the Patient

A variety of techniques and nuances exist in performing successful ureteroscopy, and the method presented here reflects the technique employed by the authors. The basic principles of the procedure remain the same even for the most experienced endoscopist.

Preparation of the patient includes informed consent and explanation of the potential complications and the possibility of insertion of an indwelling ureteral stent. Other preoperative considerations include the type of anesthesia, preoperative antibiotics, and imaging. Typically, **general anesthesia** is used, but **neuroleptic anesthesia** is also feasible (Abdel-Razzak and Bagley, 1993; Hosking and Bard, 1996; Elashry et al, 1997; Miroglu and Saporta, 1997; Hosking et al, 2003; Cybulski et al, 2004b). The majority of ureteroscopic cases can be treated as an outpatient day surgical procedure.

Antibiotic Prophylaxis
